5 to 8 July 2020

Abstracts

36th Virtual Annual Meeting of the

European Society of

Human Reproduction and Embryology,

5 to 8 July 2020

The abstracts are available on-line to all Human Reproduction/Update/Molecular Human Reproduction subscribers and are also freely available to all visitors to the following website www.humrep.oxfordjournals.org, and on the ESHRE website: www.eshre.eu

Note to the media: All abstracts are strictly embargoed until the time and date of presentation at the conference.

The opinions or views expressed in this abstracts supplement are those of the authors and do not necessarily reflect the opinions or recommendations of ESHRE. The abstracts have been reviewed by the Congress Scientific Committee and revised accordingly by the authors. The selection of abstracts is based on the scores given by an international panel of peer reviewers.

Dosages, indications and methods of use for products that are referred to in the abstracts by the authors are not necessarily appropriate for clinical use and may reflect the clinical experience of the authors or may be derived from the professional literature of other clinical sources. Because of differences between in-vitro and in-vivo systems and between laboratory animal models and clinical data in humans, in-vitro and animal data may not necessarily correlate with clinical results.

The investigators of these abstracts have stated in their submission letter that prospective studies where patients are involved have institutional Ethics Committee approval and informed patient consent, and that the studies using experimental animals have institutional approval. The Publishers have endeavoured to reproduce faithfully all of the abstracts as accepted by the Conference Organisers but can accept no responsibility for inaccuracies or omissions caused by the late receipt of abstracts.

Background: Certain chemicals in cosmetics and personal care products, including low molecular weight phthalates, parabens, and phenols, have demonstrated endocrine disrupting properties. These chemicals have been associated with altered pubertal timing in animal studies, but few human studies exist.
Methods: Data were from the Center for the Health Assessment of Mothers and Children of Salinas (CHAMACOS) longitudinal cohort study that followed 338 children in the Salinas Valley, California from before birth to adolescence. Pregnant women were enrolled in 1999-2000. Mothers were mostly Latina, living below the federal poverty threshold, and had not completed high school. We measured concentrations of three phthalate metabolites (monoethyl phthalate [MEP], mono-n-butyl phthalate, and mono-isobutyl phthalate), methyl and propyl paraben, and four other phenols (triclosan, benzophenone-3, and 2,4- and 2,5-dichlorophenol) in urine collected from mothers during pregnancy and from children when they were 9 years of age. Pubertal timing was assessed among 179 girls and 159 boys every 9 months between ages 9 and 13 using clinical Tanner staging. Accelerated failure time models were used to obtain mean shifts of pubertal timing associated with concentrations of prenatal and peripubertal biomarkers.
Results: In girls, we observed associations of earlier onset of pubic hair development with increased prenatal urinary MEP concentrations and earlier menarche with increased prenatal triclosan and 2,4-dichlorophenol concentrations. With peripubertal biomarkers, we observed earlier breast development, pubic hair development, and menarche with increased methyl paraben urinary concentrations; earlier menarche with propyl paraben concentrations; and later pubic hair development with 2,5-dichlorophenol concentrations. In boys, we observed no associations with prenatal urinary biomarker concentrations, and only one association – of earlier pubic hair development with propyl paraben – with peripubertal concentrations.
Conclusions: We found associations of altered pubertal timing with early life exposure to chemicals in personal care products in girls, but little evidence in boys. This study contributes to a growing literature that suggests that exposure to certain endocrine disrupting chemicals may impact timing of puberty in children.

[4]*IRCCS San Raffaele Scientific Institute, Division of Genetics and Cell Biology, Milan, Italy*

Study question: Does assisted hatching of vitrified/warmed blastocysts improve clinical outcomes?
Summary answer: No significant difference was found in clinical pregnancy rate (CPR).
What is known already: Recently, the Human Fertilization and Embryology (HFEA) declared that the assisted hatching (AH) is an unproven add-on intervention and the guidelines of the National Institute for Clinical Excellence (NICE) do not recommend the use of AH to improve pregnancy rates. Of note, available data are mainly focused on the effect of AH in fresh-cleavage stage embryo transfers while data regarding the effect of laser AH (LAH) on blastocysts, especially after cryopreservation, are inconclusive since they are based on studies with small sample sizes and may hide a type II error.
Study design, size, duration: A multicentric prospective comparative study with a parallel randomized controlled design. The sample size (700 blastocysts) was calculated considering a 10% difference in live birth rate (LBR) between LAH-group and no LAH group. The primary outcome was live birth rate and the secondary outcomes were implantation, biochemical pregnancy, clinical pregnancy, miscarriage, multiple pregnancies, obstetrical and neonatal complications rates. An interim analysis based on CPR was performed including cycles between September 2018 and October 2019.
Participants/materials, setting, methods: Women ≤ 40 years and with ≤ 2 previous oocyte retrievals undergoing IVF cycles and scheduled for elective single embryo transfer (eSET) with vitrified/warmed blastocysts were considered for enrollment in each of the two units. Warmed blastocysts were randomized immediately after warming to the study group (LAH) or to the control group

(without LAH). The allocation sequence was stratified according to woman's age and blinded to the physicians and participants.
Main results and the role of chance: Since the beginning of the study, 291 women were recruited (n=145 in LAH-group and n= 146 in the control group). At the time of transfer, hatching and hatched blastocyst rates were significantly higher in the LAH group compared to the control group (respectively 55% vs 16%, p<0.001). The clinical pregnancy rate in the whole cohort was similar in LAH and control group, being 45% and 43%, respectively (p=0.81). The clinical pregnancy rate in the age group <38 years was 45% in the LAH group compared to 39% in the control group (p=0.37). In addition, in the age group ≥ 38 years, the clinical pregnancy rates were 44% in the LAH group and 56% in the control group, respectively (p=0.30).
Limitations, reasons for caution: Being an interim analysis, the sample size is not powered enough to detect differences <10% between groups. At this step, it is not possible to evaluate LBR which is the main outcome of the study.
Wider implications of the findings: This study could clarify the real potential of AH on vitrified-warmed blastocysts in terms of live birth leading to evidence-based changes in current clinical practice.
Trial registration number: NCT03623659

O-004 The euploid blastocysts produced after either follicular-phase or luteal-phase-stimulation show similar live-birth rates: a prospective multicenter study including 293 vitrified-warmed single-embryo-transfers

A. Vaiarelli[1], D. Cimadomo[1], S. Colamaria[1], E. Trabucco[2], A. Sansone[2], E. Alviggi[2], A. Della Ragione[2], F. Golia[2], F. Fiorini[3], N. Barnocchi[3], L. Papini[3], A. Conforti4, C. Alviggi[4], L. Rienzi[1], F.M. Ubaldi[1]

[1]Clinica Valle Giulia, Genera centers for reproductive medicine, roma, Italy ; [2]Clinica Ruesch, Genera centers for reproductive medicine, Naples, Italy ; [3]Genera Umbria, Genera centers for reproductive medicine, Umbertide, Italy ; [4]University of Naples- Federico II, Department of Neuroscience- Reproductive Science and Odontostomatology, Naples, Italy

Study question: Is there any difference in the reproductive competence of euploid blastocysts produced after follicular-phase-stimulation (FPS) or luteal-phase-stimulation (LPS) during vitrified-warmed single-embryo-transfers?
Summary answer: LPS-derived vitrified-warmed euploid blastocysts showed similar live-birth-rate (LBR), obstetrical and perinatal outcomes as FPS-derived ones.
What is known already: Multiple follicular waves arise during a single ovarian cycle in humans, thereby highlighting a novel folliculogenesis pattern overtaking the classic theory. Several studies conducted by numerous groups worldwide consistently showed a similar developmental competence between FPS- and LPS-derived cohorts of oocytes in terms of fertilization, blastulation, and euploidy rates. These observations supported the further implementation of unconventional protocols for ovarian stimulation in poor-prognosis patients, like patients fulfilling the Bologna criteria, advanced-maternal-age women, oncologic patients: random-start,LPS-only and FPS+LPS in the same ovarian cycle (DuoStim). Nevertheless, it still needs to be outlined whether LPS-derived blastocysts show similar reproductive competence as FPS-derived ones.
Study design, size, duration: Multicenter study conducted between October2015–March2019 including all vitrified-warmed euploid single blastocyst transfers after DuoStim with preimplantation-genetic-testing (PGT). Only first transfers of good quality blastocysts (≥BB according to Gardner and Schoolcraft's classification) were included. In the presence of euploid blastocysts produced after both FPS and LPS (n=100/293,34%), the embryo to transfer was chosen in a blinded fashion (random.org). The primary outcome was the LBR per transfer. Biochemical-Pregnancy-Loss (BPL), Miscarriage-Rate (MR) and obstetrical/perinatal outcomes were also monitored.
Participants/materials, setting, methods: DuoStim was proposed to poor-prognosis patients respecting two of these criteria: AMH≤1.5ng/ml, antral-follicle-count≤6, ≤5 oocytes from previous cycle(s), advanced-maternal-age. Ovarian stimulations were performed with recombinant-gonadotrophins in an antagonist protocol. LPS was started five days after the first retrieval. Embryos were cultured to blastocyst, underwent trophectoderm biopsy and vitrification. Only full-chromosome meiotic aneuploidies were reported. Overall, 293 first transfers were included (139 FPS- and 154 LPS-derived euploid blastocysts). All transfers were performed in an artificial cycle.
Main results and the role of chance: To achieve 80% power (α=0.05) to rule-out a 15%-difference in LBR between FPS- and LPS-derived euploid blastocysts ~300 first SETs were required. The blastocysts in the two groups were equally distributed according to morphology and day of development. The study arms were similar for age, sperm factor, kind and cause of infertility and indication to PGT. The positive-pregnancy-tests-rates were 59.7% (n=83/139) and 63.6% (n=98/154) from FPS- and LPS-derived euploid blastocysts, respectively. The BPL rates were 10.8% (n=9/83) and 9.2% (n=9/98). The MRs were 10.8% (n=8/74) and 11.2% (n=10/89). The LBRs were 47.5% (n=66/139) and 51.3% (n=79/154;p=0.6). Among patients with euploid blastocysts produced after both FPS and LPS, the LBRs were also similar (51.9% [n=28/54] and 54.3% [n=25/46]; p=0.8). Four out of 66 (6.0%) FPS-derived pregnancies showed gestational issues (one gestational diabetes, one icterus, one polyhydramnios, one embryo twinning). Five out of 79 (6.3%) LPS-derived pregnancies showed gestational diabetes. Gestational age (38.1±1.3weeks versus 38.2±1.7weeks;p=0.6), birthweight (3309±438g versus 3232±471g;p=0.4) and length (47.9±10.2cm versus 47.6±11.4cm;p=0.9) were similar. Four out of 67 (6.0%) FPS-derived new-borns showed perinatal issues (one neonatal respiratory distress involving 7 days in the neonatal-intensive-care-unit, one diaphragmatic hernia, one single kidney, one hydrocephalous).No neonatal issue has been reported among LPS-derived new-borns.
Limitations, reasons for caution: LPS-derived embryos were produced only in a DuoStim approach. The reproductive competence of poor-quality blastocysts was not assessed. The study was powered to investigate the primary outcome, hence the analysis of secondary outcomes should be considered observational.
Wider implications of the findings: The adoption of unconventional ovarian stimulation protocols for the treatment of peculiar populations of poor-prognosis infertile and oncologic patients is increasing worldwide. This study further reinforces the hypothesis that FPS- and LPS-derived embryos have comparable competence. Therefore, if required, LPS might be adopted.
Trial registration number: none

O-005 Cleavage stage embryo transfer impairs cumulative live birth rates and time to livebirth as compared to blastocyst transfer in oocyte recipients. A randomized controlled trial

E. Clua Obradó[1], I. Rodríguez[1], G. Arroyo[1], F. Martínez[1], L. Latre[1], B. Coroleu[1], N.P. Polyzos[1]

[1]USP Instituto Universitario Dexeus, Medicina de la Reproducción, Barcelona, Spain

Study question: Does embryo transfer day (D5 *vs* D3) affect cumulative pregnancy (CPR), cumulative live birth rates (CLBR) and time to livebirth (TTL) in oocyte donation programs?
Summary answer: Embryo transfer at cleavage stage(D3) results in ~20% relative reduction in CPR and 15% in CLBR, while increases the TTL as compared with blastocyst(D5) transfer.
What is known already: Blastocyst embryo transfer has been traditionally associated with very good pregnancy outcomes due to embryo self-selection after the embryonic genome activation on day 3.

In IVF/ICSI cycles among infertile women using their own oocytes, evidence from RCTs suggest that blastocyst transfer results in significantly higher live birth rates; still no difference has been identified between D3 and D5 in terms of cumulative live birth rates. However, it is unclear whether D3 or D5 embryo transfer may result in different CPR and CLBR in women included in an oocyte donation program.
Study design, size, duration: In a single-center randomized trial conducted between March 2017-August 2018, 134 oocyte recipients were randomized to cleavage stage (D3-group) or to blastocyst stage (D5-group) embryo transfer.
Participants/materials, setting, methods: Eligible women were recipients between 18-50 years, in their 1st/2nd synchronous cycle (excluding: PGT-A, implantation failure). At first consultation and prior to oocyte donation cycle, recipients were randomly allocated to D3 or D5 transfer.

Co-primary outcomes were, CPR (first pregnancy) and CLBR (first live birth) per patient, within 12 months from the first embryo transfer, considering fresh and subsequent frozen embryo transferred. In addition, we analyzed TTL (time from 1st embryo transfer until 1st livebirth).

Main results and the role of chance: Whereas 250 recipients were planned to be enrolled, the study was prematurely terminated, with an unplanned interim analysis, when 134 women completed treatment, for ethical reasons, due to the clinically and statistically significant inferior outcomes in D3 arm.

Although the number of supernumerary frozen embryos was significantly higher in D3-group (5.3±2.7) than in D5-group (3.6±2.3), pregnancy outcomes were substantially inferior in patients allocated to D3-group.

CPR were significantly lower in the D3 vs D5 group (67.2% vs. 85.9%) with a proportion difference of -18.7% 95%CI [-32.8% to -4.3%]. Similarly, CLBR were lower in the D3 vs D5 group (55.2% vs. 70.3%) with a proportion difference of -15.1% 95%CI [-30.9% to 1.6%], although results did not reach statistical significance for this outcome.

Finally, TTB was significantly longer in D3 group as compared with D5 log rank test p=0.027. In order to reach a 50% cumulative live birth rate, D3 group required 6 months more than D5 group and always D5 group maintained a higher live birth rate.

Limitations, reasons for caution: This randomized trial was prematurely terminated, with an unplanned interim analysis, due to the clinically and statistically significant inferior results for the D3 group following evaluation by the institutional review board.

Wider implications of the findings: Transfer of embryos in cleavage stage (D3) should be discouraged in oocyte recipients with good prognosis since it significantly impairs cumulative pregnancy rates, appears to reduce cumulative live birth rates, while significantly increases time to live birth and costs due to higher number of cryopreserved embryos.

Trial registration number: NCT03088735

O-006 Blastocyst versus cleavage stage transfers: who benefits?

E.K. Dirican, Ph.D[1], Ş. Olgan[1], M. Çağlar[1], M. Sakıncı[1], O. Ertürk, Kadir[1], Z. Kasabalı[1], U. Çakmaklı[1]

[1]Akdeniz University- Faculty of Medicine, Obstetrics & Gynecology- Reproductive Endocrinology and Infertility, Antalya, Turkey

Study question: What is the outcome of cleavage and blastocyst transfers with regards to transfer cancellation, embryo selection and embryo-endometrium synchronization?

Summary answer: Transfer cancellations due to extended culture did not affect the pregnancy outcomes and patients with 6 or more zygotes benefited from embryo selection.

What is known already: Despite improvements in embryo culture, there is still a concern whether the *in vitro* extended culture supports embryo development to the same extent as *in vivo* or not. In addition, transfer cancellations often result in an unpleasant patient counseling. As a precaution for transfer cancellation, some clinics offer extended culture only when abundant embryos are available. However, the relative contributions of transfer cancellation against embryo selection during extended culture to the cycle outcome have not been fully documented. On the other hand, the effects of the proposed asynchrony between the cleavage stage embryo and the endometrium are also contradictory.

Study design, size, duration: This was a single center retrospective comparative cohort study in a university based medical assisted reproduction (MAR) center. 1710 entries from January 2018 to December 2019 were evaluated. In this cohort, embryos were not transferred on weekends. Regardless of patient and cycle characteristics, Monday and Tuesday egg retrievals were called back for transfer on day 3 (d3) (n=584), Wednesday and Thursday retrievals were on day 5 (d5) (n=532). Friday retrievals were excluded.

Participants/materials, setting, methods: Fresh cycles were included and primary outcomes were clinical pregnancy and implantation rate. Cycles were stratified on the basis of zygote numbers and analyzed using the intention to treat principle. Outcome of embryos with a known implantation status were used to demonstrate the effects of transferring earlier or later on embryo development. Statistical analyses were performed with T or chi-squared tests. Logistic regression analysis was carried out to calculate the effects of confounders.

Main results and the role of chance: For the patients having 6 or more zygotes, clinical pregnancy rates were significantly higher in the d5 group compared with d3 (48.3% (72/149) vs. 25.7% (29/113), p<0.0001). A logistic regression was performed to account for most relevant confounders and transfer day was the only significant factor (OR (95% CI) = 3.12 (1.8 – 5.43), p<0.0001). The clinical pregnancy outcome of d5 versus d3 groups for 1 (11.9% (7/59) vs. 13.7% (19/139), p=0.73), 2 (18.4% (16/87) vs. 22.9% (30/131), p=0.42), 3 (34.8% (31/89) vs. 31.8% (28/88), p=0.67), 4 (26.8% (22/82) vs. 39.1% (27/69), p=0.11), 5 (36.4% (24/66) vs. 36.4% (16/44), p=1) and ≤5 zygotes (26.1% (100/383) vs. 25.5% (120/471), p=0.83) were all comparable. Patients having ≤5 zygotes were also analyzed by logistic regression and transfer day did not matter at all. Outcome of embryos with a known implantation status were compared between d5 and d3 groups and implantation rates were comparable (9.1% (13/143) vs. 12.95% (32/247) respectively, p=0.12). Although implantation rate per number of transferred embryos of d5 group was significantly higher (31.28% (183/585) vs. 20.52% (157/765), p<0.0001), the number of transferable embryos (embryos transferred plus cryopreserved) were significantly higher in d3 group (29.14% (681/2337) vs. 46% (961/2088), p<0.0001).

Limitations, reasons for caution: The retrospective nature of this study may not eliminate potential bias. On the contrary, the strength of our study is that patients were allocated to the d5 and d3 groups regardless of patient and cycle characteristics. More research is needed to prove our findings.

Wider implications of the findings: Developmental potential of embryos was neither compromised nor supported by transferring earlier or later. Embryo-endometrium synchronization and *in vitro* versus *in vivo* embryo development does not appear to make any significant contribution to treatment outcome. Embryo selection in extended culture makes sense in patients with a larger zygote cohort.

Trial registration number: not applicalble

O-007 High grade trophectoderm is associated with monozygotic twinning in frozen-thawed single blastocyst embryo transfer

Q. Zheng[1], S. Xu[1], M. Mo[1], F. Xiong1, X. Hu[1], Y. Zeng[1]

[1]Shenzhen Zhongshan Urology Hospital, Fertility center, Shenzhen, China

Study question: What specific risk factors make monozygotic splitting at the blastocyst embryo stage?

Summary answer: High grade trophectoderm (TE), but not inner cell mass (ICM) or blastocyst expansion, is associated with monozygotic splitting after frozen-thawed single blastocyst ET.

What is known already: Elective single blastocyst embryo transfer (eSET) contributes to high live-birth rate per embryo transfer cycle and low multi-pregnancy rate, and is well perceived in clinical practice. However, blastocyst transfer is considered as the major risk factor of monozygotic splitting.

Study design, size, duration: This was a retrospective observational study including a cohort of 2863 single blastocyst-transferred pregnancies between January 2011 and June 2019 in a single fertility center in South China. The study was approved by the hospital's Ethics Committee.

Participants/materials, setting, methods: Monozygotic splitting pregnancy was identified as the number of foetuses exceeded the number of gestational sacs (GSs). The incidence of splitting regarding the oocyte age, paternal age, ovarian stimulation protocol, insemination method, type of frozen cycle, Gardner grading of expansion, ICM and TE were calculated. The serum E2, P level and endometrium thickness on hCG/progesterone day, and serum HCG levels on day 11 after ET were compared between the splitting and non-splitting pregnancies

Main results and the role of chance: There were 51 splitting cases in total among the 2863 single blastocyst-transferred pregnancies, the incidence of splitting was 1.78%. High TE grade was associated with monozygotic splitting (*P*=0.022), *aOR* for grade A and B TE were 3.96 (95% CI: 1.20-13.06) and 4.24 (95% CI: 1.24-14.46) compared to that of grade C TE respectively. While the ICM grade and blastocyst expansion were not statistically significant. There were no statistically significant differences in oocyte age, ovarian stimulation protocol, insemination method, type of frozen cycle, serum E2, P and endometrium thickness between the splitting and non-splitting pregnancies. Serum hCG levels on 11 d after ET were significantly higher in the splitting cases than those in the non-splitting pregnancies (*P*=0.020). We hypothesized that increased secretion of HCG from the high grade TE may widen the implantation window and support the monozygotic splitting.

Limitations, reasons for caution: The primary limitation of this study was its retrospective nature and small sample size. The second limitation was that MZT pregnancy was mainly diagnosed by ultrasound evaluation but not conformed by the DNA profiling for the zygosity.

Wider implications of the findings: Clinicians should consider whether to counsel couples about the slightly increased risk of monozygotic splitting

associated with high grade TE. The transfer of an embryo with an optimal TE reduces monozygotic splitting.

O-008 Day7 blastocyst: is it worth it? A systematic review and meta-analysis

G.C. Cermisoni[1], L. Corti[1], A. Alteri[1], P. Vigano'[2], E. Giacomini[3], M. Noventa[4]

[1]San Raffaele Scientific Institute - Milan - Italy, U.O. Obstetrics and Gynecology, Milan, Italy ;
[2]San Raffaele Scientific Institute - Milan - Italy, Reproductive Sciences Laboratory, Milan, Italy ;
[3]San Raffaele Scientific Institute - Milan - Italy, Reproductive Sciences Lab - Division of Genetics and Cell Biology, Milan, Italy ;
[4]University of Padua, Department of Woman and Child Health-, Padua, Italy

Study question: What are the differences in pregnancy outcomes and euploid rate between blastocysts developed on Day7 (D7) and faster blastocysts developed on Day5 (D5) or Day6 (D6)?
Summary answer: Frozen D7 blastocyst transfers are associated with lower clinical pregnancy and live birth rates than D5/6 blastocysts. Euploid rate of screened D7 blastocysts similarly lower.
What is known already: Human embryos optimally reach the blastocyst stage after five days of culture but some have a slower development. Albeit blastocysts developing on Day 7 can be viable and result in a healthy live birth, slowly developing embryos after D6 are routinely discarded. Recent studies provide evidence supporting the idea that D6 blastocysts have a decreased reproductive potential compared to D5 ones. There is however scanty evidence regarding the clinical outcomes of Day 7 blastocysts compared to blastocysts developing on D5 or D6.
Study design, size, duration: Systematic review and meta-analysis of published studies that have evaluated the effect of delayed blastulation in frozen ART cycle. The intervention group consisted of patients with blastocysts cryopreserved on D7. Searches were conducted on 28/08/2019 using the following search terms: blastocyst, Day 5, Day 6, pregnancy, implantation, live birth and embryo transfer. The primary outcome was the clinical pregnancy rate (CPR). Secondary outcomes were euploid and survival rates after thawing and live birth rate (LBR).
Participants/materials, setting, methods: The systematic review was written following the PRISMA guidelines. Sixty-three full-text articles were preselected based on title and abstract. Study selection and data extraction were performed according to Cochrane methods. The pooled results of euploid rate, CPR and LBR were compared according to the day of blastocyst development. Odds ratios (OR) with 95% confidence intervals (CI) were calculated for outcome measures. Random-effect meta-analysis was performed and a p-value less than 0.05 was considered statistically significant.
Main results and the role of chance: Data from 11 relevant articles were extracted. The meta-analysis of 7 studies showed a lower proportion of euploid embryos comparing D7 vs. D5 (OR 0.47, 95%CI 0.39-0.57; p<0.0001) with moderate heterogeneity (I_2=69%) and comparing D7 vs. D6 (OR 0.68, 95%CI 0.61-0.75, p<0.0001) with low heterogeneity (I_2=19%).

A lower proportion of CPR (evaluated in 7 studies) was evident when transfers of blastocysts frozen in D7 were compared to those of blastocysts frozen in D5 (OR 0.37, 95%CI 0.23- 0.59; p<0.0001) with moderate heterogeneity (I_2=66%). Similarly, CPR was reduced comparing D7 vs. D6 (OR 0.49, 95%CI 0.35- 0.69, p<0.0001) with moderate heterogeneity (I_2=38%). A lower proportion of LBR (evaluated in 11 studies) was found comparing transfers of blastocysts frozen in D7 to those of blastocysts frozen in D5 (OR 0.21, 95%CI 0.16-0.27; p<0.0001) with low heterogeneity (I_2=0%) and comparing D7 vs. D6 (OR 0.34, 95%CI 0.26-0.45, p<0.0001) with low heterogeneity (I_2=0%). These findings were confirmed in a subgroup of PGT-A screened embryos. A lower survival rate (evaluated in 5 studies) was demonstrated for blastocysts frozen in D7 vs. D5 (OR 0.31, 95%CI 0.11-0.82; p=0.02) with moderate heterogeneity (I_2=72%), while the comparison of D7 vs. D6 was not statistically different.
Limitations, reasons for caution: The validity of meta-analysis results depends mainly on the number and the quality and of the included studies: this meta-analysis included retrospective studies only. The low number of D7 embryo transfers and the heterogeneity of laboratory strategies are limitations of this paper.
Wider implications of the findings: The results of this original meta-analysis confirm that delayed blastulation is associated with a poorer prognosis in terms of euploid rate and pregnancy outcomes following frozen transfers. On the other hand, the results presented do not support the discharge of embryos deriving from a delayed blastulation.

SESSION 03: STRATEGIES TO IMPROVE THE OUTCOMES OF OVARIAN STIMULATION I

06 July 2020 Parallel 2 10:00 - 11:30

O-009 Progestins as an alternative to Gonadotropin-Releasing hormone analogues: A retrospective study comparing in vitro fertilization outcomes during follicular and luteal phase stimulation.

L. Yamakami[1], M. Nakano[1], F. Ramos[1], L. Matsumoto[1], R. Tomioka[1], O. Duarte Filho[1], V. Heinrich-Oliveira[1]

[1]VidaBemVinda, Medical department, Sao Paulo, Brazil

Study question: May progestins instead Gonadotropin-Releasing Hormone analogues (GnRH-analogues), for suppressing premature Luteinizing Hormone (LH) surge, affects embryo viability and *in vitro* fertilization (IVF) outcomes?
Summary answer: Ovarian stimulation using Progestins does not affect chromosomal rearrangements and pregnancy outcomes; however, it increases the fertilization rate.
What is known already: The use of progestin during ovarian stimulation is effective in preventing LH surge. Development of this protocol is supported by the freezing all strategy and by multiple follicular recruitment waves, respectively, preventing detrimental effects of progesterone on embryo implantation odds, and enabling greater flexibility to physicians and patients. Nonetheless, although it has been demonstrated that progestin does not influence neither the number or the quality of the oocytes, greater depth about the embryo viability and pregnancy achievement is required.
Study design, size, duration: This retrospective study included data from 140 "freeze-all" cycles conducted between August/2018 and December/2019 and split according to pituitary suppression regimen: Gonadotropin-releasing hormone antagonists at follicular phase (GnRH-antagonists, n=53), Progestin at follicular phase (FP, n=38), and Progestin at luteal phase (LP, n=49). We consider follicular phase as day cycle 2 or 3 and luteal phase was defined based on features of transvaginal ultrasound performed after presumed ovulation.
Participants/materials, setting, methods: Women received gonadotropins for follicular recruitment and their respective method for pituitary suppression. Laboratorial procedures were conducted according to standard practice. When indicated, a blastocyst biopsy was performed for 24-chromosome analysis by Next-Generation Sequencing (NGS). The effects of stimulation protocols on IVF outcomes and embryo impairments in terms of chromosomal rearrangements were evaluated using adjusted general linear models. SPSS Statistics 20 was used for data analysis and an α of 5% was adopted.
Main results and the role of chance: There were no differences between groups regarding to female age, body mass index, basal follicle stimulation hormone (FSH), anti-müllerian hormone (AMH) and antral follicle count. Total gonadotropin doses were different between GnRH-antagonist and progestin groups (GnRH-antagonist: 2199±719 vs FP: 2512± 543; p=0.04 and LP: 2695±438; p<0.01). Twenty-nine cycles (54%) from GnRH-antagonist group, twenty-seven (71%) from FP group and twenty-six (53%) from LP group had their embryos undergoing to NGS. The euploidy rate was similar among the tree protocols, as well as the biochemical and clinical pregnancy rates. However, fertilization rate was significantly higher in the FP (86.0%) and LP (90.5%) groups when compared to GnRH-antagonists (86.0% vs 90.5% vs 72.9%, respectively, p<0.01) with Pearson' correlation (r=0.43). There was no difference among the three groups regarding endometrial priming protocol and mean endometrial thickness for frozen embryo transfers.

Limitations, reasons for caution: The present study has limitations inherent to this retrospective design, as a wide range of patient ages, as so different drugs for ovarian stimulation and triggering. Moreover, it was a single center study with a relatively small cohort.
Wider implications of the findings: Progestin use for pituitary suppression, either in follicular and luteal phases, does not affect euploid blastocyst or clinical pregnancy rates, which go against the belief that high levels of progesterone during ovarian stimulation impair oocyte and embryo quality. In addition, we highlighted that progestins provides better oocyte competence for fertilization.
Trial registration number: not applicable

O-010 Can serve Medroxiprogesterone acetate (MPA) as pituitary suppressor instead of GnRH antagonist during ovarian stimulation (OS) in oocyte donation (OD) cycles trigger with GnRH agonist?

J. Giles[1], P. Alama[1], P. Gamiz[2], C. Vidal[1], P. Badia[1], E. Bosch[1]
[1]IVIRMA Valencia, Human Reproduction, Valencia, Spain ;
[2]IVIRMA Valencia, IVF Laboratory, Valencia, Spain

Study question: Is ovarian response of oocytes donors when pituitary is suppressed with MPA comparable to the conventional treatment with GnRH antagonist cycles?.
Summary answer: MPA serve as pituitary suppressor during OS in OD since it does not present lower number of MII or worse reproductive outcome compared to antagonist.
What is known already: Administering progestins orally in the follicular phase since the beginning of OS is an efficient alternative to prevent LH from peaking, related to its effect on LH pulse frequency and amplitude**,** with similar results to conventional protocols.

Progestins have been successfully used in normo-ovulating patients, Polycistic Ovarian Syndrome, endometriosis and low-responders.

A randomized controlled trial (RCT) in OD reported no differences with GnRH antagonist in OS parameters, mature oocytes and top quality embryos. However, pregnancy outcomes were lower.

In contrast, no differences were observed between the two groups in terms of reproductive outcomes in other recently published retrospective studies.
Study design, size, duration: University-affiliated infertility clinic. Prospective RCT study, from October 2017 to June 2019, to evaluate ovarian response in terms of number of oocytes. We randomized 318 donors in two groups in a 1:1 ratio. A difference of ± 3 oocytes respect a mean of 21 in the reference group was considered as an equal response (NCT03300960).

Cycle outcome of the recipients were later analysed retrospectively. Oocytes obtained were assigned to 364 recipients (1910-VLC-091-JG).
Participants/materials, setting, methods: In MPA group 161 participants received intervention (10 mg daily administered orally during OS) and 156 were treatad with antagonist (started once the leading follicle reached 13 mm). Transvaginal ultrasound and serum estradiol (E2), LH, and progesterone (P) were performed during monitoring controls.

Other parameters that were analyzed: endocrine profile (in serum and follicular fluid), number of MII, pregnancy outcomes. For the latest, a questionnaire was offered to all participants after the oocyte retrieval.
Main results and the role of chance: No significant differences were observed in donor demographic characteristics. The number of oocytes retrieved were 21.41±11.71in the MPA group vs. 21.26±9.27 in the antagonist group (P=0.949) (Mean difference 0.14 [95%CI= -2.233, 2.517]).

The total dose of rFSH, length of OS and endocrine profile in follicular fluid in the oocyte pick-up procedure (FSH, estradiol, LH, progesterone) were comparable between groups. LH values on the day of trigger were significantly lower in study group (1.8±2.0 vs 0.9 ±1.1, p=<0.001), while no early luteinization was observed in either group.

No differences between groups were observed for implantation rate (78% vs. 73.9% p=0.441), clinical pregnancy rate (78.3% vs. 73.3, p=0.383), ongoing pregnancy rate (70.9 vs. 67%, p=0.592) and early pregnancy loss (9.7% vs. 8.0%, p=0.669). Live birth rate would be presented at the congress since there are still gestations in progress

There is a significant difference in favor of the MPA group in questions related to ease of administration and number of injections. In donors with previous cycle with antagonists level of satisfaction has been very high / high with respect to the previous cycle in 92.74%.
Limitations, reasons for caution: This is a non-inferiority study with number of retrieved oocytes as the primary outcome. The limitations of this RCT include that treatment could not be blinded, because of the different administration route of the medication in study. Another limitation to take into account is that oocyte recipients were not randomized.
Wider implications of the findings: We observed comparable oocyte retrieval, endocrine profile, viable embryo numbers and similar pregnancy outcomes in the two groups. Therefore, MPA is useful for OS in OD and provides a more friendly approach.
Trial registration number: NCT03300960

O-011 Optimising follicular development, down regulation, triggering and luteal phase support during in vitro fertilisation (IVF): a Delphi consensus

Study question: How can outcomes of *in vitro* fertilisation (IVF) be improved using the evidence-based opinion of clinical experts?
Summary answer: Eighteen statements were developed concerning improving outcomes of IVF; 17 statements reached consensus during the first vote and one reached consensus after a second vote.
What is known already: The ESHRE 2019 Guidelines provide clinicians with valuable evidence-based recommendations to optimise ovarian stimulation and IVF. However, data from such guidelines are primarily based on randomised controlled trials (RCTs) with highly selected populations that are conducted under very controlled conditions. Furthermore, these trials are limited by the fact that only ~35% of the general patient population has been reported to meet their inclusion criteria.
Study design, size, duration: A Delphi consensus was conducted to formulate expert opinion on how IVF outcomes could be improved. Step 1: statements/supporting references were discussed/amended by 11 experts. Step 2: 35 experts voted on their level of agreement/disagreement with each statement. Consensus was reached if the proportion of participants agreeing/disagreeing with a statement was >66%. If consensus was not achieved, the statement was revised and re-voted until consensus was reached. Step 3: consensus results communicated to participating experts.
Participants/materials, setting, methods: Step 1 involved the Scientific Board, comprising the Scientific Coordinator, who developed the initial statements and supporting references (which included RCTs, meta-analyses, systematic reviews, as well as retrospective studies and review articles), and 10 additional experts. The Scientific Board discussed and refined the final statements and references. Step 2

involved 35 experts who rated their level of agreement or disagreement with each statement and were asked to provide reasons for their rating.
Main results and the role of chance: Consensus was achieved for 18 statements, the most relevant of which are summarised below:

- Follicular development/gonadotropins (n=9 statements):
- Oocyte number and live birth rate (LBR) are strongly correlated; there is a positive linear correlation with cumulative LBR
- Exogenous FSH alone is sufficient for follicular development in normogonadotropic patients aged <35 years
- Different FSH preparations have identical polypeptide chains but different glycosylation patterns, affecting the biospecific activity of r-hFSH
- rLH supplementation demonstrates improved pregnancy rates and cost efficacy versus hMG in patients with severe FSH/LH deficiency
- Pituitary suppression (n=2):
- GnRH antagonists are associated with lower rates of any grade OHSS and cycle cancellation versus agonists
- Final oocyte maturation triggering (n=4):
- hCG represents the gold standard in fresh cycles
- GnRH agonist trigger, in GnRH antagonist protocol, is recommended for final oocyte maturation in women at risk of OHSS
- Current evidence supports significantly higher pregnancy rates with hCG + GnRH agonist versus hCG alone, but further evidence is needed
- The efficacy of hCG triggering for frozen transfers in modified natural cycles is controversial compared with LH peak monitoring
- Luteal-phase support (n=3):
- Vaginal progesterone therapy represents the gold standard for luteal-phase support

Limitations, reasons for caution: The statements only represent the collective opinion of the experts included. Furthermore, not all statements reached 100% agreement, with some statements reaching consensus even though some participants disagreed with them.
Wider implications of the findings: This Delphi consensus provides a real-world clinical perspective from a diverse international group of experts. Additional guidance from clinicians on IVF strategies could complement guidelines and policies, and may help to further improve treatment outcomes.
Trial registration number: not applicable

O-012 Predicted high-responder women diagnosed with oligoovulation may benefit from stimulation with highly purified human menopausal gonadotrophin (HP-hMG)

P. Heiser[1], E. Foster[1], A. Sinha[1], O. Elci[1], G. Daftary[2]

[1]Ferring Pharmaceuticals- Inc., Clinical Development, Parsippany, U.S.A. ;
[2]Ferring Pharmaceuticals- Inc., Medical Affairs, Parsippany, U.S.A.

Study question: Do gonadotrophin-related differences in efficacy exist in predicted high-responder women undergoing assisted reproductive technology based upon underlying infertility diagnosis?
Summary answer: Ongoing pregnancy rates after fresh blastocyst transfer are significantly higher with HP-hMG versus recombinant follicle stimulating hormone (rFSH) in predicted high-responder women with oligoovulation.
What is known already: Women predicted to be high-responders are a heterogenous cohort with diverse infertility etiologies and unique treatment challenges. Post-hoc analyses of previous trials suggest that these patients exhibit differential treatment response based on type of gonadotrophin administered. Use of HP-hMG is associated with fewer oocytes retrieved, higher pregnancy rates, and fewer interventions for ovarian hyperstimulation syndrome (OHSS) versus rFSH (Anckaert 2012, Arce 2012, Arce 2013). These findings required further evaluation through prospective clinical trials.
Study design, size, duration: Planned analysis of a multicenter, randomised, assessor-blind, controlled non-inferiority trial in 620 women, 21-35 years, with BMI 18-30 kg/m^2 and serum anti-Mullerian hormone (AMH) ≥35.7 pmol/L undergoing intracytoplasmic sperm injection and single blastocyst transfer. Patients were randomised to a 150IU dose of rFSH (N=309; GONAL-F, Merck) or HP-hMG (N=311; MENOPUR, Ferring), receiving 150 IU daily for the first five days with 75 IU adjustments permitted thereafter in a gonadotrophin releasing hormone (GnRH) antagonist protocol.
Participants/materials, setting, methods: Oocyte maturation was triggered with human chorionic gonadotrophin except for those with OHSS risk where GnRH agonist was substituted and fresh transfer cancelled. The primary endpoint was ongoing pregnancy rate (presence of at least 1 intrauterine pregnancy with fetal heartbeat 8-9 weeks after fresh transfer). Planned sensitivity analyses in the modified intent-to-treat population (all randomized subjects who received at least 1 dose of gonadotrophin) included assessment of primary endpoint rate by infertility diagnoses.
Main results and the role of chance: The non-inferiority objective for the primary endpoint of ongoing pregnancy was met. HP-hMG was associated with numerically higher ongoing pregnancy rates vs rFSH (35.5% vs 30.7%, P>0.05). The average number of oocytes per patient (±SD) in the rFSH arm (22.2±11.54) was higher than in the hMG arm (15.1±10.12), a difference in ovarian response that was accompanied by statistically significant increases in rates of OHSS (21.4% vs 9.7%; p<0.05). There were no significant differences in ongoing pregnancy rate between treatment groups in those diagnosed with endometriosis, male factor, tubal infertility, idiopathic, or other. However, among those diagnosed with oligoovulation, HP-hMG treatment (N=50) was associated with a 19.2% higher ongoing pregnancy rate (95% confidence interval 1.2%-37.3%) than rFSH (N=56). Relative to the rest of the trial population, those with oligoovulation had higher mean AMH (52.10 vs. 60.95 pmol/L, p<0.001), luteinizing hormone (6.45 vs 7.55 U/L, p=0.007), and testosterone (1.00 vs. 1.14 nmol/L, p=0.006) although FSH and BMI were similar. Comparisons between populations with and without oligoovulation were made using either t-tests (continuous parameters) or Fisher's exact test (categorical parameters). HP-hMG differs from rFSH in its FSH isoforms and presence of LH activity; either or both of which could account for differences observed.
Limitations, reasons for caution: The present trial was not powered to detect differences in pregnancy outcomes based upon infertility diagnoses. Additional comparative trials are required to confirm this finding.
Wider implications of the findings: The current study highlights a possible opportunity for optimization of stimulation protocols for predicted high-responders with oligoovulation through the use of HP-hMG.
Trial registration number: NCT02554279

O-013 A drop in serum progesterone levels on day of fresh blastocyst transfer, using standard luteal phase support is associated with significantly lower ongoing pregnancy rates

E. Uyanık[1], M. Polat[2], S. Mumusoglu[1], I. Yarali Ozbek[3], G. Bozdag[1], P. Humaidan[4], H. Yarali[1,2]

[1]Hacettepe University, Obstetrics and Gynecology, Ankara, Turkey ;
[2]Anatolia IVF and Women Health Center, Obstetrics and Gynecology, Ankara, Turkey ;
[3]Anatolia IVF and Women Health Center, Histology and Embryology, Ankara, Turkey ;
[4]Aarhus University- Skive Hospital, Obstetrics and Gynecology, Skive, Denmark

Study question: Do early- and mid-luteal serum progesterone (P_4) levels impact ongoing pregnancy rates (OPRs) in fresh blastocyst transfer cycles, using a standard luteal phase support (LPS)?
Summary answer: A drop in serum P_4 level from oocyte-pick up (OPU)+3 to OPU+5, using a standard LPS, is associated with a 2.8 fold decrease in OPR.
What is known already: In fresh embryo transfer cycles, significant inter-personal variation occurs in serum P_4 levels during the luteal phase, possibly due to differences in endogenous P_4 production from corpora lutea after hCG trigger and/or differences in bioavailability of exogenously administered P_4 via different routes. Although exogenous P_4 may ameliorate this drop in serum P_4 in fresh transfer cycles, there is paucity of data exploring the possible impact on reproductive outcomes of a reduction in P_4 levels.
Study design, size, duration: Using a prospective cohort study design, a total of 101 patients were consecutively enrolled between February 2019 to November 2019. The inclusion criteria were; female age <40 yr-old, retrieval of ≥3 oocytes irrespective of ovarian reserve, number of previous failed cycles ≤2, body-mass index (BMI) < 35 kg/m^2, single or double fresh blastocyst transfer. Each patient was included only once. The primary outcome measure was OPR, as defined by pregnancy ≥12 weeks of gestational age.
Participants/materials, setting, methods: A GnRH-agonist (n=23) or GnRH-antagonist (n=78) protocol was used. rhCG was used for trigger in the majority of cycles (n=95). Vaginal progesterone gel (Crinone 8%, Merck) once

daily was used for LPS. Serum P_4 levels were measured in patients on five occasions; on the day of ovulation trigger, day of OPU, OPU+3, OPU+5 and OPU+14 days; the timing of blood sampling was standardized to be 4-5 hours after the morning administration of vaginal gel.

Main results and the role of chance: Female age, BMI, number of previous cycles, number of oocytes, number and quality of blastocysts transferred were comparable among patients with (n=48) or without (n=53) OP. Similarly, mean P4 level on the day of trigger, day of OPU, and OPU+3 was comparable between two groups. However, patients with OP had significantly higher P4 levels on OPU+5 (103.6±34.0 vs 86.9±37.5 ng/ml, p=0.021). More importantly, a drop in P4 level from OPU+3 to OPU+5 was seen in 35% of patients (negative-Δ= OPU+5 – OPU+3), and was associated with a significantly lower OPR when compared with positive-Δ counterparts (31.4% vs 56.3%;OR= 2.80 (95% CI; 1.17-6.68; p=0.02); this decrease in OPR was due to lower initial pregnancy rates rather than increased early pregnancy loss rates. For negative-Δ patients, magnitude of negative-Δ was a significant predictor of OP (AUC=0.80; 95% CI; 0.65-0.96); with an optimum threshold of -18.1 ng/ml, sensitivity and specificity were 54.2% and 90.9%, respectively. Of interest, for positive-Δ patients, magnitude of Δ was not a predictor of OP (AUC=0.51; 95% CI; 0.37-0.66). When logistic regression analysis was performed, only negative–ΔP4, but not serum P4 level on OPU+5 , was noted to be an independent predictor of ongoing pregnancy (OR= 0.34;95% CI; 0.11-0.99;p=0.047).

Limitations, reasons for caution: The physiological circadian pulsatile secretion of P_4 during the mid-luteal phase is a limitation when analyses are based on one blood sample, only.

Wider implications of the findings: Two measurements (OPU+3 and OPU+5days) of serum P_4 may delineate those patients with a drop in P4 (~ 35% of whole cohort), associated with 2.8 fold lower OPRs. Rescuing these IVF cycles with additional supplementation of P_4 or adopting a freeze-all policy should be tested in future randomized controlled trials.

Trial registration number: NCT04128436

O-014 Testosterone priming (short or long course) before IVF does not improve the number of oocytes retrieved in poor ovarian responders: a randomized controlled trial.

J. Subira[1,2], A. Algaba[1], S. Vazquez[1], R. Taroncher Dasi[1], S. Monzó Fabuel[1], V. Baydal[1], A. Ruiz Herreros[1], N. Garcia Camuñas[1], J.M. Rubio Rubio[1]

[1]University Hospital La Fe, Assisted Reproduction, Valencia, Spain ; [2]IVIRMA Castellon, Assisted Reproduction, Castellon, Spain

Study question: Does follicular preparation with testosterone increase the number of metaphase II oocytes retrieved in poor ovarian responders (POR) according to Bologna criteria?

Summary answer: The use of testosterone either in a short or long course before IVF does not increase the number of MII oocytes retrieved.

What is known already: POR is characterized by an androgen-depleted follicular environment. Follicular preparation with testosterone has been used in several studies showing an increase in oocyte recovery in some of them while in others no benefit was shown. Recently, some have advocated that the possible effect of testosterone would only be achieved when given for several weeks prior to IVF, given the duration of folliculogenesis in women. Most of the studies published have limited the use of testosterone to the previous luteal phase before starting ovarian stimulation and/or were not randomized. Thus, follicular testosterone preparation in POR remains a controversial intervention.

Study design, size, duration: Randomized controlled trial comparing three groups: long-testosterone (testosterone transdermal gel 12.5 mg/day during previous two cycles), short-testosterone (testosterone transdermal gel 12.5 mg/day during previous luteal phase) and control group (no testosterone). Single-blinded for physicians involved. Sample size powered to detect a difference of at least 2 MII: 21 patients per group (N=63). Serum androgen determination at randomization, before starting stimulation and on the day of trigger. Follow-up until 12th week of gestation.

Participants/materials, setting, methods: University hospital La Fe. POR patients according to Bologna criteria. Short-antagonist protocol, fixed dose 300 IU hMG throughout stimulation. Primary outcome: number of MII retrieved. Secondary outcomes: serum androgen levels at the start of stimulation, antral follicles at the start of stimulation, number of follicles on the day of trigger, cancellation rate, embryo quality, clinical pregnancy rate. Statistical test: Poisson regression.

Main results and the role of chance: Forty-nine patients (group long-testosterone= 17, short-testosterone= 17, control= 14) completed the study as 14 out of the 63 randomised abandoned or were excluded due to several reasons. Basal characteristics of the patients were as follows: age (36.51+/-2.99), BMI (23.21+/-3.6), AMH (4.37 pmol/L+/- 2.54) and days of stimulation (10.15 +/- 2.26). There were no differences between groups. Testosterone levels and free androgen index at the time of starting stimulation were significantly higher in groups receiving testosterone compared to controls. There were no differences between groups for androstendione, SHBG or DHEA. Mean number of oocytes retrieved was 3.8 +/- 3.17 and mean number of MII was 2.56 +/- 2.68. For the primary outcome there were no differences between groups (long-testosterone=2.12+/-2.66, short-testosterone 2.71+/-2.95, control 2.92+/-2.43, p=0.98). The rest of results are still under analysis so we can only report on the primary outcome at this moment. Shortly we will have the remainder of results regarding cycle parameters and outcomes and we will update this abstract accordingly.

Limitations, reasons for caution: The drop-out rate was higher than expected (22%, sample size calculated for 15%) which could affect the power to detect differences. We present only partial results regarding mainly the primary objective.

Wider implications of the findings: Based on these preliminary results the use of testosterone in POR, either in a short or long course does not appear to increase the number of MII retrieved and therefore should not be considered as a priming strategy.

Trial registration number: NCT03378713

SESSION 04: MALE FERTILITY RELATED PREDICTORS AND THEIR USE

06 July 2020 Parallel 3 10:00 - 11:30

O-015 Paternal contribution to embryo morphokinetics in a time-lapse incubator system

A. Setti[1,2], D. Braga[1,2], R. Provenza[3], A. Iaconelli Jr.[4], E. Borges Jr.[2,4]

[1]Fertility Medical Group, Scientific research, São Paulo, Brazil ; [2]Instituto Sapientiae- Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific research, São Paulo, Brazil ; [3]Fertility Medical Group, Andrology laboratory, São Paulo, Brazil ; [4]Fertility Medical Group, Clinical department, São Paulo, Brazil

Study question: Can paternal age and semen quality influence embryo morphokinetic events in a time-lapse incubator system (TLS)?

Summary answer: Embryo morphokinetic parameters are negatively influenced by paternal age and positively influenced by the seminal quality.

What is known already: Although male-factor infertility is known to play a role in 50% of the cases of infertility, the impact of male partner characteristics on IVF is often ignored. The sperm contribution to the success of IVF shouldn't be underestimated, however, few studies have focused on the influence of male factors on IVF, with conflicting results. The TLS provides the opportunity of multiple observations of the embryo developmental changes, while optimal culture conditions are maintained. Therefore, the identification of morphokinetic events affected by paternal factors may contribute to a better understanding of morphologic mechanisms in fertilization and behavior of early human embryos.

Study design, size, duration: Kinetic data were analyzed in 139 patients and 1220 zygotes cultured until day five in a TLS between March/2019 and November/2019. Timing of specific events from the point of insemination was determined using time-lapse imaging. Abnormal cleavage patterns, such as reverse cleavage and direct uneven cleavage, and the presence of multinucleation were also recorded. Multivariate linear regression analyzes were used to evaluate the influence of paternal factors on embryo morphokinetic events.

Participants/materials, setting, methods: This study was performed in a private university–affiliated IVF center. Recorded kinetic markers were: pronuclei

appearance (tPNa), timing to pronuclei fading (tPNf), timing to two (t2), three (t3), four (t4), five (t5), six (t6), seven (t7), and eight cells (t8), and timing to blastulation (tB). Durations of the second (t3-t2) and third (t5-t3) cell cycles (cc2 and cc3, respectively) and timing to complete synchronous divisions s1 (t2-tPNf), s2 (t4-t3), and s3 (t8-t5) were also calculated.

Main results and the role of chance: The paternal age was directly correlated with longer t2 (B: 0.043, p: 0.024), t3 (B: 0.056, p: 0.044), t4 (B: 0.066, p: 0.012), t6 (B: 0.080, p: 0.042), tB (B: 0.120, p: 0.041), and the presence of multinucleation (Exp(B): 1.027, p: 0.004), while the implantation rate (B: -1.933, p<0.001) and the odds of pregnancy rate (Exp(B): 0.784, p<0.001) were negatively affected by paternal age. The progressive sperm motility was negatively correlated with t4 (B: -0.016, p: 0.037), t6 (B: -0.028, p: 0.027), t7 (B: -0.044, p: 0.003), t8 (B: -0.054, p: 0.002), s3 (B: -0.033, p: 0.019), and tB (B: -0.033, p: 0.019). In addition, the total motile sperm count was inversely correlated with t8 (B: -0.009, p: 0.021), S3 (B: -0.009, p: 0.005), and tB (B: -0.011, p:0.019).

Limitations, reasons for caution: Retrospective nature of this study and the small sample size may be a reason for caution.

Wider implications of the findings: The association between embryonic growth rate and embryo quality is well recognized. Implantation and live-birth rates are lower with slow-growing embryos. We demonstrated that increasing paternal age and poor seminal quality correlates with delayed cell cleavage and blastulation. This finding highlights the importance of paternal contribution for the IVF success.

Trial registration number: Not Applicable

O-016 Low male testosterone results in a substantial decrease of fresh live birth rates in couples with non-male factor infertility undergoing IVF

P. Drakopoulos[1], F. Di Guardo[1], C. Blockeel[1], M. De Vos[1], E. Anckaert[1], G. Verheyen[1], S. Santos-Ribeiro[2], A. Racca[1], L. Boudry[1], S. Mackens[1], H. Tournaye[1], V. Vloebergs[1]

[1]UZ Brussel, Center for Reproductive Medicine, Jette- Brussels, Belgium ; [2]IVI-RMA, Department of reproductive medicine, Lisbon, Portugal

Study question: Are male testosterone levels associated with reproductive outcomes in couples with non-male factor infertility undergoing IVF?

Summary answer: Low male serum testosterone levels in couples with non-male factor infertility are associated with a decrease in fresh live birth rates after fresh embryo transfer

What is known already: Low serum testosterone is found in approximately 15% of subfertile men. Although testosterone is essential in spermatogenesis, it is unclear whether low testosterone levels may have a negative impact on reproductive outcomes in couples with non-male factor infertility. Furthermore it is debatable whether the initial evaluation of the subfertile male should include an endocrine assessment

Study design, size, duration: This was a 7 years (2011 to 2018) retrospective, single-center cohort study conducted at a tertiary fertility clinic.

Participants/materials, setting, methods: All couples with non-male factor infertility who underwent their first IVF cycle in a GnRH antagonist protocol were included. All asymptomatic men provided morning blood samples (before 10 am) and none had been on exogenous testosterone or other relevant medication. Low total testosterone (TT) was defined as TT<264 ng/dL in line with the recently published guidelines of the endocrine society. Testosterone assay used was the same for all patients.

Main results and the role of chance: In total 1026 couples were included in the analysis. Among them, 136 (13.3 %) had low TT. Semen concentration, progressive (A+B) motility (WHO 2010) and morphology using Kruger's strict criteria were lower, but not significantly different between patients with low and normal TT [median (IQR): 52.8 x 10^6 (28-109) vs. 54.3 x 10^6 (27-93), 58% (41-68) vs. 59 (45-69) and 5% (4-8) vs. 6% (4-10), p value=0.6, 0.3 and 0.3, respectively]. However, fresh live birth rates (LBR) after fresh embryo transfer were significantly lower in patients with low TT (13.2% vs. 23.2%, p value=0.009). Multivariate regression analysis allowing adjustment for relevant confounders revealed that TT status was significantly associated with fresh LBR. The odds of fresh LB decreased by 65% in couples whose male partner had low TT (adjusted OR =0.35, 95% CI=0.15-0.79,p value=0.01). The results were also replicated when TT was considered as a continuous variable and when free calculated testosterone was used in the regression model

Limitations, reasons for caution: This is a large observational study based on retrospective data collection. Despite our robust methodological approach, the presence of biases related to retrospective design cannot be excluded

Wider implications of the findings: Our findings underscore the importance of a complete endocrine evaluation of the subfertile male. Efforts to evaluate and maybe optimize even asymptomatic low TT in male partners should be considered. Future research might need to identify a new cut-off in the definition of "normal" TT, in an infertility context

Trial registration number: N/A

O-017 Negative impact of elevated DNA fragmentation index (DFI) and human Papillomavirus (HPV) presence in sperm on the outcome of intra-uterine insemination (IUI)

C. Depuydt[1], G. Donders[2], L. Verstraete[1], J. Beert[1], G. Salembier[1], E. Bosmans[1], D. Nathalie[3], W. Ombelet[3]

[1]AML- Sonic Healthcare, Department of Hormonology and Reproductive Health- AML, Antwerp, Belgium ; [2]University Hospital Antwerpen, Department of Obstetrics and Gynecology, Antwerp, Belgium ; [3]Genk Institute for Fertility Technology- ZOL Hospitals, Zorgprogramma Reproductieve Geneeskunde B ZRGB, Genk, Belgium

Study question: To determine the impact of DFI and HPV-DNA positivity on fertility outcome (biochemical and clinical pregnancy rate) in sperm before its use in IUI.

Summary answer: DFI and HPV status in sperm from male partners are independent predictors of clinical pregnancies (CP) in women undergoing IUI.

What is known already: Recent evidence identified HPV infections as a possible cause of male and couple infertility in IUI. While the pathogenesis of HPV infection in the cervix can be divided in two pathways, (an infectious, virion-producing and a non-infectious, cell transforming, cancer-inducing pathway), in sperm, the HPV DNA always originates from infectious virons only and is limited in time. HPV virions can bind syndecan-1 present at two distinct sites along the equator of the spermatozoon's head, not only causing detrimental effects on sperm parameters but also damages the DNA of the spermatozoids, impacting on gamete interaction and causing temporal subfertility.

Study design, size, duration: Non-interventional prospective multi-center study (12-month study period) in which we measured both the DFI and HPV DNA in sperm before its use in IUI in a cohort of 161 consecutive infertile couples (209 IUI cycles).

Participants/materials, setting, methods: DFI was measured with the sperm chromatin structure assay and HPV DNA was detected with type specific quantitative PCRs (HPV 6,11,16,18,31,33,35,39,45,51,52,53,56,58,59,66 and 68) in sperm before its use in IUI. We analyzed the impact of DFI and HPV positivity on fertility outcome (biochemical and clinical pregnancy rate) and calculated the clinical cutoff value for DFI.

Main results and the role of chance: A DFI criterion value of 25.7% was calculated by ROC curve analysis. Couples with DFI >26% had significantly less CP than couples with DFI ≤26% (OR 31.8, 1.8-510.9, p = 0.017). In total, 31 sperm samples from 169 different men were HPV positive, resulting in an HPV prevalence of 14.8% per IUI cycle and a high-risk HPV prevalence of 9.6% per IUI cycle (20/209). HPV positive sperm samples had a significantly higher DFI compared to HPV negative sperm samples (29.8% vs 20.9%; p=0.011). None of the 31 inseminations in which the sperm tested positive for HPV led to pregnancy, even when DFI% was below 26%.

Limitations, reasons for caution: HPV positivity (virions) in female partners could also lead to DNA damage of spermatozoa and influence the clinical pregnancy rate per cycle even more. Therefore, to have a complete picture of the prediction model both partners should be tested for HPV and ideally each time an IUI cycle is performed.

Wider implications of the findings: Because men can easily infect women and these HPV infected women have longer duration of transient infections resulting in (longer) infertility period. Considering the low IUI success rates IVF or ICSI might be indicated in HPV-positive couples and in couples with a DFI above 26% to increase the pregnancy rate.

Trial registration number: EudraCT number: 2017-004791-56

O-018 Proteomic characterization of spermatozoa from patients with idiopathic infertility.

I. Urizar Arenaza[1], B. Navarro[2], B. Gómez-Giménez[1], A. Odriozola[1], S. Martín-González[1], I. Muñoa-Hoyos[1], M. Gianzo[1], T. Ganzabal[2], N. Subiran[1]

[1]University of the Basque Country UPV/EHU, Physiology, Leioa, Spain ; [2]Quirón Bilbao, Assisted Reproduction Unit., Bilbao, Spain

Study question: Which is the proteomic profile of spermatozoa belonging to patients with idiopathic infertility?
Summary answer: Compared to normozoospermic samples, we identified a total of 385 differentially expressed proteins that are involved in human sperm metabolism.
What is known already: Infertility has become a medical and social problem that affects over 186 million people worldwide and male factors represent approximately 45% of clinical cases. Among other factors, anatomical or genetic abnormalities, problems in spermatogenesis or environmental factors are responsible for abnormal sperm parameters which contribute to male infertility. However, approximately 20-30% of men with normal sperm parameters have impaired fertility caused by unknown deficiencies. Thereby, the molecular mechanisms underlying idiopathic infertility are poorly understood.
Study design, size, duration: We used 80 normozoospermic samples and 80 pathological samples belonging to men with idiopathic infertility. Male idiopathic infertility was considered when spermatozoa presented normal sperm parameters but there was a repeated failure in the Assisted Reproduction Techniques. Samples were obtained from the Quirón Bilbao Clinic and were isolated and capacitated by swim up.
Participants/materials, setting, methods: We adopted a Tandem Mass-Tag (TMT) 6-plex isotopic labeling strategy and generated samples for LC-MS/MS. We extracted proteins from normozoospermic samples and samples with idiopathic infertility and after proteomic procedures we run the generated peptides in a Q Exactive mass spectrometer. Protein searches were performed using the MaxQuant Software. Perseus software (v.1.6.0.7) was employed for the calculation of the statistical significance and fold changes between samples with idiopathic infertility and normozoospermic samples ($p<0.05$).
Main results and the role of chance: In the present study we identified a total of 1722 human sperm proteins. Differential proteomic studies showed an increase in the relative abundances of 176 proteins and a decrease in the relative abundances of 209 proteins. According to the proteins that are upregulated, there are involved in metabolical processes, being the most enriched ones the acetyl-CoA biosynthetic process, ADP transport and 2-oxoglutarate metabolic process. Regarding proteins that are downregulated, there are involved in ATP metabolic processes, protein targeting and nucleotide processes. According to our results, human sperm metabolism may be key in the finding of targets that may cause idiopathic infertility. This finding suggests that altered metabolic parameters may lead human sperm to idiopathic infertility.
Limitations, reasons for caution: We need further studies to identify and validate specific protein targets that may alter specific metabolic processes and consequently cause idiopathic infertility.
Wider implications of the findings: The study of human sperm metabolism may be essential to understand the causes of many idiopathic infertility cases. This supports the idea that proteins involved in metabolic processes could be used as therapeutic targets in the treatment of idiopathic infertility.
Trial registration number: CEISH/61/2011.

O-019 extremely low serum AMH level correlates with a high sperm retrieval rate of micro-TESE in men with idiopathic azoospermia

J. Zhang[1], X. Liang[1]

[1]the Sixth Affiliated Hospital- Sun Yat-sen University, reproductive center, Guangzhou- Guangdong, China

Study question: To investigate the value of serum anti-Müllerian hormone (AMH) level in predicting the sperm retrieval rate (SRR) of micro-TESE for patients with idiopathic azoospermia.
Summary answer: Idiopathic azoospermia cases with low AMH level (<1.0ng/ml) would have more opportunity to present heterogeneous seminiferous tubules when micro-TESE was performed and had higher SRR.
What is known already: For infertile patients with non-obstructive azoospermia (NOA), micro-TESE is considered to have higher SRR than traditional methods. However, Serum inhibin B, follicle-stimulating hormone (FSH) and various clinical parameters are not reliable predictors for the presence of focal spermatogenesis and SRR. SRR of micro-TESE between NOA patients with different etiology varies widely. Idiopathic azoospermia would have much lower SRR than orchitis, cryptorchidism, AZFc deletion, Klinefelter syndrome and other cases when micro-TESE is performed. Therefore, it is still controversial that whether micro-TESE have an advantage in patients with idiopathic azoospermia.
Study design, size, duration: This is a retrospective study. From Sept. 2014 to Jan. 2020, 163 idiopathic azoospermia patients treated with micro-TESE by single surgeon were divided into three groups according to their serum AMH level: group A <1.0ng/ml (n=41), group B 1.0-5.0ng/ml (n=68), group C >5.0ng/ml (n=54). Patient's age, testicular volume, serum FSH and AMH level, SRR and heterogeneous seminiferous tubules presenting rate were evaluated.
Participants/materials, setting, methods: Micro-TESE was performed at x10 to x20 magnification. An attempt was made to identify seminiferous tubules that were larger and more opaque than others. The procedure was terminated when sperm were retrieved. If all tubules were seen to have an identical appearance, at least three samples (upper, middle, and lower) were extracted. Venous blood samples were drawn from each patient (7–10 AM) after an overnight fast. FSH and AMH were measured by electrochemiluminescence immunoassay.
Main results and the role of chance: Testicular sperms were successfully retrieved in 55 cases (SRR=33.7%). There was no statistical difference in age, testicular volume, FSH level between the patients who succeeded and failed to obtain sperm (33.3±5.1 years, 5.4±3.0 ml, 26.7±15.7 IU/L vs. 32.5±5.7 years, 6.0±2.8 ml, 26.1±12.6 IU/L, p>0. 05 respectively). The patients who obtained sperms had lower serum AMH level than those without sperm (2.87±3.79ng/ml vs. 4.99±4.64ng/ml, p<0. 05). SRR and heterogeneous seminiferous tubules presenting rate were 56.1% (23/41), 70.7% (29/41) in group A vs. 30.9% (21/68), 27.9% (19/68) in group B vs. 20.4% (11/54), 13.0% (7/54) in group C (p<0. 05 respectively). In group A (AMH=0.36±0.29ng/ml), SRR and heterogeneous seminiferous tubules presenting rate were highest, meanwhile they were lowest in group C (AMH=9.26±4.37ng/ml).
Limitations, reasons for caution: Seminal AMH level should be included in the following study to confirm our conclusion. Randomized controlled trial comparing micro-TESE and traditional TESE would demonstrate that whether idiopathic azoospermia patients with serum AMH level higher than 1.0ng/ml could not have benefit by microsurgery.
Wider implications of the findings: Recently, in our pathologic research, NOA patients with extremely lower serum AMH level are observed to have more opportunity to present severe hyalinization in their seminiferous tubules. Tubules with severe hyalinization have less Sertoli cells and seem very thin. Therefore, tubules with spermatogenesis would be easy to identify during micro-TESE.
Trial registration number: Not Applicable

O-020 MACS Vs TESA for raised sperm DNA fragmentation index – A RCT

K.C. Mantravadi[1], D.R. Gedela[1], S. Thakur[1], P. Shetty[1]

[1]Oasis Fertility, Fertility, Hyderabad, India

Study question: In Individuals with raised Sperm DNA Fragmentation Index (DFI), sperm selection by magnetic activated cell sorting (MACS) or surgical retrieval of testicular sperms (TESA) optimize the reproductive outcomes?
Summary answer: TESA seems like a beneficial intervention to optimize sperm selection and reproductive outcomes for Individuals with raised sperm DFI.
What is known already: It is evident that raised sperm DFI negatively affects the reproductive outcomes. Management for raised sperm DFI to optimize reproductive outcomes is still elusive.
Study design, size, duration: This is an ongoing Randomised Control Trial (RCT) with prior approval from institutional Ethical Committee (IEC). This is preliminary data of the pilot study. Study duration 6months (March – October 2019). Couples undergoing IVF stimulation with raised sperm DFI were

randomised into MACS group (n=30) and TESA group (n=30) for sperm selection. Couples with history of one failed IVF cycle were offered testing for sperm DFI. Individuals with sperm DFI>30% were included in the study.
Participants/materials, setting, methods: Sperm DFI testing was done with SCSA method and randomized using software. Intra Cytoplasmic Sperm Injection (ICSI) was the method of insemination in all cases. Extended embryo culture till blastocyst stage was done and a freeze all policy was opted. Two Blastocysts that showed 100% survivals were transferred in a Frozen Embryo transfer (FET) cycle. Implantation rates (IR) and Clinical Preganacy Rates (CPR) were compared between both groups.
Main results and the role of chance: MACS group showed 38% blastocyst formation rates with a CPR of 50% and IR of 43%

TESA group showed 31% blastocyst formation rates with a CPR of 83% and IR of 72%

Though MACS group had slightly more percentage of blastocyst formation; TESA group had significantly higher CPR and IR.

Individuals with history of failed implantation and raised sperm DFI, TESA seems to be beneficial intervention to optimize reproductive outcomes.
Limitations, reasons for caution: Small sample size. TESA is a surgical intervention.
Wider implications of the findings: Testicular sperm seem to have better DNA quality than ejaculated sperm. In couples with failed IVF attempts and raised sperm DFI we can offer TESA as an active intervention to optimize reproductive outcomes.

SESSION 05: ENDOMETRIOSIS AND UTERINE DISORDERS. NEW CLINICAL INSIGHTS

06 July 2020 Parallel 4 10:00 - 11:30

O-021 Laparoscopic surgery for endometriosis: a Cochrane systematic review (Cochrane update).

C. Bafort[1,2], Y. Beebeejaun[3], C. Tomassetti[1,2], J. Bosteels[2,4], J. Duffy[5]

[1]UZ Leuven, OBGYN/Leuven University Fertility Center, Leuven, Belgium ;
[2]KULeuven, Dept of Development and Regeneration, Leuven, Belgium ;
[3]Guy's and St. Thomas' Hospital NHS Foundation Trust, Assisted Conception Unit, London, United Kingdom ;
[4]Imelda Hospital, Department of obstetrics and gynaecology, Bonheiden, Belgium ;
[5]University of Oxford, Nuffield Department of Primary Care Health Sciences, Oxford, United Kingdom

Study question: Does laparoscopy improve pain and/or infertility associated with endometriosis compared to any other laparoscopic or robotic intervention, holistic or medical treatment or diagnostic laparoscopy only?
Summary answer: This updated review shows that laparoscopic surgery reduces pain and improves live birth rates. When comparing different surgical techniques, no difference in outcomes was shown.
What is known already: Endometriosis is defined by the presence of endometrial glands and stroma in ectopic locations such as the pelvic peritoneum, ovaries and rectovaginal septum. Symptoms include pain and/or infertility. Treatment options for endometriosis include medical therapy (hormonal therapy and non-steroidal anti-inflammatory drugs) and surgery. Laparoscopic surgery may benefit in treating overall pain and infertility associated with mild to moderate endometriosis. Although the laparoscopic management of endometriosis is widely accepted, the ideal surgical techniques are still being debated.
Study design, size, duration: For the update of this Cochrane systematic review we conducted electronic searches of the Cochrane Gynaecology and Fertility Specialised Register of Controlled Trials, CENTRAL, MEDLINE, EMBASE, PsycINFO and CINAHL from inception to July 2019 to identify relevant randomized controlled trials (RCTs). Three independent review authors (CB, YB, CT) independently selected trials and extracted data for meta-analysis. Any disagreements were resolved by discussion or by a third review author (JD).
Participants/materials, setting, methods: Participants: Women with endometriosis confirmed with a visual diagnosis at diagnostic or operative laparoscopy. Intervention: Laparoscopic intervention. Comparison: Another laparoscopic or robotic intervention, holistic or medical intervention or diagnostic laparoscopy. Risk ratios (RR) were calculated for dichotomous data and mean differences (MD) for continuous data, with 95% confidence intervals (CI). Heterogeneity was examined via the I^2 statistic. Primary analysis was conducted on data per woman randomised. Primary outcomes: overall pain and live birth.
Main results and the role of chance: For this update, we screened 812 titles and abstracts. We identified 5 new studies (including one ongoing study). We included a total of 14 studies with 1102 women in the review. Laparoscopic surgery (ablation or excision) was associated with decreased overall pain (measured as 'pain better or improved') at 6 months (RR6.58, 95%CI3.31to13.10, three RCTs, n=171, I^2=0%, moderate-quality evidence) and 12 months postoperatively (RR10.00, (95%CI3.21to31.17, one RCT, n=69, low-quality evidence) compared to diagnostic laparoscopy only. Laparoscopic surgery was associated with an increased live birth or ongoing pregnancy rate (RR1.94, 95%CI1.20to3.16, two RCTs, n=382, I^2=0%, moderate-quality evidence).Laparoscopic surgery was associated with decreased overall pain at 12 months (measured as 'pain free at 12 months') postoperatively compared to diagnostic laparoscopy and medical treatment (RR5.63, 95%CI1.18to26.85, one RCT, n=35, low-quality evidence).On comparing laparoscopic ablation with laparoscopic excision, there was no evidence of a difference in overall pain (12 months) (MDon0to10VAS0.00, 95%CI-1.22to1.22, one RCT, n=103, low-quality evidence). Live birth was not reported in any of the included trials. We included three studies in this comparison, while one study is awaiting classification.Due to the limited available evidence it is unclear if a certain surgical technique is superior. We included 2 studies, both are awaiting classification.
Limitations, reasons for caution: The quality of some of the included studies, the heterogeneity of the disease among the different studies and limited long-term follow-up are the major limitations of this systematic review. Furthermore, there were few studies for each comparison and meta-analysis could rarely be performed.
Wider implications of the findings: Surgical (laparoscopic) treatment of endometriosis appears to beneficially influence pain and pregnancy outcomes. Further high-quality RCT are required to further differentiate between various treatment options (whether or not surgical) and their corresponding effect on the different outcomes of the core outcome set for endometriosis.
Trial registration number: NA

O-022 Long-term treatment with norethindrone acetate decreases the postoperative recurrence of deep endometriosis at long-term follow-up

S. Ferrero[1], C. Scala[2], G. Evangelisti[1], F. Barra[1]

[1]IRCCS Ospedale Policlinico San Martino - University of Genoa, Academic Unit of Obstetrics and Gynecology, Genoa, Italy ;
[2]Gaslini Hospital, Unit of Obstetrics and Gynecology, Genoa, Italy

Study question: Does postoperative treatment with norethindrone acetate (NETA) decrease the risk of endometriosis recurrence following surgical treatment of endometriosis?
Summary answer: Postoperative administration of NETA significantly decreases the risk of recurrence of both endometriosis related symptoms and ultrasonographically diagnosed endometriotic lesions at long-term follow-up.
What is known already: Progestins are widely used to treat endometriosis-related symptoms. Postoperative administration of hormonal therapies may decrease the recurrence of endometriosis-related pain and ovarian endometriomas. Limited information is available on the role of postoperative treatment with NETA in preventing recurrence of endometriosis.
Study design, size, duration: The study was performed between June 2014 and December 2019. Four hundred thirty-seven women were enrolled. The patients, after being undergone surgical excision of deep endometriosis, either received continuous postoperative treatment with NETA or did not receive any hormonal therapy, were enrolled. Patients exit the study when they interrupted the protocol started immediately after surgery.
Participants/materials, setting, methods: The choice of receiving NETA was based on the preference of the patients (including previous experiences with hormonal therapies and their adverse effect, contraindications to hormonal therapies and/or desire to conceive). Patients underwent a follow-up consultation

(including transvaginal ultrasonography) every six months. Presence and intensity of pain symptoms were assessed. Quantity of life was evaluated using the EHP30 and sexual function was evaluated using the Female Sexual Function Index (FSFI).
Main results and the role of chance: Demographic characteristics, severity of endometriosis (assessed by the rASRM classification), prevalence of endometriomas and length of follow-up were similar in patients who received postoperative NETA (n = 309) and in those who did not receive postoperative therapy (n = 128). At a median length of follow-up was 46 months (range, 12-73 months), the rate of ultrasonographic diagnosis of endometriosis recurrence was significantly lower in patients treated with NETA (16/309; 5.2%) than in those who did not receive hormonal therapy (22/128; 17.2%; $p < 0.001$). NETA significantly decreased the risk of recurrence of endometriomas ($p < 0.001$) and of deep endometriotic nodules ($p < 0.01$). NETA decreased the occurrence of *de novo* endometrioma and deep endometriotic lesions during the follow-up ($p < 0.05$). Similarly, the recurrence of endometriosis-related pain symptoms was significantly lower in patients treated with NETA (31/309; 10.0%) than in those who did not receive hormonal therapy (46/128; 35.9%; $p < 0.001$). Quality of life and sexual function were better in patients treated with NETA than in those who did not receive postoperative hormonal therapy ($p < 0.001$ and $p < 0.001$, respectively).
Limitations, reasons for caution: The study was not randomized. Only NETA was investigated in this study; it remains to be evaluated if other hormonal therapies are more efficacious than NETA in preventing postoperative endometriosis recurrence.
Wider implications of the findings: Patients undergoing surgery for endometriosis who do not desire to conceive should be advised to use postoperative hormonal therapy to decrease the risk of endometriosis recurrence.
Trial registration number: Not applicable

O-023 Relugolix combination therapy improves hemoglobin levels in anemic women with heavy menstrual bleeding due to uterine fibroids: results from the LIBERTY Phase 3 program

R. Venturella[1], E.A. Stewart[2], A. Al-Hendy[3], J. Kang[4], L. McKain[4], A. Lukes[5]

[1]University Magna Graecia, Obstetrics and Gynecology, Catanzaro, Italy ;
[2]Mayo Clinic, Department of Obstetrics & Gynecology, Rochester- Minnesota, U.S.A. ;
[3]University of Illinois/Chicago, Department of Obstetrics and Gynecology, Chicago- Illinois, U.S.A. ;
[4]Myovant Sciences Inc., Myovant Sciences Inc., Brisbane- California, U.S.A. ;
[5]Carolina Woman's Wellness Center, Obstetrics and Gynecology, Durham- North Carolina, U.S.A.

Study question: What is the impact of 24 weeks of relugolix combination therapy (Relugolix-CT) on hemoglobin in women with uterine fibroids (UF) and anemia at baseline?
Summary answer: In women with UF and anemia at baseline, Relugolix-CT, an oral gonadotropin-releasing hormone with estradiol/norethindrone, significantly improved hemoglobin concentrations at Week 24 ($p < 0.0001$).
What is known already: In the LIBERTY 1 and 2 Phase 3 studies, Relugolix-CT (once-daily relugolix 40 mg, estradiol [E2] 1.0 mg, and norethindrone acetate [NETA] 0.5 mg) significantly reduced menstrual blood loss (MBL) in women with UF-associated heavy menstrual bleeding (HMB) and was well tolerated. In the pooled analysis of Phase 3 data, the proportion of responders was 72.3% in the Relugolix-CT group (n=254) and 16.8% in the placebo group (n=257); $p < 0.0001$. Additional benefits included a clinically meaningful reduction of UF-related pain and a high rate of amenorrhea. Coadministration of E2/NETA maintained bone mineral density and minimized incidence of vasomotor symptoms.
Study design, size, duration: LIBERTY 1 and 2 were randomized, double-blind, placebo-controlled, international, Phase 3 trials to assess the efficacy and safety of Relugolix-CT for 24 weeks of treatment. Women were randomized 1:1:1 to one of three arms: Relugolix-CT for 24 weeks, Delayed Relugolix-CT (relugolix 40 mg alone for 12 weeks followed by Relugolix-CT for 12 weeks), or placebo for 24 weeks. Data were pooled from LIBERTY 1 and 2 for this analysis.
Participants/materials, setting, methods: Premenopausal women (aged 18–50 years) with an MBL volume of ≥ 80 mL/cycle (assessed using the alkaline hematin method) and ultrasound-confirmed UF were eligible. The results of an analysis of a subset of women with hemoglobin ≤ 10.5 g/dL at baseline who had a hemoglobin value at Week 24 are reported. The proportion of patients who had a 2 g/dL hemoglobin increase from baseline and an absolute percentage change from baseline hemoglobin was assessed.
Main results and the role of chance: The proportion of women with anemia was 33% (n=83) in the Relugolix-CT group and 32% (n=83) in the placebo group. The anemic women were notably different than the women in the overall study populations of LIBERTY 1 and 2. They were more likely to be Black/African American women (65.2% vs 51.2%) and from North America (85.9% vs 75.5%]). Their baseline MBL volume was greater (mean: 285.5 mL vs 228.8 mL) with larger proportion having baseline MBL volumes ≥ 225 ml (52.0% vs 34.8%) and they had a larger baseline uterine volume (mean: 488 cm^3 vs 408 cm^3).

Nonetheless, a significantly greater proportion of women had a clinically meaningful increase in hemoglobin levels of ≥ 2 g/dL in the pooled Relugolix-CT arms (55.7%) compared with the placebo arms (11.7%; $p < 0.0001$). Similarly, the mean percentage increase in hemoglobin concentration was greater in the pooled Relugolix-CT arms (23.0%) compared with the placebo arms (6.4%; $p < 0.0001$).
Limitations, reasons for caution: Patients with evidence of iron deficiency anemia, at any time during the trial, were required to receive parenteral or oral iron supplementation. However, iron therapy was not standardized. Therefore, outcomes may have been impacted by differences in methods of supplementation (oral versus parenteral) and patient adherence to therapy.
Wider implications of the findings: Overall, these significant improvements in hemoglobin concentrations from baseline with Relugolix-CT treatment relative to placebo reflect the impact that HMB had on study participants and how reductions in MBL volume translate into clinically meaningful improvements in hemoglobin levels in patients with UF.
Trial registration number: NCT03049735 and NCT03103087

O-024 Relugolix combination therapy reduced patient-reported distress from bleeding and pelvic symptoms and improved daily activities in patients with uterine fibroids in the LIBERTY program

E. Stewart[1], A. Al-Hendy[2], R. Venturella[3], A. Poindexter III[4], C. Villarroel[5], Y. Li[6], R.B. Wagman[6], E. Hunsche[6], A. Lukes[7]

Study question: What is the effect of relugolix combination therapy (Relugolix-CT) on patient-reported distress from common uterine fibroids (UF) symptoms and on activities in women with UF?
Summary answer: Relugolix-CT treatment for 24 weeks significantly reduced patient-reported distress from common UF symptoms and improved physical and social activities vs placebo (nominal $p < 0.001$).
What is known already: The efficacy and safety of Relugolix-CT treatment (once-daily relugolix 40 mg, estradiol [E2] 1.0 mg, and norethindrone acetate [NETA] 0.5 mg for 24 weeks), in women with UF-associated heavy menstrual bleeding (HMB) was demonstrated in the LIBERTY 1 and 2 Phase 3 trials. Relugolix-CT achieved a statistically significant and clinically meaningful reduction in menstrual blood loss and in pain among patients with moderate to severe pain at baseline, a high rate of amenorrhea, and a clinically meaningful hemoglobin increase in patients with anemia. Furthermore, bone mineral density was maintained, and vasomotor symptoms minimized, as in the placebo group.
Study design, size, duration: 388 and 382 premenopausal women with clinically significant uterine fibroids and alkaline-hematin documented HMB, respectively, were randomized 1:1:1 to: Relugolix-CT for 24 weeks, relugolix 40 mg for 12 weeks followed by Relugolix-CT for 12 weeks, or placebo for 24 weeks. Pooled data from both studies were used for analyses of distress from common UF symptoms, measured using a new, validated patient-reported outcome tool, and of activities assessed with the previously validated UFS-QoL revised activities scale.

Participants/materials, setting, methods: The Bleeding and Pelvic Discomfort (BPD) scale consists of three UFS-QoL items assessing distress due to HMB, passing blood clots, and pelvic pressure/tightness. The Revised Activities (RA) scale contains five items relating to physical and social activities. Both scales range from 0 to 100; least squares means (95% confidence interval [CI]) for change from baseline were obtained using mixed-effects model repeated measures, and percentage of responders were analyzed for the Relugolix-CT and the placebo groups.

Main results and the role of chance: The reduction from baseline to week 24 in distress due to HMB, passing blood clots, and pelvic pressure, measured by the BPD scale, was significantly greater with Relugolix-CT (-45.0) than with placebo (-16.1) (difference -29.9; p<0.001). With Relugolix-CT, mean BPD scale scores improved from 67.5 (CI: 63.4, 71.5) at baseline to 22.7 (CI: 17.8, 27.6) at Week 24, while the placebo group changed from 71.9 (CI: 67.8, 75.9) to 55.8 (CI: 50.9, 60.6). In addition, Relugolix-CT led to an improvement in RA scale scores from 33.8 (CI: 29.3, 38.3) at baseline to 78.4 (CI: 73.2, 83.5) at Week 24, while the placebo group changed from 29.4 (CI: 24.9, 33.9) to 43.8 (CI: 38.8, 48.9); the difference between Relugolix-CT and placebo (30.7) was statistically significant (p < 0.0001). Percentages of treatment responders, defined as those with a clinically meaningful change from baseline to Week 24 of ≥ 20 points, were significantly greater with Relugolix-CT than placebo. On the BPD scale, 61.7% vs 27.6% on Relugolix-CT vs placebo were responders, with a significant difference of 34.2% (p<0.0001). Regarding the RA scale, 60.9% and 35.4% of patients on Relugolix-CT and placebo, respectively, were responders, with a statistically significant difference of 25.5% (p<0.0001).

Limitations, reasons for caution: The BPD is a new scale that has not been used previously. Hence, results cannot be compared with other studies.

Wider implications of the findings: Relugolix-CT not only reduced HMB in women with UF, but also improved patient-reported outcomes, by reducing the distress caused by frequent UF symptoms and improving daily activities. Responder rates for both patient-reported outcomes provide meaningful results that are easy to interpret and communicate to patients.

Trial registration number: NCT03049735 and NCT03103087

O-025 Levonorgestrel-releasing intrauterine system (LNG-IUS) versus oral medroxyprogesterone acetate (MPA) in infertile women with endometrial hyperplasia without atypia: prospective evaluation of regression rates and live-birth rates

V.S. Vanni[1], G. Campo[1], E. Papaleo[2], F. Turba[1], D. Casiero[1], M. Sajdak[2], R. Villanacci[1], L. Quaranta[2], F. Pasi[2], M. Scarrone[3], S. Bordoli[3], V. Canti[3], M. Candiani[1], P. Rovere-Querini[3], P. Giardina[2]

[1]Università Vita-Salute San Raffaele, Obstetrics and Gynecology Dept., Milano, Italy ; [2]IRCCS Ospedale San Raffaele, Obstetrics and Gynecology Dept., Milan, Italy ; [3]Università Vita-Salute San Raffaele, Internal and Specialistic Medicine Dept., Milano, Italy

Study question: What is the role of Levonorgestrel-releasing intrauterine system (LNG-IUS) in the treatment of infertile women with endometrial hyperplasia without atypia (EH)?

Summary answer: EH regression rates are higher in patients receiving LNG-IUS compared to oral MPA. Live-birth rates following assisted reproduction treatments are comparable between the two groups.

What is known already: LNG-IUS is considered superior to continuous oral progestin therapy for treatment of EH in the general population (El Behery et al., 2015). Treatment of EH in infertile patients undergoing assisted reproduction treatments (ART) however requires special considerations, due to the need to preserve short-term endometrial receptivity. LNG-IUS causes downregulation of endometrial receptors to an extent that is greater than that observed after oral progesterone administration (Vereide et al., 2005). Thus, a detrimental effect of LNG-IUS on fertility outcomes could be hypothesized and should be excluded before widely adopting the use of LNG-IUS in the treatment of EH in infertile patients.

Study design, size, duration: This prospective cohort study was designed to evaluate the role of LNG-IUS as a first or second-line treatment for EH occurring in infertile patients undergoing ART. N=221 infertile women with a diagnosis of EH treated between December 2014 and April 2018 at the Reproductive Medicine Unit of the San Raffaele Hospital (Milan, Italy) were included. After EH regression, patients were admitted to ART.

Participants/materials, setting, methods: EH was diagnosed on hysteroscopic endometrial biopsies. First-line treatment was either oral MPA 10 mg daily (n=193) or LNG-IUS (n=28). In case of EH persistence, patients receiving oral MPA either switched to LNG-IUS (n=63) or continued daily MPA (n=14). Follow up biopsies were scheduled after 90 days of treatment, both for first and second line therapy. If LNG-IUS was used, it was kept in place during biopsy and removed after confirmation of negative histology.

Main results and the role of chance: Baseline characteristics and possible confounders such as age at diagnosis, BMI, parity, smoking status and duration of infertility did not differ between patients receiving LNG-IUS versus MPA as first-line treatment for EH (data not shown). EH regression rate at first follow up (3 months) was higher in the LNG-IUS group compared to the oral progestins group (28/28 and 116/193 respectively, 1000% vs 60.1%, p< 0.001). EH regression after second-line treatment was 61/63 in the group switching from MPA to LNG-IUS and 12/14 in the group continuing MPA (96.8 vs 85.7%, p=0.15). Overall, n=91 patients used LNG-IUS as either first or second-line treatment for EH, while n=130 only used MPA. The cumulative live-birth rate following ART in patients ever receiving LNG-IUS (21/91, 25.4%) was similar to the cumulative live-birth rate patients observed in patients only receiving MPA (33/130, 23.1%, p=0.75). Confounders including age at diagnosis (36.8 ± 1.8 vs 37.9 ± 0.3, Mean ± SD), BMI (23.1 ± 0.4 vs 22.1 ± 0.2, Mean ± SD) and number of previous failed ART cycles (1.3 ± 0.2 vs 1.8 ± 0.2, Mean ± SD) did not differ between patients ever receiving LNG-IUS versus patients only receiving MPA respectively.

Limitations, reasons for caution: Limitations of this study are the relatively small number of patients included and the fact that treatment's choice was not based on randomization but rather on patient's preference after thorough counselling. Another relevant information that is currently missing is a cost-analysis comparing the two groups.

Wider implications of the findings: LNG-IUS should be the preferred therapy for EH without atypia in infertile patients, as it provides very high curing rates already after 3 months of treatment and does not impair endometrial receptivity in the following ART cycles. Further prospective data collection and studies confirming our results will be of interest.

Trial registration number: na

O-026 Endometrial cancer risk in women with histological proven endometriosis or adenomyosis; a retrospective nationwide cohort study.

M. Hermens[1], I. Velthuis[2], R. Bekkers[1], H. Van Vliet[1], S. Bert[3], A. Van Altena[2]

[1]Catharina Hospital, Obstetrics and Gynaecology, Eindhoven, The Netherlands ; [2]Radboudumc, Obstetrics and gynaecology, Nijmegen, The Netherlands ; [3]Radboudumc, Pathology, Nijmegen, The Netherlands

Study question: What is the association between histological proven endometriosis/adenomyosis and endometrial cancer?

Summary answer: Women with histological proven endometriosis/adenomyosis have an increased risk of endometrial cancer.

What is known already: Women with histological proven endometriosis/adenomyosis have an increased risk of ovarian cancer. Smaller studies show conflicting results on the endometrial cancer risk in women with histological proven endometriosis/adenomyosis.

Study design, size, duration: A population-based retrospective cohort study of 131,646 women with histologically proven endometriosis/adenomyosis, matched with 132,700 women with a benign dermal nevus selected from the Dutch nationwide registry of histopathology and cytopathology (PALGA) between January 1990 and July 2017. In the endometriosis/adenomyosis group 1,820 (1.4%) women had histological reports on endometrial cancer and in the nevus group 771 (0.6%) women. Crude and age-adjusted incidence rate ratios (IRR) for endometrial cancer and its subtypes were estimated.

Participants/materials, setting, methods: We selected all women with histological proven endometriosis/adenomyosis and women with a benign dermal nevus diagnosed between 1990 and 2015 from the Dutch nationwide registry of histopathology and cytopathology.

Main results and the role of chance: The age-adjusted IRR for endometrial cancer overall was 29.60 (95%CI 26.40-33.18). Age at endometrial cancer diagnosis was similar for the endometriosis/adenomyosis and nevus group, 61 (IQR 55-69) and 62 (IQR 56-68), p=0.28, respectively.

After excluding the first year of follow-up the age-adjusted IRR was 1.19 (95%CI 0.94-1.52), indicating that endometrial cancer is most often found at time of histological diagnosis of endometriosis/adenomyosis. In 25.2% of the endometrial cancer cases in the endometriosis/adenomyosis group, the endometrial cancer diagnosis was not made until after hysterectomy. These women had not had prior (micro)curettage or biopsy.

Limitations, reasons for caution: These results are limited to women with histological proven endometriosis/adenomyosis, and prone to detection bias. Furthermore, no clinical information is available on possible confounders.

Wider implications of the findings: This study shows an association between endometriosis/adenomyosis and endometrial cancer. In most women, diagnosis of endometrial cancer and endometriosis/adenomyosis is at time of hysterectomy. To develop preventive strategies future studies should focus on the detection of women at risk for endometrial cancer in the group of women suspect for endometriosis/adenomyosis.

Trial registration number: not applicable

O-027 Efficacy and safety of linzagolix on heavy menstrual bleeding (HMB) due to uterine fibroids (UF): Results from a placebo-controlled, randomized, Phase 3 trial

H. Taylor[1], J. Donnez[2], R. Taylor[3], E. Bestel[4], J.P. Gotteland[5], A. Humberstone[4], E. Garner[6]

[1]Yale University- School of Medicine, Dept. of Reproductive Endocrinology and Infertility, New Haven- CT, U.S.A. ;
[2]Catholic University of Louvain, Société de recherche pour l'infertilité, Brussels, Belgium ;
[3]University of Utah Health, Department of Obstetrics and Gynecology, Salt Lake City, U.S.A. ;
[4]ObsEva SA, Clinical, Geneva, Switzerland ;
[5]ObsEva SA, Research and Development, Geneva, Switzerland ;
[6]ObsEva SA, Clinical, Boston, U.S.A.

Study question: Do doses of 100 or 200 mg linzagolix with or without estradiol 1 mg/NETA 0.5 mg add-back therapy (ABT) reduce HMB in women with UF?

Summary answer: Once daily oral doses of linzagolix 100 and 200 mg with and without ABT significantly reduced HMB compared to placebo after 24 weeks of treatment.

What is known already: Suppression of estradiol (E2) using GnRH analogues has been shown to be an effective treatment for UF-associated HMB. Full E2 suppression to postmenopausal levels is highly efficacious but requires hormonal ABT to prevent hypoestrogenic symptoms and bone mineral density (BMD) loss. Linzagolix is an investigational, oral GnRH receptor antagonist, which dose-dependently reduces E2 levels, providing full suppression (serum E2 < 20 pg/mL) and partial suppression with once daily oral dosing of 200 mg and 100 mg, respectively. We hypothesized that partial E2 suppression could reduce HMB without the marked BMD loss observed with full suppression.

Study design, size, duration: PRIMROSE 2 is a Phase 3, double-blind, randomized, placebo-controlled, multicenter trial evaluating 100 or 200 mg linzagolix with or without ABT for 52 weeks. 535 patients were randomized and equally distributed among treatment groups. Subjects randomized to placebo were crossed-over to 200 mg linzagolix + ABT after 24 weeks. Individual active *vs* placebo efficacy comparisons were conducted at 24 weeks using a 0.0125 significance level to account for multiplicity of four active treatment groups.

Participants/materials, setting, methods: Participants had HMB (> 80 mL menstrual blood loss (MBL)/cycle). The primary efficacy endpoint was HMB reduction at 24 weeks; responders were defined as having MBL (alkaline hematin method) of ≤ 80 mL and ≥ 50% reduction from baseline. Other assessments included amenorrhea, pain, uterine and fibroid volume, haemoglobin levels, and quality of life. E2 levels were measured. BMD was assessed centrally using Dual Energy X-ray Absorptiometry. Calcium/vitamin D were not provided or recommended.

Main results and the role of chance: Subjects had a mean age of 43 years and 218 mL baseline MBL; 5% were Black. At 24 weeks, responder rates were significantly higher (p<0.001) in all linzagolix groups compared to placebo (29.4%); 93.9%, 77.7%. 77.2% and 56.7% in the 200 mg with ABT, 200 mg without ABT, 100 mg with ABT and 100 mg without ABT groups, respectively. Amenorrhea rates were 80.6%, 70.9%, 63.4%, and 34.0% in the corresponding groups, compared to 11.8% for placebo (p<0.0125). All linzagolix treatments significantly (p<0.0125) reduced pain and uterine volume, and significant (p<0.0125) reduction in fibroid volume was observed for 200 mg linzagolix with and without ABT. Median serum estradiol levels were suppressed below 20 pg/mL in the 200 mg linzagolix without ABT group and were maintained from 20 to 60 pg/mL in the other groups.

Mean percent (95% CI) lumbar spine BMD changes from baseline to week 24 in the placebo, 100 mg, 100 mg + ABT, 200 mg and 200 mg + ABT dose groups were: 0.514% (-0.019;1.048), -2.068% (-2.630;-1.506), -0.992% (-1.572;-0.412), -4.019% (-4.668;-3.371), -1.305 (-1.923;-0.687), respectively. Changes in femoral neck and total hip BMD showed a similar pattern but were generally smaller.

Limitations, reasons for caution: This Phase 3 trial of linzagolix for UF-associated HMB included a relatively narrow population of primarily Caucasian European patients treated for 52 weeks. Post-treatment follow-up will provide more information on symptom recurrence and BMD recovery. Effects on BMD of calcium/vitamin D supplementation with linzagolix in UF are not known.

Wider implications of the findings: Two linzagolix doses were identified for treatment of UF-associated HMB: 200 mg with ABT, with a responder rate of 94%, and 100 mg without ABT, which has the potential for long-term treatment without ABT. Data from a similar ongoing US trial should provide information on linzagolix in a broader population.

Trial registration number: NCT03070951

SESSION 06: FROZEN VERSUS FRESH EMBRYO TRANSFER. AN ONGOING CHALLENGE ON CHILDREN'S HEALTH

06 July 2020 Parallel 5 10:00 - 11:30

O-028 Cardiac remodeling in fetuses conceived by assisted reproductive technologies following fresh versus frozen embryo transfer

M.L. Boutet[1], G. Casals[1], B. Valenzuela-Alcaraz[1], L. García-Otero[1], F. Crovetto[1], E. Vidal[1], D. Manau[1], E. Gratacos[1], F. Crispi[1]

[1]Barcelona Center for Maternal-Fetal and Neonatal Medicine Hospital Clínic and Hospital Sant Joan de Déu- ICGON- IDIBAPS- Universitat de Barcelona- Barcelona-Spain, Institut Clínic de Ginecologia- Obstetrícia i Neonatologia, Barcelona, Spain

Study question: Do fetuses conceived after frozen embryo transfer (FET) present signs of cardiac remodeling and dysfunction similar to those observed in fresh embryo-transfer (ET)?

Summary answer: Both fresh ET and FET present signs of fetal cardiac remodeling and dysfunction, with more pronounced changes in the fresh ET as compared to FET.

What is known already: We and others have previously demonstrated that fetuses and children conceived by assisted reproductive technologies present cardiac remodeling and dysfunction (Scherrer et al. Circulation 2012, Valenzuela-Alcaraz et al. Circulation 2013, Valenzuela-Alcaraz et al. BJOG 2018). These fetuses show more globular hearts, dilated atria, reduced longitudinal motion and impaired relaxation. Cardiac changes were already present in utero and persisted after birth. However, 90% of the fetuses included in these studies were conceived by in vitro fertilization (IVF) after fresh ET. It is unknown whether fetal cardiac remodeling is also present in FET.

Study design, size, duration: Prospective cohort study of 397 singleton pregnancies recruited from December 2010 to December 2019, including 132 spontaneously conceived (SC) pregnancies, 116 conceived by IVF following FET and 149 IVF after fresh ET. Fetal structural and functional echocardiography was performed in all pregnancies.

Participants/materials, setting, methods: Pregnancies conceived by IVF were recruited from a single Assisted Reproductive center, ensuring high homogeneity in IVF stimulation protocols, endometrial preparation for FET, laboratory procedures and embryo culture conditions. SC pregnancies from fertile couples (obtained after a period no longer than 12 months) were randomly selected from low-risk population and paired to IVF pregnancies by maternal age. Fetal

echocardiography was performed at 29-33 weeks of pregnancy to assess cardiac structure and function in all pregnancies.

Main results and the role of chance: Parental age, ethnicity, body mass index and smoking were similar among study groups. Median gestational age at echocardiography (29-33 weeks) and estimated fetal weight (1400-2000g) were similar in all study groups. Both fresh ET and FET groups showed significant signs of fetal cardiac remodeling and dysfunction, with more pronounced changes in the fresh ET as compared to FET. IVF fetuses showed larger atria (right atria-to-heart ratio: fresh ET median 18.1% [SD 18.1-18.2] vs FET 17.7% [17.6-17.8] vs SC 17.1% [17.1-17.2]; linear tendency P-value <0.001), more globular ventricles (right ventricular sphericity index: fresh ET 1.60 [1.58-1.62] vs FET 1.62 [1.60-1.64] vs SC 1.68 [1.66-1.70]; <0.001) and thicker myocardial walls (relative wall thickness: fresh ET 0.80 [0.78-0.81] vs FET 0.76 [0.73-0.77] vs SC 0.65 [0.63-0.66]; <0.001) as compared to SC pregnancies. Both fresh ET and FET groups had also signs of systolic and diastolic dysfunction with reduced left shortening fraction (fresh ET 36% [35.9-36] vs FET 37.1% [37-37.2] vs SC 37.3 [37.1-37.3]; <0.001) and increased left myocardial performance index (fresh ET 1.58 zscores [1.54-1.61] vs FET 1.54 [1.49-1.57] vs SC 1.30 [1.27-1.32]; <0.001) as compared to SC pregnancies. All differences remained statistically significant after adjustment by birthweight centile, preeclampsia and prematurity.

Limitations, reasons for caution: The cardiac changes reported here are subclinical, with most cardiovascular indexes lying within normal ranges.

These milder features in FET fetuses cannot condition the technique´s choice and must be considered together with the global perinatal results related to these gestations.

Wider implications of the findings: Although these features are recognized as potential cardiovascular risk factors, their association with adult cardiovascular disease remains to be proven. Identification of cardiac remodeling in these fetuses represent an opportunity to recognize them as potential high-risk population that might benefit from early preventive measures to improve their future cardiovascular health.

Study question: Are the adverse perinatal outcomes seen after transfer of fresh and cryopreserved embryos in assisted reproductive technology (ART) a consequence of maternal or treatment factors?

Summary answer: Fetal growth is more strongly influenced by treatment, whereas risk of preterm birth is more strongly influenced by maternal factors.

What is known already: Perinatal outcomes differ between children born after transfer of fresh (fresh-ET) and cryopreserved (cryo-ET) embryos. Fresh-ET children have lower birthweights, higher risk of small-for-gestational age (SGA) and preterm birth (PTB), while cryo-ET children have higher birthweights, risk of large-for-gestational age (LGA) and PTB, compared to spontaneously conceived children (SC). It is unknown to what extent these adverse outcomes are caused by parental or treatment factors.

Sibling comparisons help disentangle the parental and treatment contributions to perinatal health in ART children. Previous sibling studies show conflicting results, and most could not separate children born after fresh-ET and cryo-ET.

Study design, size, duration: Registry-based cohort study including liveborn singletons in the Committee of Nordic ART and Safety (CoNARTaS) cohort from Denmark (1994-2014), Norway (1988-2015) and Sweden (1988-2015). The population level analyses included 53,345 children born after fresh-ET, 14,405 after cryo-ET, and 2,563,837 spontaneously conceived (SC) children. In total, 27,041 maternal sibling groups with at least two different conception modes were identified.

Outcomes were birthweight, SGA, LGA, preterm birth (<37 weeks) and very preterm birth (VPTB, <32 weeks).

Participants/materials, setting, methods: Data from nationwide medical birth registries and ART registries/databases, were linked using unique national identity numbers. We compared perinatal outcomes according to treatment modes in multilevel linear and logistic models, where fixed effects (within sibling groups) were attributed to treatment. Fixed effects models included adjustment for birth year and maternal age, parity, smoking, and body mass index. For comparison, random effects models provided population estimates, additionally adjusted for country and maternal height.

Main results and the role of chance: Children born after cryo-ET had higher birthweights (mean difference 73 grams, 95% confidence interval [CI] 59 to 87) and increased risk of LGA (odds ratio [OR] 1.75, 95% CI 1.42-2.2) compared to their SC siblings. In contrast, children born after fresh-ET had lower birthweights (mean difference -56 grams, 95% CI -65 to -47) and increased risk of SGA (OR 1.31, 95% CI 1.13-1.52), compared to their SC siblings. These estimates were comparable to associations at the population level (random effects).

Fresh-ET showed the highest risk of PTB at the population level (OR 1.66, 95% CI 1.59-1.73), but risk was increased also for cryo-ET (OR 1.44, 95% CI 1.32-1.57). Comparing siblings, the association attenuated to a modest risk increase, similar for fresh-ET (OR 1.26, 95% CI 1.13-1.41) and cryo-ET (OR 1.23, 95% CI 1.03-1.48). VPTB showed stronger associations at the population level for both fresh-ET (OR 2.07, 95% CI 1.89-2.26) and cryo-ET (OR 1.70, 95% CI 1.40-2.04), which attenuated completely in the sibling comparisons (fresh-ET OR 1.04, 95% CI 0.81-1.34; cryo-ET OR 0.95, 95% CI 0.63-1.44).

Results were independent of which conception method was the first in each sibling group and remained similar when restricted to full siblings.

Limitations, reasons for caution: Although we could adjust for unmeasured, constant parental factors, we cannot exclude confounding from unmeasured, non-constant parental factors. Information on causes of infertility was limited. Consequently, we could not investigate if parental contribution depends on infertility causes. Further, our study cannot identify specific mechanisms underlying treatment and parental contributions.

Wider implications of the findings: Adverse perinatal health after ART can be attributed to a combination of parental and treatment factors. Risk of PTB is primarily caused by parental factors whearas fetal growth deviation (SGA in fresh-ET and LGA in cryo-ET) is primarily caused by treatment factors. Further investigations of responsible treatment factors are warranted.

Trial registration number: Not applicable

O-030 Birth weight and large-for-gestational-age in singletons born after frozen compared to fresh embryo transfer by gestational week at birth: a Nordic cohort study

A. Terho[1], S. Pelkonen[1], S. Opdahl[2], L.B. Romundstad[3], C. Bergh[4], U.B. Wennerholm[4], A.K.A. Henningsen[5], A. Pinborg[5], M. Gissler[6], A. Tiitinen[7]

Study question: When does the intrauterine growth difference become apparent between singletons born after frozen embryo transfer (FET) and fresh embryo transfer (fresh ET)?
Summary answer: Mean birth weights and proportion of large-for-gestational-age (LGA) become significantly higher among FET singletons starting from gestational week (GW) 33 and 36, respectively.
What is known already: In recent years there has been a steep rise in recorded FET treatments, enabling widespread use of elective single embryo transfer, thus reducing the risks associated with multiple gestations. However, FET singletons are heavier and there is a higher risk of LGA (birth weight > 90 percentiles) compared to fresh ET singletons. In turn, risk of small-for-gestational-age (SGA, birth weight < 10 percentiles) is lower in FET singletons compared to fresh ET singletons. The reasons, timing and consequences of these differences remain largely unclear. There is limited evidence that this difference in growth develops by the last trimester of pregnancy.
Study design, size, duration: A retrospective Nordic register-based cohort comparing singletons born after FET (*n* = 17 500) to singletons born after fresh ET (*n* = 69 510) and spontaneous conception (SC) (*n* = 3 311 588). All live born singletons between the years 2000 and 2015 in Denmark, Norway and Sweden with gestational age ≥ 22 weeks at birth were included from the population-based Committee of Nordic ART (assisted reproductive technology) and Safety (CoNARTaS) study population.
Participants/materials, setting, methods: FET children were compared to fresh ET and SC for mean birth weight and proportion of LGA and SGA for each GW at birth. χ^2 test and test for relative proportions were used to compare categorical and Student's t-test to compare continuous variables. Adjusted odds ratios for LGA and SGA were calculated using logistic regressions, adjusting for year of birth, maternal age, parity, BMI, chronic hypertension, diabetes, smoking and offspring sex.
Main results and the role of chance: Mean birth weights were significantly higher for FET boys compared to fresh ET boys starting from GW 33 and for FET girls starting from GW 34 (range from p<0.001 to p=0.046 by week). FET boys had a significantly higher proportion of LGA (11.0-15.1%) at birth between GW 36-42 compared to fresh ET (7.1-9.4%) (range from p<0.001 to p=0.048 by week). For FET girls this was seen between GW 37-42 (10.6-13.4%) compared to fresh ET (6.6-8.0%) (range from p<0.001 to p=0.009 by week).

The proportion of SGA was lower among FET boys (7.6-8.7%) compared to fresh ET (11.9-13.6%) between GW 36-42 (range from p<0.001 to p=0.016 by week). For FET girls this was seen between GW 38-42 (7.0-9.3%), compared to fresh ET (13.0-14.6%) (p<0.001).

The rate of LGA was significantly higher for FET boys between GW 38-41 (p<0.001) and for FET girls between GW 37-40 (range from p<0.001 to p=0.018 by week) compared to SC children.

All singletons born after FET had a higher risk of LGA compared to singletons born after fresh ET (adjusted odds ratio (aOR) 1.87, 95% confidence interval (95% CI) 1.76 - 1.98) and singletons born after SC (aOR 1.28, 95% CI 1.22 - 1.35).
Limitations, reasons for caution: There may be residual confounding factors that we were not able to control for, most importantly the causes of preterm birth, which may also have an influence on the fetal growth. Also, the number of children born extremely preterm or post-term is limited even in a large study design.
Wider implications of the findings: This is, to date, the largest study on birth weights among preterm and term ART singletons with a population-based design and SC control group. Growth differences are an important aspect of the safety profile of ART. More research is needed on the long-term outcome of these children.

[5]University of Adelaide, Fertility SA, Adelaide, Australia ;
[6]School of Medicine- Monash University, Department of Obstetrics and Gynecoloy, Melbourne, Australia

Study question: What are the long-term development outcomes in children born after freeze-only versus fresh embryo transfer (ET) in women without polycystic ovary syndrome (PCOS)?
Summary answer: Children born from non-PCOS women undergoing frozen ET had better problem solving and possibly better fine motor skills than children born from fresh ET.
What is known already: A recent randomized controlled trial (RCT) showed comparable ongoing pregnancy and live birth rates after use of a freeze-only versus fresh ET strategy in non-PCOS women undergoing IVF/ICSI (NCT02471573; Vuong LN, et al. NEJM 2018;378:137-147). Birth weight was significantly higher in children born from frozen ET compared with fresh ET. Here, we report on the development of babies born after frozen versus fresh ET.
Study design, size, duration: This was a long-term follow-up study (NCT04099784) of babies born alive after the first ET in the original RCT. Of 391 couples randomised, live birth occurred in 132 (97 singleton/35 twins) and 123 (95 singleton/28 twins) women in the freeze-only and fresh ET group, respectively; 113 parents (86%) from the freeze-only group (147 babies) and 99 (80%) from the fresh ET group (120 babies) returned questionnaires for this follow-up study.
Participants/materials, setting, methods: At least 2 years after birth, parents of all babies born alive from the first transfer after freeze-only or fresh ET in the RCT were contacted via postal mail and e-mail and asked to complete and return the Developmental Red Flags and Ages & Stages Third Edition (ASQ-3) Questionnaires. Parents received training and completed questionnaires at home, and returned questionnaires via postal mail, e-mail or instant messenger.
Main results and the role of chance: The mean age of children at the end of follow-up was 37 months. Height (95.0±6.1 vs 95.7±5.6 cm; p=0.382) and weight (14.9±2.6 vs 14.8±2.6 kg; p=0.903) were comparable in the freeze-only and fresh ET groups (results were also similar when singletons and twins were analysed separately). ASQ-3 scores for problem solving were significantly better in the freeze-only versus fresh ET group (overall: 53.6±8.4 vs 51.1±10.2, p=0.041; singletons: 52.3±10.1 vs 51.0±9.9, p=0.776; twins: 55.0±5.5 vs 51.4±11.1; p=0.202), and there was at trend towards higher fine motor skills scores in the freeze-only versus fresh ET group (overall: 47.8±11.6 vs 44.9±12.6; p=0.056; singletons: 46.0±13.4 vs 45.4±12.6, p=0.992; twins: 49.85 ± 8.72 vs 43.93 ± 12.71, p=0.060). The overall proportion of children with abnormal ASQ-3 (6.8% vs 8.3%) or abnormal Red Flags (5.4% vs 6.7%) findings in the freeze-only and fresh ET groups was low and did not differ significantly between groups. In a quartile-based analysis including predictive variables for ASQ-3, there was no significant association between estradiol or progesterone concentrations and ASQ-3 overall or problem solving scores.
Limitations, reasons for caution: This analysis includes only babies born alive after IVF/ICSI, and not all parents from the original study returned the study questionnaires.
Wider implications of the findings: Use of a freeze-only strategy resulted in better problem solving and possibly better fine motor skills scores than fresh embryo transfer, with comparable results in other domains. This highlights the importance of evaluation of normal development in children born after fresh compared with frozen embryo transfer.
Trial registration number: NCT04099784

O-032 Health in childhood following assisted reproductive technology (HiCART) - an ongoing study of 600 children born after assisted reproductive technology (ART) in Denmark

L.L. Asserhøj[1,2], A.S.L. Kjaer[1,2], I. Mizrak[1], G.F. Heldarskard[1], T.D. Clausen[3], G. Greisen[4], K.M. Main[2], P.L. Madsen[5,6], R.B. Jensen[2], A. Pinborg[1]

[2]Rigshospitalet, Department of Growth and Reproduction, Copenhagen, Denmark ;

[3]Nordsjællands Hospital- Hillerød, Department of Obstetrics and Gynecology, Hillerød, Denmark ;
[4]Rigshospitalet, Department of Neonatology, Copenhagen, Denmark ;
[5]Herlev-Gentofte Hospital, Department of Cardiology, Copenhagen, Denmark ;
[6]Copenhagen University, Department of Clinical Medicine, Copenhagen, Denmark

Study question: Is body composition of children born after frozen embryo transfer (FET) different compared to children born after fresh embryo transfer and spontaneously conceived (SC) children?
Summary answer: Inclusion is ongoing, but preliminary results revealed an increased fat-percentage in the cohort despite a BMI close to mean according to a normal reference material.
What is known already: Children conceived after FET are at increased risk of being born large for gestational age (LGA) compared with children conceived after fresh embryo transfer and SC children, whereas children conceived after fresh embryo transfer have an increased risk of being born preterm and small for gestational age (SGA) compared with SC children. Studies suggest that ART may induce epigenetic variations around implantation, fertilization and at the early embryonic stages, but the potential long-term effects of ART on the health of the offspring and the underlying mechanisms are scarcely explored.
Study design, size, duration: This cohort study consists of 600 pre-pubertal singletons born after FET (n=200), fresh embryo transfer (n=200) or spontaneous conception (n=200) in Denmark from 2009-2012. All children are identified by their mother's personal identification number in the national ART and medical birth registry. The recruitment and examination started January 2019 and is expected to be completed in September 2020. Currently, 289 children (134 boys, 155 girls) have been examined.
Participants/materials, setting, methods: The children (age 6-9 years) undergo a clinical examination with anthropometric measurements including body mass index (BMI), whole body DXA-scan, blood pressure, pubertal staging and blood sampling (e.g. glucose profile, lipid profile, calcium homeostasis, hormonal levels (e.g. IGF-I, IGFBP-3, androgen status, AMH) genetic and epigenetic analyses). Both parents fill in a questionnaire regarding the pregnancy, medical history and current health.Maternal, obstetric and neonatal medical data are obtained from the national ART and birth registry.
Main results and the role of chance: Children born after FET had higher birth weight (SDS) compared to children born after fresh embryo transfer and SC children (FET vs. fresh embryo transfer: 0.31 [SD 0.96] vs. -0.20 [SD 1.05], p=0.001, FET vs. SC: 0.31 [SD 0.96] vs. -0.11 [SD 0.97], p=0.006). Mothers conceiving after ART were older (FET vs. SC: 35.1 vs. 32.2 years, p<0.001, fresh embryo transfer vs SC: 34.2 vs. 32.2 years, p=0.002) and of lower parity compared to mothers conceiving spontaneously (FET vs SC: 1.50 vs. 1.76, p=0.02, fresh embryo transfer vs. SC 1.28 vs. 1.76, p<0.001). There were no differences regarding pregestational BMI and gestational age.To preserve blinding and avoid false preliminary conclusions results are presented only for girls and boys respectively. Height (SDS) was 0.19 [SD 1.04] in boys and 0.16 [SD 1.02] in girls. Weight (SDS) was 0.09 [SD 1.07] in boys and 0.10 [SD 0.99] in girls. BMI (SDS) was 0.01 [SD 1.11] in boys and 0.04 [SD 1.02] in girls. These results are in accordance with Danish sex-matched references. DXA-scans showed a fat-percentage (SDS) of 1.70 [SD 0.78] in boys and 1.06 [SD 0.69] in girls which was markedly higher for boys compared to reference material.
Limitations, reasons for caution: The study is powered to detect a difference of 0.3 SD in BMI (primary endpoint). Thus, smaller differences may be overlooked. Other outcomes may be relevant, but analyses are exploratory by definition. Mothers included in the two ART groups may have different infertility background which may bias the results.
Wider implications of the findings: This study will provide important information on the health of children born after ART that may influence the choices made early in the planning of a fertility treatment. The study has the potential to reduce some of the uncertainties associated with the long-term consequences of ART.
Trial registration number: ClinicalTrials.gov identifier: NCT03719703

O-033 Do assisted reproductive treatments impact the risk of congenital anomalies in singletons? A longitudinal national French study

J. De Mouzon[1], P. Fauque[2], G. Viot[3], A. Devaux[4], F. Pessione[5], A.W.G. ART women and children health[6]

[1]Epidemiology, Infertility, Paris, France ;
[2]Université Bourgogne Franche-Comté - INSERM UMR1231, Biologie de la Reproduction, Dijon, France ;
[3]Clinique de La Muette, Unité de Génétique, Paris, France ;
[4]CHU d'Amiens, Centre d'assistance médicale à la procréation- biologie de la reproduction, Amiens, France ;
[5]Agence de la biomédecine, Pole Evaluation Biostatistique, La Plaine Saint Denis, France ;
[6]Agence de la Biomedecine, Working group ART women and children health, La Plaine Saint Denis, France

Study question: Do some specific assisted reproductive treatments (ART) present a higher risk of congenital anomalies in singletons?
Summary answer: After multivariate adjustments, including female infertilities, the increased risks of congenital defects associated with intra-uterine insemination were no longer significant, they only subsisted in IVF-group.
What is known already: Many epidemiological studies suggest that singletons born from assisted reproductive technologies (ART) have a higher risk of birth defects, specifically for musculoskeletal, cardiovascular and urogenital disorders. However, most of these studies were established on data at birth or in neonatal period and from relatively small population or from several registries. Moreover, to our knowledge, the female infertility, a major potential confounder, was not included into the risk calculation.
Study design, size, duration: Using data from the French National System database (SNDS), we conducted a comparative cohort study on all singleton births (deliveries ≥22 weeks of gestation and/or >500g of birthweight) that occurred in France over a 5-year period (2013-2017) resulting from fresh embryo or frozen embryo transfers (fresh-ET or FET from IVF/ICSI cycles), intrauterine insemination (IUI) and natural conceptions (NC). Data was available for this cohort of children at least up to early childhood (2.5 years old).
Participants/materials, setting, methods: A total of 3,501,496 singleton births were included (including 20,218 from IUI, 45,303 from fresh-ET; 18,885 from FET). Data were extracted from national health databases. We monitored the major birth defects. Malformations were classified according to the International Classification of Disease (ICD-10). To analyse the effect of ART conception, multivariate analyses were performed with multiple logistic regression models adjusted for maternal age, primiparity, obesity, smoking, history of high blood pressure or diabetes and female infertility.
Main results and the role of chance: In our cohort of children, the whole prevalence of congenital malformations was 3.8%: 3.8% after NC, 4.5% after fresh-ET, 4.4% after FET, and 3.9% after IUI. Compared with infants conceived naturally, children born after fresh-ET and after FET had a significantly higher prevalence of malformations, with an aOR of 1.15 [95%CI 1.10–1.21, p<0.0001] and aOR of 1.12 [95%CI 1.05–1.21, p=0.001], respectively. Among the fifteen relevant subgroup of malformations studied, we observed a significant increased risk for eight of them in the fresh-ET group compared with the NC group (i.e. cleft lip and/or palate: aOR 1.39 [95%CI 1.11–1.74, p=0.004], respiratory: aOR 1.38 [95%CI 1.08–1.78, p=0.012], musculoskeletal: aOR 1.19 [95%CI 1.09–1.30, p<0.0001], nervous: aOR 1.26 [95%CI 1.09–1.47, p=0.002], digestive: aOR 1.25 [95%CI 1.09–1.44, p=0.002], urinary: aOR 1.14 [95%CI 1.01–1.28, p=0.029], cardiovascular systems with namely heart defects: aOR 1.14 [95%CI 1.03–1.26, p=0.013]). In the FET group, this increased risk was observed for face (aOR 2.83 [95%CI 1.39–5.75, p=0.004]) and digestive systems (aOR 1.27 [95%CI 1.03–1.57, p=0.002]. The overall risk of congenital malformations was similar in the IUI group and the NC group, as well as for specific anomalies.
Limitations, reasons for caution: For some extremely rare malformations, the sample size may be too small to reliably conclude that there was no difference between groups. Male infertility, the *in vitro* fertilization method and embryo stage at transfer could not be taken into account in the analyses. Furthermore, residual confounding cannot be excluded.
Wider implications of the findings: In this large study, after multivariate maternal adjustments the increased risks of children defects subsisted after IVF but relatively moderate, and those associated with IUI were no longer significant. These findings highlight that underlying parental infertility could contribute to the increased risk of children defects associated with ART.

O-034 Delaying cryopreservation for up to 48 hours does not adversely affect ovarian tissue used for fertility preservation

B. Bjarkadottir[1], M. Zemyarska[1], X. Wei[1], C. Walker[1], S. Lane[2], J. Davies[3], S. Williams[1]

[1]University of Oxford, Nuffield Department of Women's and Reproductive Health, Oxford, United Kingdom ;
[2]Children's Hospital Oxford. Oxford University Hospitals NHS Foundation Trust, Department of Paediatric Oncology and Haematology, Oxford, United Kingdom ;
[3]Children's Hospital Oxford- Oxford University Hospitals NHS Foundation Trust, Oxford Cell and Tissue Biobank, Oxford, United Kingdom

Study question: Does delaying processing and cryopreservation of ovarian tissue by 24 or 48 hours adversely affect primordial follicles?
Summary answer: A 24 or 48 hour delay before cryopreservation of ovarian tissue does not negatively impact primordial follicle morphology nor follicle growth after 10-day xenotransplantation.
What is known already: Ovarian tissue cryopreservation is becoming an increasingly common method of fertility preservation. While in most cases the tissue is processed and cryopreserved immediately upon procurement, delaying processing for up to 24 or even 48 hours could help with workload management. In addition, ovaries may be procured at a satellite site and transported to a cryopreservation facility, which necessitates a delay in processing. Little is known about the effects delayed processing may have on primordial follicle health and the functional potential of the tissue.
Study design, size, duration: Lamb ovaries (n=6 pairs of ovaries) were used to model human ovarian tissue. One ovary per pair was either processed into cortical strips immediately or stored whole at 4°C for 24 or 48 h before processing. Cortical strips were fixed fresh or after cryopreservation and thawing. Cryopreserved-thawed tissue (immediate processing, 24 or 48 h delay) was xenografted subcutaneously into immunocompromised mice (n=3) for 10 days to allow follicle development. Fixed samples were embedded and sectioned.
Participants/materials, setting, methods: Up to 50 primordial follicles from each cortical strip (one per condition/animal) stained with haematoxylin and eosin were classified by morphology as healthy or unhealthy. A proportional odds model was used to determine whether a delay in processing with or without cryopreservation affected follicle health. A logistic regression model was used to determine the odds of follicles being classified as growing after xenotransplantation. Data is presented as odds ratio (OR) with 95% confidence intervals (CI).
Main results and the role of chance: A processing delay of 24 h did not impact the health of primordial follicles in fresh (OR=0.78, 95%CI 0.38-1.60, $p>0.05$) and cryopreserved-thawed tissue (OR=0.93, 95% CI 0.61-1.41, $p>0.05$; no delay n=6; 299 fresh follicles, 287 cryopreserved follicles; 24 h delay n=3; 149 fresh follicles, 132 cryopreserved follicles). Conversely, a processing delay of 48 h (fresh tissue, n=3; 149 follicles) resulted in primordial follicles being more likely to be graded as unhealthy compared to immediately-processed tissue (OR=2.47, 95%CI 1.29-4.71, $p<0.01$). Interestingly however, tissue cryopreserved after a 48 h processing delay (n=3, 149 follicles) was less likely to contain unhealthy follicles compared to the immediately-processed cryopreserved control (OR=0.56, 95% CI 0.36-0.87, $p<0.01$). Xenografting of cryopreserved ovarian tissue after 0, 24 or 48 h processing delay demonstrated that grafts from all groups were functional, with no difference in the proportion of growing follicles between groups (immediate processing: 17.3±30.0%; 24 h delay: 46.0±2.8%; 48 h delay: 45.3±10.8%). Furthermore there was no difference in the health of primordial follicles in xenografted tissue after a 24 (OR=1.30, 95% CI 0.59-3.22, $p>0.05$) or 48 h delay (OR=1.26, 95% CI 0.55-3.96, $p>0.05$).
Limitations, reasons for caution: These findings should be validated using human ovarian tissue with a larger sample size to account for the natural variability between subjects. Ovaries were left intact prior to processing and the findings may therefore not be applicable to biopsied tissue. These results reflect follicle health and not follicle number.
Wider implications of the findings: These results demonstrate that ovaries can be stored for up to 48 h prior to cryopreservation with no adverse effect on primordial follicles after transplantation and *in vivo* development of the tissue. This may have implications on the way ovarian tissue cryopreservation is organised on a local and national level.
Trial registration number: N/A

O-035 Ovarian function recovery in newly diagnosed advanced Hodgkin lymphoma patients treated with PET-adapted regimen: prospective analysis of a multicentric randomized phase 3 trial (AHL2011).

Study question: Does de-escalated treatment strategy by switching regimen (BEACCOPP to ABVD) in early responder reduce the risk of ovarian damage and infertility compared to standard escalated BEACOPP regimen?
Summary answer: Although both treatments affected the ovarian reserve, de-escalated regimen decreased the risk of premature ovarian insufficiency compared to standard regimen in Hodgkin lymphoma patients.
What is known already: Chemotherapy-induced ovarian damage is a major concern for young patients treated for advanced Hodgkin lymphoma. Six cycles of bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone (BEACOPP escalated) showed an improved progression-free survival rate compared to doxorubicin, bleomycin, vinblastine, and dacarbazine (ABVD) in advanced stage diseases but induced high risk of immediate and long-term toxicities. AHL2011 trial recently demonstrated that the use of ABVD after two cycles of induction with BEACOPP in early responder based on PET-driven strategy was safe while minimizing toxicities (Casasnovas et al, Lancet Oncol 2019). Here we investigated its benefit on ovarian function in young patients.
Study design, size, duration: AHL2011 is a prospective randomized non inferiority trial enrolling 823 patients from May 19, 2011, to April 29, 2014 in 90 centers across Belgium and France. All female patients under 45-year old participating to AHL2011 trial were recruited for this prospective sub-analysis of the ovarian function and fertility at baseline, end of the treatment, and every year during 5 years of follow-up.
Participants/materials, setting, methods: Ovarian function was assessed by use of serum levels of FSH, estradiol and anti-mullerian hormone (AMH). All AMH measurements were centralized. Data on menstruation, use of oral contraceptive, fertility preservation, pregnancies and oncological outcomes were also collected. Acute premature ovarian insufficiency (POI) was defined as FSH value above 24 IU/L twice during 5-years follow-up when available, with estradiol below 50pg/ml, and low ovarian reserve by AMH value below 0.16ng/ml. Statistics were performed using STATA15.
Main results and the role of chance: A total of 146 patients were eligible for ovarian function assessment, 70 in the standard (BEACOPP escaladed) and 76 in the study (PET-driven strategy) groups. Mean age was similar between both groups (26.7±6.6 and 26.9±6.6 years old, respectively) as well as

oncological characteristics. As expected, the patients in the study group received significantly less cumulative doses of alkylating agents within a shorter timeframe. Ovarian function was similar between groups before treatment but became significantly different during follow-up. FSH values were significantly higher in the standard group while AMH values were lower. Thirty-two patients faced POI (46.1% versus 14.5% in standard and study groups, respectively). The risk of POI was significantly associated with age, total dose of alkylating agents, and groups with a lower risk in the study group (OR 0.20, 95% CI 0.08-0.50; p<0.001). Interestingly, low ovarian reserve was not associated with groups (OR 0.7, 95% CI 0.31-1.69; p=0.46). Although OR was always lower in the study group, association between low ovarian reserve and chemotherapy doses does not reach significance except for etoposide (OR 0.36, 95% CI 0.14-0.96; p<0.04 for doses <5000mg). A total of 29 and 30 patients reported pregnancies after treatment in standard and study groups, respectively (p=0.81).

Limitations, reasons for caution: Although this is the larger prospective study analyzing ovarian function in young advanced Hodgkin lymphoma patients considering a new therapeutic strategy, the number of patients remains limited and hormonal levels were not available at all time-points for all patients during the 5 years of follow-up.

Wider implications of the findings: The PET-driven treatment in young advanced Hodgkin lymphoma patients allows to reduce the risk of POI by 5 times compared to standard regimen. Although the ovarian reserve is also better preserved using PET-driven strategy, around 60% of the patients had a low AMH levels during the follow-up in both groups.

Trial registration number: NCT01358747

O-036 Live birth rate and utilization rate of eggs and embryos following fertility preservation (FP) in 879 female cancer patients over 19 years

D. Khalife[1], S. Ali[1], Y. Khalaf[1], N. Reddy[1], J. Kopeika[1]

[1]Guy's and St Thomas' NHS Foundation Trust, Assisted Conception Unit, London, United Kingdom

Study question: We aim to investigate the rate of women proceeding to FP at the time of cancer diagnosis, the return, utilization and live birth rates after cancer treatment.

Summary answer: Nearly half of newly diagnosed cancer patients proceed to FP and return for follow-up within 21 months post-cancer treatment. The livebirth rate (LBR) is 72.1%.

What is known already: FP is an established part of cancer services in many countries. It is used now more and more frequently. However, very little is published about long term utilization of gametes/embryos after FP. In male population of cancer patients concern is being raised that in spite of "routine" storage of sperm, less than 10% of patients return to use the stored gametes. Not much information is found for female cancer survivors.

Study design, size, duration: A prospective cohort study was conducted on 879 young women diagnosed with cancer who sought FP counseling at the Assisted Conception Unit (ACU) at Guy's and St Thomas' Hospital (GSTT), London, United Kingdom between January 2000 and December 2019.

Participants/materials, setting, methods: Data on 879 cancer patients were analyzed. Baseline characteristics include age, AMH, AFC, and cancer type. The primary outcome measure was total LBR. The secondary outcomes were return and utilization rates which were calculated as the number of patients who returned for follow-up and those who undergone embryo transfer. Means and frequencies were used to describe continuous and categorical variables respectively. Student t-test analysis was used with p <0.05 considered being statistically significant.

Main results and the role of chance: A total of 879 cancer patients received FP counseling at GSTT with breast cancer being the most common malignant disease accounting for 63.1% of the cases. The mean age, AMH, and BMI were 33.8 ± 7.8 years, 18.8 ± 20.5 pmol/L and 23.7 ± 4.2 kg/m^2 respectively. A total of 373 patients (42.4%) underwent FP of whom 40.7 % opted for embryo cryopreservation, 53.4% for oocyte cryopreservation, 5.1% had both and 0.76% opted for ovarian tissue cryopreservation in a different facility.

As for the return rate, 33.8% (297/879) of cancer patients returned for follow-up for assessment of ovarian function, menopausal symptoms, Hormone Replacement Therapy, and fertility treatment. Until today, utilization rate among those who had frozen gametes is16.4 % (61/373) and the overall LBR is 72.1% (44/61) of which 9.1% (4/44) are twin births. The miscarriage rate is 12.2% (8/61). The overall mean time to follow-up is 21.2 ± 19 months (range 1-132 months), with 66% of returning patients doing so within 2 years after cancer diagnosis.

Patients with breast cancer were more likely to return to use their gametes (27/61: 44.3%) and had significantly higher LBR (19/27: 70.3%) in comparison to patients with lymphoma (3/8: 37.5%) (p-value <0.001).

Limitations, reasons for caution: Although we are certain of capturing the outcome of those who had fertility treatment, we can't be as certain of capturing all births resulting from natural conception.

A proportion of patients may need a longer time to be able to attempt pregnancy, thus the calculated LBR can be underestimated.

Wider implications of the findings: This is a demonstration of how FP can be effective. Over nearly two decades of follow-up, 1 in 6 patients who underwent FP utilized their stored gametes/embryos with a good outcome. This is the first published account of the utilization rate after FP and the longest reported period.

Trial registration number: Not applicable

O-037 Long-term fertility and pregnancy outcomes in men and women with a history of childhood cancer: a nationwide population-based linkage analysis

M. Das[1], C. Wang[2], S. Oberg[3]

[1]Chelsea and Westminster Hospital NHS Foundation Trust, Reproductive Medicine- Obstetrics and Gynaecology, London, United Kingdom ; [2]Karolinska Institutet, Medical Epidemiology and Biostatistics, Stockholm, Sweden ; [3]Karolinska Institutet- Harvard T.H.Chan School of Public Health, Medical Epidemiology and Biostatistics, Stockholm, Sweden

Study question: What are the long-term fertility and pregnancy outcomes in men and women with a history of childhood cancer as compared to the general population?

Summary answer: Childhood cancer survivors are less likely to have had at least one biological child and are more likely to need assisted reproductive techniques to conceive.

What is known already: Childhood cancer survivors may face reproductive challenges due to the disease itself or the necessary cancer treatments. There is however a paucity of data from large population-based studies on the actual estimates of fertility, need for assisted reproduction techniques (ART) and pregnancy outcomes in young men and women childhood cancer survivors.

Study design, size, duration: We identified all individuals born in Sweden from 1958-1975 (n=2,703,888) and used linkage of national registers to follow their reproductive outcomes prospectively. Men and women with a history of childhood cancer before the age of 18 (n= 6,770) were compared with the general population without a history of childhood cancer (n=2,019,645). We assessed the occurrence of childbearing in the entire population and of trouble conceiving, use of ART and pregnancy outcomes for the first birth.

Participants/materials, setting, methods: Cancer in childhood was identified from the Cancer Register, childbearing from the Multi-generation Register and pregnancy outcomes from the Medical Birth Register. First live birth was modelled in Kaplan Meier and Cox regression, whereas risks related to the first birth were modelled with logistic regression. We performed a sibling comparison to account for unmeasured confounding by matching each individual with cancer to the nearest unaffected sibling.

Main results and the role of chance: Childhood cancer survivors were less likely to have had at least one biological child by the age of 37; hazard ratio adjusted for birth year and sex was 0.83 (95% CI: 0.80,0.86). Moreover, births were more likely to have been preceded by trouble conceiving and use of assisted reproductive techniques (ART) in both men and women surviving childhood cancer, compared to the general population. The differences were more pronounced in males than in females [males: infertility: OR, 95% CI: 1.29 (1.02,1.63); use of ART: 2.17 (1.67, 2.81); females: infertility: OR, 95% CI:1.15 (1.00, 1.32); use of ART: 1.29 (1.02, 1.61)]. Female cancer survivors had a significantly higher risk of preterm birth (<37 weeks gestation) compared to the general population (OR, 95% CI: 1.56 (1.36, 1.79), and they were also at higher risk of caesarean section. In sibling comparison, survivors of childhood cancer remained at greater risk of infertility and use of ART, and the risk of preterm birth was largely unchanged when female cancer survivors were compared to their unaffected sisters [OR, 95% CI: 1.52 (1.09, 2.10)].

Limitations, reasons for caution: Detailed information on individual cancer treatments was not available, so the effects of specific treatment regimens on fertility could not be assessed.
Wider implications of the findings: Both male and female childhood cancer survivors had poorer reproductive outcomes. These findings will help to counsel young cancer survivors and their families about the effects of cancer and cancer therapies on their future fertility and pregnancy outcomes and will help to provide individual risk estimates to guide management.
Trial registration number: Not applicable

O-038 A new strategy to assess safety of controlled ovarian stimulation protocols for oocyte vitrification as a fertility preservation technique in breast cancer patients.

M.J. Soriano[1], J. Martínez[1], R. Lopez[1], S. Herraiz[1], C. Díaz-García[1,2]

[1]IVI Foundation- IIS La Fe, Reproductive Medicine, Valencia, Spain ;
[2]IVI-RMA Global- IVI London, Reproductive Medicine, London, United Kingdom

Study question: Could controlled ovarian stimulation (COS) protocols affect the proliferative and metastatic potential of breast cancer (BC) cells?
Summary answer: Ovarian stimulation with Letrozole for oocyte vitrification might be safely used as a fertility preservation (FP) technique in hormone-dependent breast cancer women.
What is known already: BC is the most common malignancy in women at reproductive age. Treatment with high-dose chemotherapy in female patients may impose deleterious effects on the ovary. COS protocols to obtain oocytes for vitrification are frequently used within FP patients but associate a rise in supra-physiological estradiol (E2) levels. This effect could increase the proliferation of tumour cells, being probably detrimental for BC women. Nevertheless, standard COS has been recently adapted by using aromatase inhibitors such as Letrozole, leading a maximum E2 peak similar to that found in a natural cycle. Unfortunately, there is still little evidence regarding safety of such approaches.
Study design, size, duration: Experimental in vivo study. Forty 5-week old Nude-nu female mice were allocated to the following experimental groups: BC (n=10), BC and FSH stimulation (BC-FSH, n=10), BC and Letrozole stimulation (BC-LTZ, n=10), Control FSH stimulation (CT-FSH, n=5) and Control Letrozole stimulation (CT-LTZ, n=5). BC was induced in the three first groups while controls received a saline solution injection. Animals were maintained for 5 months and then sacrificed to collect tissue and blood samples for further analysis.
Participants/materials, setting, methods: One million of human MCF-7 BC cells, previously transfected with the mCherry fluorescent protein, were injected into the left renal capsule of BC, BC-FSH and BC-LTZ mice. Two days after xenograft, COS was induced by 10IU FSH or 1mg/ml Letrozole + 10IU FSH, followed by ovarian triggering with 10IU hCG at 48h. Cell proliferation was biweekly monitored by a non-invasive in vivo imagen system (IVIS) to record fluorescence signal and also assessed by Ki-67 immunostaining.
Main results and the role of chance: When tumour growth was assessed by means of total radiant efficiency signal ([p/s]/[μW/cm^2), BC and BC-LTZ mice presented a statistically significant lower expression when compared to BC-FSH group ($6.1x10^{10}$±$2.0x10^{10}$, $9.6x10^{10}$±$3.2x10^{10}$ and $1.6x10^{11}$±$4.5x10^{10}$; p<0.01 and p<0.05, respectively), five months after xenograft. Metastasis was not detected in the BC and BC-LTZ groups, nevertheless, metastatic lesions were observed in BC-FSH mice. The in vivo monitoring results by IVIS were concordant with the histological assessment of tumour lesions after sacrifice. Tumour size was slightly lower in BC group than in BC-LTZ (0.3±0.2 cm^2 vs 0.5±0.2 cm^2). However, lesions in BC-FSH group were considerably increased (1.2±0.3 cm^2, p<0.01). Cell proliferation, by Ki-67 immunostaining, was also performed in kidney samples to validate these data. Similar proliferation levels were found in the BC and BC-LTZ groups (10.3±0.9% and 11.5±0.6%). However, BC-FSH revealed a significant increase in tumour cell proliferation (28.8±1.6%, p<0.01). Lastly, mean serum E2 levels of BC and both Letrozole stimulated groups were comparable (BC: 186.9±56.0 pg/ml, BC-LTZ: 193.9±78.2 pg/ml and CT-LTZ: 119.8±50.7 pg/ml) whereas FSH-treated animals registered significantly higher E2 concentrations (BC-FSH: 431.2±56.2 pg/ml and CT-FSH: 330.9±57.0 pg/ml, p<0.05). All these results confirmed that COS with Letrozole did not induce the tumour development.
Limitations, reasons for caution: This is the first experimental study evaluating the effect of COS protocols over a human BC tumour cell line using a non-invasive in vivo system to monitor cell growth. Although the promising results, further experiments with primary human tumour cells would be required to validate the current data.
Wider implications of the findings: This study provides evidence on the safety of COS with Letrozole for BC patients. These results could be essential in reassuring current indications for FP techniques and counselling to patients and health-care professionals. Thus, patients with BC could safely underwent the gold standard FP technique, oocyte vitrification.
Trial registration number: Not applicable.

O-039 Thyroid cancer treatment and subsequent infertility diagnosis in female adolescents and young adults: a population-based cohort study

M.P. Velez[1], H. Imsirovic[2], H. Richardson[2]

[1]Queen's University, Obstetrics and Gynecology, Kingston, Canada ;
[2]Queen's University, Public Health Sciences, Kingston, Canada

Study question: Is thyroid cancer treatment associated with subsequent infertility diagnosis?
Summary answer: Thyroid cancer treatment is not associated with an increased risk of infertility diagnosis
What is known already: Thyroid cancer has undergone the most rapidly increasing incidence rate among all major cancers, most likely due to the increase of surveillance and the use of diagnostic technologies. Normal thyroid function is important to maintain normal reproduction. Previous limited literature suggests that there is little to no adverse effects of thyroid cancer treatment on gonadal function (serum gonadotrophins or sex steroids), fertility (live birth rates) or pregnancy outcomes in women treated for thyroid cancer. However, studies with larger sample sizes are needed to better elucidate the risk, if any, of different types of thyroid cancer treatment on subsequent infertility diagnosis.
Study design, size, duration: A population-based cohort study using universal health care databases in the province of Ontario, Canada. All women 15-39 years of age who received thyroid cancer treatment from 1992-2011 were identified through the Ontario Cancer Registry (N=4,926) and linked to several health care datasets. Women were followed up until December 31, 2016
Participants/materials, setting, methods: Thyroid cancer treatment was categorized as: less than total thyroidectomy-LTT, total thyroidectomy-TOT, or total thyroidectomy plus radioactive iodine therapy-TOT+RAI. Women with infertility, tubal ligation, oophorectomy, or hysterectomy previous to cancer diagnosis were excluded. Infertility diagnosis was identified using physician billed claims (ICD-9 628). Modified Poisson regression models were used to calculate the risk of infertility diagnosis adjusted for sociodemographic factors. Models were further stratified by parity at the time of cancer diagnosis (nulliparous and parous).
Main results and the role of chance: Treatment distribution was: 849 (17%) LTT, 2457 (50%) TOT, 1620 (33%) TOT + RAI. The mean age at cancer diagnosis was 31.04 years (SD=5.99). The median follow-up time for cancer survivors was 10.78 years (IQR=6.96-15.77). A total of 563 (11%) had a subsequent diagnosis of infertility. The frequency of infertility diagnosis was similar among treatments (p=0.99), with a similar mean time to infertility diagnosis (p=0.69). Mean age at infertility diagnosis was 35.26 years (SD=5.48). Compared to women with LTT, women who received TOT or TOT+RAI did not have a higher risk of subsequent infertility diagnosis (RR=0.98, 95% CI: 0.78, 1.24, p=0.86; RR=0.93, 95% CI: 0.72, 1.20, p=0.55 respectively). Parity did not modify the estimates.
Limitations, reasons for caution: The accuracy of infertility diagnosis using ICD-9 codes in administrative datasets has not been validated. Non-biologic factors that may influence the likelihood of seeking a fertility assessment may not be captured in administrative databases.
Wider implications of the findings: Thyroid cancer treatment in female adolescents and young adults is not associated with an increased risk of infertility diagnosis.
Trial registration number: not applicable

O-040 Impact of In Vitro Fertilization treatments on the risk of recurrence in fertility-sparing management of endometrial atypical hyperplasia and grade 1 adenocarcinoma

M. Vaugon[1], M. Peigné[2], E. Larouzée[1], J. Phelippeau[1], C. Gonthier[3], M. Koskas[1]

[1]Bichat Hospital, Gynecology and Obstetrics Department, Paris, France ;

[2]Jean Verdier Hospital, Assisted Reproductive Technology, Bondy, France ; [3]Pitié Salpetriere Hospital, Gynecology and Obstetrics Department, Paris, France

Study question: What is the risk of recurrence after In Vitro Fertilization (IVF) treatment for patient with endometrial atypical hyperplasia and grade 1 adenocarcinoma (AH/EC) who received conservative treatment with progestins?
Summary answer: There is no significant difference of the rate of recurrence at 24 months between patient who received IVF treatment or not.
What is known already: About 5% of endometrial cancer affect young women in reproductive age. In this particular case of AH/EC, conservative treatment, such as chlormadinone acetate, can be offered to safeguard their fertility. A quick pregnancy is recommended after progestin treatment and therefore IVF is often started. Preliminary results are encouraging: in 2013, Park's study[1] concluded that the use of fertility drugs was not associated with a higher incidence of recurrence (5-year disease free survival rate: 73% p=0,335); in 2019 Kim's study[2], the rate of recurrence was 27,3% with fertility drugs. However, they are retrospectives and not homogeneous studies.
Study design, size, duration: Multicentric prospective cohort study conducted from January 2008 to July 2019. The study is homogeneous: all the 60 patients had an AH/EC and received progestins treatment by chlormadinone acetate at least 3 months.31 patients received IVF treatment and 29 did not
Participants/materials, setting, methods: All the patients received expert advice from the National Observatory of the Gynecology and Obstetrics Department at Bichat Hospital (PREFERE center) and then enter the cohort. The choice between IVF treatment or not was made by the gynecologist and the patient, after advice from PREFERE center. Survival rates were calculated using the Kaplan-Meier method, and differences in the survival rates between groups were compared using the log-rank test.
Main results and the role of chance: The mean follow-up was 19 months in the IVF group and 11 months in no IVF group. The end of the follow-up was the time of the last news or the time of the surgery in the case of hysterectomy. The probability of 2 years recurrence was 37,7% (+/- 10,41%) in the IVF group and 55,7% (+/- 14,02%) in the no IVF group. The difference was not significant (p=0,13). We find no additional risk of recurrence according to obesity, nulliparity, PCOS, age and tumor characteristics. Twenty-three patients had a pregnancy (15 in the group IVF and 8 in the group no IVF). Among all the patients who had a pregnancy, 7 had a recurrence of the disease in the first 24 months (30%). Whereas among the 37 patients who didn't have a pregnancy, 17 patients had a recurrence in 24 months (45%). The difference was significant (p<0.01, IC 0.06-0.61). Whether the number of cycles, the E2 maximum concentration, the type of protocol chosen, the dose of gonadotrophin or the thinness of the endometrium, there were no significant differences on the risk of recurrence in the subgroup IVF.
Limitations, reasons for caution: The main inconvenient is the size of our groups but we chose to include only patient treated with chlormadinone acetate in order to have a homogenous population.
Wider implications of the findings: IVF treatment after fertility sparing management of HA/EC does not seem to increase the risk of recurrence. Therefore, it is an acceptable strategy to decrease the time to pregnancy. Overall, the rate of recurrence is high in both groups which implies a close monitoring of these patients.
Trial registration number: not applicable

Abstract text

Our work follows that of four earlier studies. Adjuk et al. (2011) and Swann et al. (2012) first explored the potential of particle image velocimetry (PIV) (an optical method to measure fluid and particles dynamics) for the study of cytoplasmic dynamics occurring during mouse fertilisation. Bui et al. (2017) and Cavalera et al. (2018), by complementing the detection of cytoplasmic flows with artificial neural networks (ANN), further perfected this imaging approach, succeeding in the prediction of the developmental competence of mouse oocytes. After the presentation of these results, we will describe our latest work on human preimplantation embryos.

The ANN approach was undertaken to assess retrospectively the ability of human embryos to develop to the blastocyst stage. The analysis focused on 113 embryos generated in 32 IVF cycles, carried out between October 2015 and May 2018. Female age was 36.3±4.9 years. To minimize possible patient-based bias, cycles were recruited ensuring to have in the same cohort both embryos able to develop to the blastocyst stage and arresting at earlier stages. Embryos were subject to time-lapse assessment to monitor development and perform trophectoderm biopsy for preimplantation genetic testing of aneuploidy. Fertilisation was achieved by ICSI. Time-lapse monitoring started immediately after ICSI, with a 15 min interval between consecutive observations. Of 230 embryos analysed, 112 reached the blastocyst stage (BL-group) and 118 arrested sometime after the 2-cell stage (NoBL-group). ANN analysis was performed, at this stage, only during the first two cell divisions (44 hr, 175 frames).

Based on morphological criteria, embryos were first blindly classified by an expert operator as belonging to the BL or NoBL group, attaining a 75.4% accuracy, 76.5% sensitivity and 74.3% specificity. Then, the time-lapse images corresponding to the first 175 frames (44 hr) were anlaysed with PIV to extract their cytoplasmic movement profiles, and subsequently with the AI models (k-NN and LSTM-NN). The results showed a classification accuracy comparable to that reported by the operator (75.4%). Next, the results of the operator were integrated to those obtained with the AI models, and this led to a further classificaton attaining a 82.6% accuracy, 79.4% sensitivity and 85.7% specificity. Taken as a whole, these data indicate the possibility of predicting blastocyst development as early as the 4-cell stage; also, these results highlight the strenght of combining the huge experience owned by an expert clinical embryologist with that obtained thanks to AI tools.

The study represents a proof-of-principle for the chosen embryo assessment approach. Further observations are required to trenghten these data and to assess the impact of possible confounding variables such as patient typologies, culture conditions and time-lapse equipment.

To the best of our knowledge this study represents the first attempt to classify very early human preimplantation embryos using AI. Further refinement of the approach is expected to impact embryo assessment ability and improve efficiency in assisted reproduction treatments.

Study question: What are the reported data on ART cycles, IUI and fertility preservation (FP) interventions in 2017 as compared to previous years, as well as main trends over the years?
Summary answer: The 21st report shows a progressive increase in reported treatment cycle numbers in Europe, a slight decrease in the number of transfers (IVF + ICSI) with more than one embryo, stable multiple delivery rates (DRs), unchanged outcomes for IUI cycles and higher pregnancy rates (PRs) and DRs after FER compared to fresh IVF and ICSI cycles.
What is known already: Since 1997, ART aggregated data generated by national registries and professional organisations have been collected, analysed by the European IVF-monitoring Consortium (EIM) and reported in 20 manuscripts published in *Human Reproduction* and *Human Reproduction Open*.
Study design, size, duration: Yearly collection of European medically assisted reproduction and FP data by EIM for ESHRE; data on treatments performed between January 1 and December 31 2017 in 30 European countries were provided by either National Registries or registries based on professional organisations.
Participants/materials, setting, methods: 1229 clinics offering ART services in 30 countries reported a total of 840 138 treatment cycles, involving 147 934 with IVF, 351 588 with ICSI, 238 665 with frozen embryo replacement (FER), 33 721 with preimplantation genetic testing (PGT), 62 811 with egg donation (ED), 369 with IVM of oocytes and 5050 with frozen oocyte replacement (FOR). Data on IUI using husband/partner's semen (IUI-H) and donor semen (IUI-D) were reported from 1170 institutions, including 141 647 treatments with IUI-H in 24 countries and 48 918 treatments with IUI-D in 20 countries. A total of 18 540 FP interventions from 11 countries including oocytes, semen, as well as ovarian and testicular tissue in pre-and postpubertal patients were reported.
Main results and the role of chance: 1229 IVF clinics (94.5% of registered clinics in participating countries) and 1170 IUI providers reported their data. In the 30 reporting countries, after IVF the clinical pregnancy rates (PRs) per aspiration and per transfer were 29.5% and 39.4%, respectively (versus 28.5% and 34.6% in 2016). Corresponding rates after ICSI were 27.2% en 39.8% (versus 26.2% and 33.2% in 2016). After FER with own embryos the PR per thawing is still on the rise, from 30.9% in 2016 to 31.9% in 2017. After ED the PR per fresh embryo transfer was 49.1% (49.4% in 2016) and per FOR 43.1% (43.6% in 2016).

In IVF and ICSI together, the trend towards the transfer of fewer embryos continues with the transfer of 1, 2, 3 and ≥4 embryos in 45.4%, 49.8%, 4.5% and 0.2% of all treatments, respectively (versus 41.5%, 51.9%, 6.2% and 0.4% in 2016). This resulted in a proportion of singleton, twin and triplet DRs of 85.4%, 14.3% and 0.3%, respectively (versus 84.8%, 14.9% and 0.3% in 2016). Treatments with FER resulted in twin and triplet DRs of 11% and 0.2%, respectively (versus 11.9% and 0.2% in 2016).

After IUI, the DRs remained similar at 8.7% after IUI-H (8.9% in 2016) and at 12.2% after IUI-D (12.4% in 2016). Twin and triplet DRs after IUI-H were 8.5% and 0.3%, respectively (in 2016: 8.8% and 0.3%) and 7.0% and 0.2% after IUI-D (in 2016: 7.7% and 0.4%). The majority of FP interventions included the cryopreservation of ejaculated sperm (n=10837 from 11 countries) and of oocytes (n=6551 from 11 countries).
Limitations, reasons for caution: As the methods of data collection and levels of completeness of reported data vary among European countries, the results should be interpreted with caution. Due to the COVID-19 pandemic, less countries than usual have sent in data by the abstract deadline.

O-045 Data from the ESHRE PGT Consortium – year 2018

A. Van Montfoort[1], M. De Rycke[2], F. Carvalho[3], C. Rubio[4], F. Bronet[5], F. Spinella[6], V. Goossens[7]

[5]IVI, IVF and PGD lab, Madrid, Spain
[6]Genoma, Molecular Genetics Laboratories, Rome, Italy
[7]ESHRE, Central Office, Grimbergen, Belgium

Study question: Which trends are shown in data collection XXI of the European Society of Human Reproduction and Embryology (ESHRE) PGT Consortium compared with previous years?
Summary answer: Data collection XXI, year 2018, represents valuable data on PGT activity in (mainly) Europe and reports on the main trends observed which are the continuous increase of trophectoderm biopsy and further expansion of comprehensive testing technology in PGT-SR and PGT-A.
What is known already: The ESHRE PGT Consortium was set up in 1997 and from that time has been collecting data on PGT and PGT-A. The PGT database comprises the world's largest collection of PGT / PGT-A data providing a valuable resource for data mining and for following trends in PGT practice. So far, up to the year 2015, data collections were carried out in a retrospective data way, from 2016 onwards a prospective data collection was in place.
Study design, size, duration: As the nature of PGT/ PGT-A treatments has changed significantly over the last years and IVF cycle management and genetic analysis techniques are getting more complex, ESHRE uses an online data collection system in which data are collected prospectively from oocyte retrieval to analysis, embryo transfer and pregnancy / live birth. Data are collected cycle by cycle on a voluntary basis.
Participants/materials, settings, method: For the 2018 data, individual centres (39) from 21 countries directly entered the data into the PGT database through software developed by ESHRE. Data were analysed at ESHRE headquarters and include all aspects of PGT/PGT-A cycles.
Main results and the role of chance: The Consortium has analysed the PGT analyses (n=28231) performed in 2018. The indications for PGT included inherited chromosomal abnormalities (n=553 analyses), monogenic disorders (n=1229 analyses), aneuploidy testing for infertility (n=868 analyses), HLA typing (n=12 analyses) and PGT for mitochondrial disorders (n=3 analyses). In addition, 701 clinical pregnancies and 411 deliveries have been analysed in detail. The methods used for biopsy were polar body (1.1%), cleavage stage biopsy (31.4%) and blastocyst biopsy (67.5%; comparable with data from 2017). The methodology used for diagnosis is also evolving, with data set XXI showing around 10% of FISH, 37% of PCR and 53% of WGA. Within WGA 79% of the analyses were done using NGS, 10% using array-CGH and in 8.5% cases SNP arrays were used. The overall pregnancy rate is about 21.5%. The baby data show that it is difficult for most centres to have a detailed follow-up.
Limitations, reasons for caution: The findings apply to the 38 participating centres and may not represent worldwide trends in PGT. Data were collected prospectively, but details of the follow-up on PGT pregnancies and babies born were limited.
Wider implications of the findings: The ESHRE PGD Consortium continues its activities as an important forum for PGT practitioners to share data and exchange experiences. The information extracted from the data collections helps to monitor quality issues in PGT and survey the introduction and effectiveness of new PGT technologies and methods

O-048 Genetic ancestry testing and the end of donor anonymity

D.Kennett[1]

[1]*University College London, Department of Genetics- Evolution and Environment, London, United Kingdom*

Abstract text

Over 30 million people around the world have now taken a direct-to-consumer genetic test with companies such as AncestryDNA and 23andMe. These tests can provide information about an individual's genetic ancestry and health but they also allow the user to opt in to receive matches with genetic relatives. As a result, donor-conceived individuals can now take a DNA test to search for their DNA relatives and identify their genetic parent. Identities can be inferred through networks of genetic cousins even if the donor is not in the database. The chances of success are increasing all the time and sometimes people are matched at the outset with a half-sibling or genetic parent. Donor origins can also be discovered unexpectedly through genetic testing if the child has not been told that they were donor conceived. The massive growth of the consumer DNA databases in the last few years has important implications for everyone working in the fertility industry and for parents who are considering using egg or sperm donation to start or complete their family. DNA testing has effectively ended anonymity for all donors regardless of the legislation in place at the time. How do we deal with the challenges of this new reality? Whose responsibility is it to provide support and counselling for those affected? How should the fertility sector adapt?

Abstract text

The critical role of female factors, especially female age, on the outcomes of assisted reproductive technologies is well recognized. Fewer data have been generated regarding the role of sperm or male factors on IVF results. Initially, sperm factors were recognized to adversely affect the fertilization step of in vitro fertilization, with variable interpretation of the reproductive competency of the embryo derived using sperm from men with abnormal semen parameters. With the advent of ICSI for management of male factor, the risk of fertilization failure due to sperm abnormalities has been largely overcome. Several male-related factors, including paternal age, have been identified that affect the outcome of IVF. One pathway for male factors to adversely affect IVF results includes sperm DNA integrity. Abnormal sperm DNA fragmentation is rarely seen in naturally fertile men, but can be present even in the presence of normal semen parameters. Sperm DNA damage can be evaluated by a variety of assays, and appears to develop during sperm transport (i.e., after leaving the testis) for the majority of men with abnormal sperm DNA fragmentation index (DFI.) It may be associated with ejaculatory dysfunction (spinal cord injury), partial obstruction (post-vasectomy), medications that effect ejaculatory efficiency (SSRI's), prolonged abstinence, advanced male age, or without identifiable cause. Abnormal sperm DFI is associated with a marked increase in the risk of spontaneous Ab, as well as decreased chance of pregnancy with IVF/ICSI. The evaluation and management of abnormal ejaculated sperm DFI will be reviewed as well as the existent data on the effect of DNA fragmentation on assisted reproductive technology results.

Abstract text

"Low responders: From natural cycles to dual stimulation?"

Filippo Maria Ubaldi, MD, PhD; clinical director of GENERA, centers for reproductive medicine, Italy

The lack of a consensus on the definition of "poor responders" (POR) in the past made it difficult to compare the proposed managements among each other. A systematic review highlighted 41 different definitions of POR out of 47 randomized control trials (RCTs). In this scenario, the Bologna criteria were the first concrete attempt to define POR grounded on an evidence-based approach. Noticeably, the predicted cumulative live birth rate per IVF cycle in patients fulfilling these criteria is not higher than 7-8% according to the existing evidence in the literature.

Recently, a panel of clinicians gathered together in the so-called POSEIDON group and suggested a novel more detailed stratification of women with a low response to controlled ovarian stimulation (COS). This group introduced a new concept in IVF: the main aim of COS is to obtain at least one embryo with a high chance to result in a live birth, namely euploid blastocyst(s). Several data exist in the literature supporting that the chance of a blastocyst to be euploid is independent of COS, its regimen, the dose of gonadotrophins used, and the number of oocytes/embryos in each cohort. Therefore, the careful choice and tailoring of the strategy that better suits each patients is critical.

The obvious and mostly-used clinical strategy for women with low AFC and/or AMH was to increase the daily dose of gonadotrophins but unfortunately without success. In fact, gonadotrophins can only support each follicular wave in its growth, but they cannot produce follicles de novo. Natural cycle has been also adopted across the years. However, it is mainly effective in patients with an expected number of oocytes retrievable lower than 2-3. The adoption of COS might be helpful, as also suggested by the recent ESHRE guidelines.

Another strategy has been outlined across the years to treat time-sensitive (oncologic and advanced maternal age) and POR patients, which is known as DuoStim (follicular and luteal phase stimulation in the same ovarian cycle). This strategy is supported from the evidence that 2-3 waves of follicular growth might arise during the ovarian cycle in women, 1-2 of which in the luteal phase. Although the ESHRE labeled this strategy still as "for research only", several evidences have been produced along the last 5 years from our group, as well as from many other groups:

- we set-up the DuoStim protocol in a pilot study,
- we confirmed the absence of differences in terms of fertilization, blastulation and euploidy rates between the cohorts of oocytes collected from the luteal and the paired-follicular phase,
- we reported the reproducibility of the DuoStim protocol among all the GENERA centers
- we reported similar clinical, obstetrical and neonatal outcomes among euploid blastocysts obtained after follicular and luteal phase stimulation through a non-selection study design
- we suggested DuoStim as a strategy to prevent drop-out in patients fulfilling the Bologna criteria, while increasing their chance of having a live birth per intention to treat from 8 to 15%
- we conducted a systematic review that highlighted the reproducibility of our data also in other clinics adopting slightly different protocols
- from a basic research perspective, we collaborate with Universities to keep building evidence in favor of DuoStim safety

Clearly RCTs and cost-effective analyses are still needed but, when indicated and depending on the setting of each IVF clinic, DuoStim might be considered a valuable strategy to prevent patients' drop-out while increasing their chance to identify at least one euploid blastocyst in the shortest possible time.

INVITED SESSION

SESSION 14: THE WAY FORWARD FOR FERTILITY PRESERVATION

06 July 2020 Parallel 4 14:00 - 15:00

O-055 Cancer during pregnancy: Outcomes for mother and child

F. Amant[1]

[1]*Netherlands Cancer Institute, The Netherlands*

O-056 Fertility preservation for children: Specificities and counselling for patients and parents

G. Quinn[1]

[1]*New York Univeristy, OB-GYN, New York, U.S.A.*

Abstract text

The use of fertility preservation in children receiving gonadotoxic therapies is often ethically challenging. Presently most countries have some type of guidelines suggesting all patients receiving a cancer or other life-threatening diagnosis, receive information on how that may impact their future fertility and be offered referrals to specialist to discuss preservation. Not all types of preservation are available in certain countries and in some cases, finances become a rate limiting factor as well as potential delay of treatment. Parents may feel uncertain about their role in making future decisions about their children's future fertility and health care clinicians may also be concerned that engaging in discussions and consultations may delay the lifesaving treatment needed. There are also psycho-social issues involved in the decision process both at the time of the diagnosis as well as in the future. There has been great controversy over the use of posthumous assisted reproduction, particularly the use of gametes stored by a minor and later used by a parent to create a grandchild. There is also the unique circumstance of the transgender/non-binary child and their family who may be considering puberty- blockers or gender affirming hormones. This presentation will explore the ethical and psycho-social issues and boundaries of the use of fertility preservation in children (minors) and explore the current related literature. The objectives of this presentation are to:

1. Identify current standard and experimental fertility preservation options for minors
2. Discuss ethical challenges faced by parents and healthcare clinicians
3. Explore current cases on decision-making and use of fertility preservation in minors
4. Compare and contract the ethics of FP on very young children (aged 0-7) compared to middle aged children (8-14) and older children (15-18)
5. Examine the issue of fertility preservation in transgender/non-binary children

Study question: Does hysteroscopic septum resection improve reproductive outcomes in women with a septate uterus?

Summary answer: In our study, hysteroscopic septum resection did not improve reproductive outcomes in women with a septate uterus.
What is known already: The septate uterus is the most common uterine anomaly with an estimated prevalence of 0.2-2.3% in women of reproductive age. Women with a septate uterus are at increased risk for subfertility, pregnancy loss and preterm birth. Hysteroscopic septum resection has been applied to improve reproductive outcome in these women, but the evidence on the effectiveness of this procedure is scarce and of low quality. We performed a randomised controlled trial to establish whether septum resection improves reproductive outcome in women with a septate uterus.
Study design, size, duration: We did an international open-label randomised controlled trial in 10 centres in the Netherlands, United Kingdom, United States of America and Iran. The trial is registered with the Netherlands Trial Register as NTR 1676.
Participants/materials, setting, methods: Women with a septate uterus and a history of subfertility, pregnancy loss or preterm birth were randomly allocated to septum resection or expectant management. The primary outcome was live birth within 12 months after randomization. Secondary outcomes were clinical pregnancy, ongoing pregnancy, pregnancy loss, preterm birth and complications following hysteroscopic septum resection. We analysed the data on intention to treat basis. We estimated differences as relative risks (RR) with 95% confidence intervals (CI).
Main results and the role of chance: Between October 2010 and October 2018 we randomly assigned 80 women (40 to septum resection and 40 to expectant management). Live birth occurred in 12 women who underwent septum resection (32.4%) and in 14 women who had expectant management (37.8%) ((RR 0.89 (95% CI 0.56-1.41). Clinical pregnancy occurred in 22 women who underwent septum resection (59.5%) and in 19 women who had expectant management (51.4%) (RR 1.18 (95% CI 0.75-1.85); pregnancy loss occurred in 10 women who underwent septum resection (43.5% of women who had a conception) and in 5 women who had expectant management (26.3% of women who had a conception) (RR 1.56 (95% CI 0.70-3.47); ongoing pregnancy occurred in 13 women who underwent septum resection (35.1%) and in 14 women who had expectant management (37.8%) (RR 0.92 (95% CI 0.58-1.48); preterm birth occurred in 5 women who underwent septum resection (38.5% of women who had an ongoing pregnancy) and in 4 women who had expectant management (28.6% of women who had an ongoing pregnancy) (RR 1.33 (95% CI 0.48-3.70). In women who underwent septum resection, one perforation of the uterus occurred during surgery. The procedure was stopped immediately and the septum was removed 4 weeks later without complications.
Limitations, reasons for caution: Our major limitation is the limited sample size.
Wider implications of the findings: Our results suggest that septum resection does not result in better pregnancy outcomes. This procedure is not without risks and should not be offered to women without proper counselling. We believe an expectant management is the preferred primary treatment in women with a septate uterus.
Trial registration number: NTR 1676

O-058 Hysteroscopic Fundus Endometrial Incision (FEI) in oocyte recipients before embryo transfer (ET) during In Vitro Fertilization

R. Najdecki[1], E. Papanikolaou[1], T. Chartomatsidou[1], F. Pakaki[1], S. Stamataki[1], P. Tatsi[1], E. Timotheou[1], F. Chouliara[1], E. Bampas[1], S. Bouchlariotou[1], G. Michos[2], A. Athanasiadis[2]

[1]Assisting Nature, IVF Unit, Thessaloniki, Greece ;
[2]Aristotle University, 3rd Department Ob Gyn, Thessaloniki, Greece

Study question: Does Hysteroscopic Fundus Endometrial Incision (FEI) in oocyte recipients before embryo transfer increase pregnancy and live birth rates?
Summary answer: Oocyte recipients who underwent FEI before ET showed statistically higher live births rates.
What is known already: Controversial results are published regarding the necessity of hysteroscopy plus uterine scratching or not before ET. For oocyte recipients, who might have previously undergone several failed IVF procedures, the importance of correct evaluation of uterine cavity is of paramount importance since there are limited psychological resources to sustain potential failure.
Study design, size, duration: Between 2014-2019, 332 egg recipients were assigned prospectively in a ratio 1:2 to undergo hysteroscopy (n=114, **Hysteroscopy group**) or not (n=218,**Non-Hysteroscopy group**). These women, who performed pre-operative hysteroscopic evaluation of the uterine cavity, also underwent fundus endometrial incision irrespectively of the presence of arcuate uterus (U2a) or not (U0) with endoscopic scissor. The relation of the FEI to pregnancy outcome was investigated.
Participants/materials, setting, methods: The age of the women included in the study ranged from 35-50 years old. The mean years of infertility was 4,6. Women received treatment with donor oocytes and the mean blastulation rate was 59%. They underwent embryo transfer with two blastocysts except from 10 cases which preferred single blastocyst transfer to avoid twins.
Main results and the role of chance: Among 114 women of the Hysteroscopy group(Storz Bettocchi 5mm) prior to embryo transfer,33 were diagnosed with U2a (partial septate, arcuate uterus), 10 with U2b (complete septate uterus) and 6 women with UIa (T shape uterus). Both women with uterine abnormality (n=49) plus the ones with normal cavity (n=65) underwent Fundus Endometrial Incision with Wolf endoscopic scissor. The rest 218 recipients did not undergo hysteroscopy prior to ET. Initial positive human Chorionic Gonadotropin (hCG) test was 73.7% in the hysteroscopy group and 57,34% in the non-hysteroscopy group. Live Birth rate was statistically significantly (p=0,015) higher in the hysteroscopy group in a rate of 56,14% (n=64/114) compared to the live birth rate of 42,2% (n=92/218) in the non-hysteroscopy group.
Limitations, reasons for caution: The sample size of the participants should be expanded in order to obtain more solid evidence of the impact of FEI in pregnancy outcomes. Moreover, the time interval between the hysteroscopy and the ET should be taken into further consideration.
Wider implications of the findings: The current findings indicate that in this particular subgroup of patients- like oocyte recipients- hysteroscopy plus FEI might increase delivery rates. Apart from the obvious benefit of recognizing obscured anomalies, requiring surgical correction, it appears that even fundus incision might improve uterine receptivity and thus pregnancy outcome.
Trial registration number: none

O-059 Improvement of symptoms after hysteroscopic isthmoplasty in women with abnormal uterine bleeding and expected pregnancy: a prospective study

D. Tran[1], T. Nguyen[2], D. Do[3], H. Nguyen[4], P. Thuong[2]

[1]Ha Noi Obstetric and Gynecology hospital, Department of high risk pregnancy, Ha Noi, Vietnam ;
[2]Ha Noi Obstetric and Gynecology hospital, Delivery department, Ha Noi, Vietnam ;
[3]Ha Noi Obstetric and Gynecology hospital, Gynecology department, Ha Noi, Vietnam ;
[4]Ha Noi Obstetric and Gynecology hospital, Assisted Reproductive Center, Ha Noi, Vietnam

Study question: To determine the effectiveness and safety of hysteroscopic repair of isthmocele to treat postmenstrual spotting and the rate of natural pregnancy after surgery
Summary answer: Our data supports that hysteroscopic isthmoplasty is safe and effective in treating isthmocele-related abnormal uterine bleeding
What is known already: A cesarean scar defect, also called as an isthmocele, is one of the consequences of cesarean section that may cause secondary infertility and postmenstrual spotting.
Study design, size, duration: 23 patients with abnormal uterine bleeding and expected pregnancy who had an isthmocele with a residual myometrium of ≥2.5mm, measured during transvaginal untrasound were performed hysteroscopic repair of isthmocele
Participants/materials, setting, methods: 23 patients with abnormal uterine bleeding and expected pregnancy who had an isthmocele with a residual myometrium of ≥2.5mm,were performed hysteroscopic repair of isthmocele using a step-wise approach: identification of relevant anatomy; resection of the cephalad edge of fibrosis; resection of the caudad edge of fibrosis; and ablation of the isthmocele base. Complications of surgery were observed and the symtoms of postmentstrual spotting and prevalence of natural pregnancy were monitored for 6 months after surgery.

Main results and the role of chance: No complications of surgery as bleeding, uterine perforation, infection was noticed. 11 (47.8%) patients had resolution of their symptoms. In the remaining cases, 7 (30.4%) patients had an improvement of symtoms with decreasing duration of postmentstrual spotting from 8.1 ±1.7 days to 4.3 ± 0.8 days ($P < 0.05$), whereas 5 (21.8%) patients did not obtain any relief. 7 (30.4%) patients had natural pregnancy after surgery 6 months.
Limitations, reasons for caution: The sample size is not enough large
Wider implications of the findings: Hysteroscopic isthmoplasty should be used to treat isthmocele-related abnormal uterine bleeding
Trial registration number: Not applicable

O-060 Conception and Reproductive Outcomes in Asherman Syndrome after hysteroscopic adhesiolysis

S. Baradwan[1], D. Alharbi[2], M. Bashir[3], A. Saleh[3], D. Al-Jaroudi[4]

[1]HealthPlus Fertility and Women's Health Center- Jeddah- Saudi Arabia., Department of Obstetrics and Gynecology, jeddah, Saudi Arabia ;
[2]King Fahad Medical City- Riyadh- Saudi Arabia, Department of Obstetrics and Gynecology., Riyadh, Saudi Arabia ;
[3]King Fahad Medical City- Riyadh- Saudi Arabia, Research Services Administration-Department of Biostatistics- Research Center., Riyadh, Saudi Arabia ;
[4]King Fahad Medical City- Riyadh- Saudi Arabia, Reproductive Endocrine and Infertility Medicine Department., Riyadh, Saudi Arabia

Study question: Dose the reproductive methods could influence pregnancy outcome in women with Asherman's syndrome ?
Summary answer: The spontaneous cumulative conception rates following hysteroscopic adhesiolysis were higher than those for the IVF-ICSI, whereas the live birth and miscarriage rates were similar.
What is known already: Hysteroscopic adhesiolysis anatomically restores the uterine cavity in cases of Asherman's syndrome. however, the extent of endometrial fibrosis could lead to implantation failure and miscarriages. The main purpose of treating infertile women with Asherman's syndrome is improve both the conception rate and the live birth rate. Few studies have evaluated the reproductive outcome after hysteroscopic adhesiolysis.
Study design, size, duration: A retrospective cohort study that included 41 women diagnosed with Asherman syndorme who attended Women's Specialized Hospital, King Fahad Medical City, from December 2010 to December 2016 and presented with a history of infertility or recurrent pregnancy loss. Patients were followed up for 2 years to monitor pregnancy. Details of reproductive methods whether with spontaneous conception or assisted reproductive technology were recorded. The main outcome measure was identification of reproductive methods and pregnancy outcome.
Participants/materials, setting, methods: all women diagnosed with Asherman syndorme who attended Women's Specialized Hospital, King Fahad Medical City, presented with a history of infertility or recurrent pregnancy loss. Patients were followed up for 2 years to monitor pregnancy. Details of reproductive methods whether with spontaneous conception or assisted reproductive technology were recorded. The main outcome measure was identification of reproductive methods and positive pregnancy tests that might have ended in miscarriage or ectopic, live birth, or no pregnancy.
Main results and the role of chance: The overall conception rate was (53.6%, n=22) after hysteroscopic adhesiolysis. The live birth rate was (34.2%, n=14) the miscarriage rate was (14.6%, n=6) and the ectopic pregnancy rate was (4.9%, n=2). The conception rate was significantly (P=0.037) higher in spontaneous conception compared with IVF- ICSI, 80% (12 out of 15) compared to 44.4% (8 out of 18), respectively. The live birth and miscarriage rate were reported by 53.3% (8 out of 15), 20% (3 out of 15) of the spontaneous conception group compared to 27.8% (5 out of 18), 16.7% (3 out of 18) of the IVF-ICSI group, respectively. This was statistically not significant.
Limitations, reasons for caution: Among the limitations of this study is the small size of the sample, as it was limited to one Hospital, which could affect the generalizability. Another limitation is the study's retrospective nature, second look hysteroscopy was not performed, and the menstrual pattern after the procedure was not documented.
Wider implications of the findings: The spontaneous cumulative conception rates following hysteroscopic adhesiolysis were higher than those for the IVF-ICSI, whereas the live birth and miscarriage rates were similar.
Trial registration number: 19-024

Abstract text

Traditional embryo morphology assessment is performed at static time points and implies interruption of embryo culture conditions. In a TLT incubator, images of embryo development are recorded at regular time intervals, which facilitates embryo monitoring. Indeed, it allows embryologists to assess embryo development thoroughly in a dynamic fashion without removing them from the incubator and thus maintaining constant culture conditions. Although TLT has been widely implemented since its release in 2010, there was no recommendation on how to introduce this technology in an IVF laboratory and no review of other aspects of its use. To address this need, a working group was constituted. It included 11 members of different nationalities with internationally recognized experience in clinical embryology and basic science embryology. The stakeholders of this project have reviewed the literature and collected published surveys and manufacturer information up to January 2019. Once a consensus was found on the content of the recommendation manuscript, a draft was released on ESHRE website for review by ESHRE members. The paper was published in HRopen (https://academic.oup.com/hropen/article/2020/2/hoaa008/5809428) and the recommendations are available on ESHRE website (https://www.eshre.eu/Guidelines-and-Legal/Guidelines/TLT). The working group listed 11 recommendations on what to do before introducing TLT in an IVF laboratory. These statements include an assessment of the pros and cons of acquiring a TLT system, selection of relevant morphokinetic parameters, selection of an appropriate TLT system with technical and customer support, development of an internal checklist and education of staff. This paper also addresses more general aspects of TLT introduction in IVF laboratory such as the potential benefit of TLT especially regarding embryo quality assessment and the identification of

parameters with biological/clinical outcomes. This document discusses in what extent TLT helps in embryo selection/deselection for transfer and how it allowed the development of algorithms thanks to the analysis of data generated during the past decade. A description of the current state of TLT is provided and the question whether to share TLT data with patients is tackled. Besides, the paper presents the non-clinical/biological interests and benefits of having TLT in IVF laboratory, which emcompass training/teaching, quality control and the management of staff time and work-flow. Overall these recommendations are mostly based on clinical and technical expertise. The paper provides technical advice, but leaves any decision on whether or not to use TLT to the individual centres.

O-063 Prolactin receptor expression and its role in cytoskeletal reorganisation in focal adhesion in human blastocysts

K. Ezoe[1], T. Miki[1], A. Yabuuchi[1], T. Kobayashi[2], K. Kato[2]

[1]Kato Ladies Clinic, R&D Division, Tokyo, Japan ; [2]Kato Ladies Clinic, Gynecology, Tokyo, Japan

Study question: What is the gene expression pattern of prolactin receptor (PRLR) in human pre-implantation embryos and what are its functions during embryonic development and adhesion process?

Summary answer: Human embryos express PRLR at the morula and blastocyst stages and PRLR signalling stimulates blastocyst adhesion by promoting integrin-based focal adhesions.

What is known already: Predecidualisation is one of the initial processes in endometrial stromal cell differentiation that occurs during embryo implantation and placentation. During this process, the decidual cells express prolactin (PRL), a decidual marker gene, prior to implantation. PRL is thus thought to influence preimplantation development and the subsequent blastocyst implantation in the uterus. It has been reported that PRL and PRLR are not expressed in human embryos at the eight-cell stage. However, their expression patterns at stages further along the first cell lineage and implantation are poorly understood.

Study design, size, duration: A total of 318 discarded human vitrified four-cell stage embryos donated for research by consenting couples were used in this study. The study was approved by the Institutional Review Board. The embryos were randomly allocated into two groups to be cultured in medium with (n = 125) or without PRL (n = 193). The rates of blastocyst development and adhesion, outgrowth area, cytoskeletal reorganisation, and nascent adhesion formation were compared between the groups.

Participants/materials, setting, methods: Human vitrified-warmed embryos were cultured to the blastocyst stage in SAGE 1-Step medium with or without 100 mg/ml of PRL. The PRL and PRLR expressions in embryos at the four-cell, eight-cell, morula, and blastocyst stages were assessed by quantitative RT-PCR and immunofluorescence staining. The blastocysts were plated on fibronectin-coated dishes and cultured for 96 h to evaluate outgrowth competence. The expression of epithelial-to-mesenchymal transition (EMT)- and focal adhesion-related genes in blastocysts were analysed.

Main results and the role of chance: PRLR mRNA expression increased significantly after embryo compaction and blastulation. The increased expression levels of the PRLR protein at the morula and blastocyst stages were also demonstrated by immunofluorescence staining. The supplementation of the embryo culture medium with PRL did not improve the rate of embryonic development to the blastocyst stage and their morphological grade. On the contrary, blastocyst outgrowth was significantly increased in embryos cultured with PRL. The phosphorylation of JAK2, downstream of the prolactin receptor family, was markedly higher in the PRL-treated embryos than in those cultured without PRL. Furthermore, the mRNA expression of ezrin-radixin-moesin proteins, which organise the cortical cytoskeleton by linking filamentous actin to the apical membrane of cells during EMT, was stimulated by the activation of PRL-JAK2 signalling. The expression of EMT-related genes, such as transforming growth factor β1, snail1, and twist1, was also promoted by PRL treatment. PRL-treated embryos exhibited higher mRNA expression of ITGA3, ITGB1, ITGAV, and ITGB3 than non-treated embryos did. Focal adhesion kinase and paxillin are recruited by integrins and are involved in cytoskeletal and adhesion assembly and organisation. There were more nascent adherent cells expressing focal adhesion kinase and paxillin in PRL-treated embryos than in non-treated embryos.

Limitations, reasons for caution: The results may vary between *in vivo* and *in vitro* conditions. Further clinical studies are thus required to explore the clinical efficacy of PRL supplementation in the culture. This can be done by assessing the pregnancy outcomes after a single blastocyst transfer.

Wider implications of the findings: To our knowledge, this is the first report demonstrating PRLR expression in human embryos after compaction and showed that culture medium supplementation with PRL improves blastocyst adhesion by promoting EMT and integrin-based focal adhesions. Therefore, PRL treatment during embryo culture would be advantageous for improving pregnancy outcomes following blastocyst transfer.

O-064 Histone variant H3.3 chaperone complex, Hira, is essential for male pronucleus formation in mouse and human

R. Smith[1], A. Saunderson[2], S. Pickering[3], J. Tait[4], J. Thong[3], R. Anderson[4], C.J. Lin[4]

[1]University of Edinburgh, MRC Centre for Reproduction Health, Edinburgh, United Kingdom ;
[2]Royal Infirmary of Edinburgh, Simpson Centre for Reproductive Health, Edinburgh, United Kingdom ;
[3]Royal Infirmary of Edinburgh, Edinburgh Fertility and Reproductive Endocrine Centre, Edinburgh, United Kingdom ;
[4]University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, United Kingdom

Study question: Is loss-of-function of H3.3 chaperone Hira complex accountable for the abnormal single pronucleus (1PN) phenotype?

Summary answer: H3.3 Chaperone Hira complex is essential for male pronucleus formation in both mice and humans.

What is known already: The Hira complex comprises Hira, Cabin1, and Ubn1. In mouse, it is responsible for H3.3 incorporation into the male genome, chromatin reconstruction, and male pronucleus formation after fertilisation. Hira-mutant zygotes show a 1PN phenotype due to failure of formation of the male pronucleus. An abnormal 1PN phenotype is commonly found following assisted reproductive technologies (ART) in IVF clinics: however, the etiology is unknown and no investigation of whether the other subunits in the complex are required for zygote formation in mouse or human has been carried out.

Study design, size, duration: Mouse model: We have generated new loss-of-function mouse models of Hira, Cabin1, and Ubn1 respectively.

Human samples: An HFEA Research Licence allowed us to collect abnormal one-pronucleus zygotes from the Edinburgh Fertility and Reproductive Endocrine Centre, during 2018-2019. We obtained consent from 144 couples and collected 21 1PN zygotes from 16 patients.

Participants/materials, setting, methods: We used mouse models to conditionally knockout Hira and Cabin1 in oocytes using Zp3-Cre, and morpholino microinjection to study the knockdown of Ubn1. We studied the consequences of the loss-of-function on the formation of the 1PN phenotype. Embryos were generated using a combination of ART (microinjection, IVM/IVF/IVC). Histology (H&E, IHC), cytological (confocal imaging) and molecular analyses (qRT-PCR, IF, Proximity Ligation Assay) were then applied.

Human zygotes had IF and confocal imaging applied to them.

Main results and the role of chance: Results of mouse studies: We demonstrated that all the subunits of the Hira complex are maternal factors present in oocytes, and they are incorporated into male chromatin after fertilisation and interact with each other. It is important to note that loss-of-function Hira complex oocytes formed abnormal 1PN after fertilisation.

Results of Human studies: In the human abnormal 1PN zygotes we collected, we observed that Hira chaperone molecules failed to incorporate into male

chromatin. This finding is based on the detection of IF signal in male chromatin [100% of Hira (n=4); 100% of Ubn1 (n=4), and 50% of Cabin1 (n=4)]. Since the human data agreed with the mouse data, we proposed that the mechanism of action is likely conserved.

Limitations, reasons for caution: We obtained consent from only 144 couples, and collected 21 1PN zygotes. Ethical and HFEA regulations prevented us from collecting normal 2PN human zygotes. However, we were able to collect morphological abnormal but cytological normal samples as controls to demonstrate that Hira incorporates into male chromatin in the human zygote.

Wider implications of the findings: The Hira complex is critical during fertilisation in both mice and humans. The feasibility of rescuing 1PN zygotes using overexpression or nuclear transfer approaches as an alternative to the 3 parent-IVF strategy could potentially be developed into a novel personalised medicine for patients who have previously produced1PN zygotes after ART.

O-065 The telomere link between extended fertility and longevity

J. Michaeli[1], K. Rotshenker Olshinka[1], N. Srebnik[1], R. Smoom[2], N. Serruya[2], S. Yanai[2], O. Michaeli[2], T. Eldar-Geva[1], Y. Tzfati[2]

[1]Shaare Zedek Medical Center, IVF Unit- Obstetrics and Gynecology, Jerusalem, Israel ;
[2]The Hebrew University of Jerusalem, Department of Genetics- The Silberman Institute of Life Sciences, Jerusalem, Israel

Study question: Is extended fertility associated with longer telomeres?

Summary answer: Extended fertility is associated with longer leukocyte telomere length suggesting a novel biomarker of oocyte quality.

What is known already: Telomeres are nucleoprotein complexes that protect the ends of eukaryotic chromosomes. Telomeres gradually shorten with age and eventually cause aging-related pathologies. Longer telomeres are associated with longevity. Telomeres have a cardinal role in meiosis and the development of germ cells. Many demographic studies correlated late reproduction with general health and longevity. We hypothesized that telomere length provides a link between extended female fertility and longevity. Furthermore, while anti-mullerian hormone (AMH) levels indicate the number of remaining follicles, we hypothesized that telomere length might indicate the quality of the oocytes and the ability to conceive and deliver a genetically-healthy offspring.

Study design, size, duration: A prospective experimental study evaluating: (1) leukocyte mean telomere length and AMH levels in 30 women age 43-48y who naturally conceived and delivered healthy babies, and 30 age-matched controls, previously fertile, who do not use contraceptives but failed to conceive after the age of 41y; (2) leukocyte mean telomere length in 20 women age 30-35y who delivered their first child compared to 20 age-matched women who delivered their 6^{th} to 10^{th} child. Study conducted 2018-2019.

Participants/materials, setting, methods: Blood samples obtained (1) study group: at delivery and 5-6 months later, and from the control group, and (2) at delivery of the first or $\geq 6^{th}$ child. Erythrocytes were lysed and high molecular weight genomic DNA was extracted from leukocyte by a standard proteinase K/phenol method. Average telomere length measured by Southern blot, analyzed by *TeloTool* software. AMH levels were measured (in the study group, 5-6 months postpartum) by an automated assay (Elecsys Cobas, Roche).

Main results and the role of chance: In study 1, mean age, 45y, and demographic characteristics were similar between the study and control groups. Average telomere length in the study group was 9700 bp, significantly longer than that of the control group, 9270 bp ($p<0.05$). When plotting telomere length according to parity, in women with less than 9 children, the difference in telomere length between cases and controls increased to over 1000 bp ($p=0.009$). While in the subpopulation of women with ≥9 children, the difference was insignificant. This led us to examine the immediate effects of pregnancy and delivery, and the long-term effect of parity on telomere length (study 2). Both short and long term effects were found insignificant. AMH levels were similar in the study and control groups (averaged 0.80 and 0.82 ng/ml, respectively). Our results indicate clear correlation between extended fertility and longer telomeres, particularly in the subpopulation of women with up to 8 children, which is unlikely to be found by chance ($p=0.009$). We propose that in this population of women, the quality of the oocytes, reflected by longer telomeres, is a major factor enabling successful conception. In women with more children, other factors compensate for the declined oocyte quality typical to their age.

Limitations, reasons for caution: We have measured telomere length in leukocytes, and it remains to be shown whether it reflects oocyte telomere length. In addition, the association of telomere length with oocyte quality and infertility should be studied more directly in a subfertile population of women.

Wider implications of the findings: Our findings biologically support previous demographic reports and explain the known link between extended fertility and longevity. We suggest that longer telomeres, associated with extended fertility, reflect improved general health and reproductive fitness. We propose that telomere length should be further explored as a possible novel biomarker of oocyte quality.

Trial registration number: Shaare Zedek Medical Center ethical committee approval number: 0145-16-SZMC

O-066 Cytoskeleton, ultrastructure and viability of human biopsied embryos on day 3 vs day 5 following vitrification

A. Chatzimeletiou[1], N. Petrogiannis[2], A. Sioga[3], A. Makedos[1], M. Filippa[2], B. Tarlatzis[1], E. Kolibianakis[1], A. Handyside[4], G. Grimbizis[1]

[1]Aristotle University Papageorgiou Hospital, IVF Unit, Thessaloniki, Greece ;
[2]Naval Hospital of Athens, IVF Unit, Athens, Greece ;
[3]Aristotle University, Embryology Laboratory, Thessaloniki, Greece ;
[4]Illumina, Illumina, Cambridge, United Kingdom

Study question: Are there any differences in viability, cytoskeletal abnormalities and mitochondrial and other organelles' structure/ number/ function amongst embryos biopsied on day3 vs day5 following vitrification?

Summary answer: No statistically significant differences are observed in viability, spindle/chromosome configurations and the ultrastructure of human embryos biopsied on day 3 vs day 5 following vitrification.

What is known already: Most studies in human biopsied vitrified embryos concentrate on assessing the success of the procedure on survival rates and clinical outcomes following transfer. Indeed several clinical trials have confirmed promising results. Limited studies have however examined the effects of biopsy and vitrification on spindle structure/chromosome alignment in human embryos, and only in animal models cell viability using fluorescent markers and the ultrastructure of the cellular organelles in vitrified biopsied embryos have been investigated in detail. This is the first study to examine in human embryos biopsied at 2 different stages cell viability, cytoskeleton and ultrastructure before and after vitrification.

Study design, size, duration: 240 Day3 biopsied embryos that developed to blastocysts but were rejected for transfer following PGT-M or PGT-A were divided into 2 groups: A) 120 blastocysts treated for Viability, Cytoskeletal and TEM analysis(fresh n=20,n=20,n=20 and following vitrification/warming n=20,n=20,n=20), B) 120 embryos were rebiopsied at the blastocyst stage and treated for Viability, Cytoskeletal and TEM analysis(fresh n=20,n=20,n=20 and following vitrification/warming n=20,n=20,n=20). Also, 60 vitrified blastocysts biopsied only on Day5 were treated for Viability, Cytoskeletal and TEM analysis.

Participants/materials, setting, methods: Viability was assessed by CFSE/PI staining. Cytoskeletal analysis by confocal laser scanning microscopy was performed following immunostaining with α-tubulin, γ-tubulin and acetylated-tubulin antibodies in combination with DAPI or /PI. For ultrastructure assessment by transmission electron microscopy(TEM), blastocysts were fixed in gluteraldehyde, incubated in osmium, aqueous uranyl acetate, dehydrated through ethanol series and immersed in Epon. The Ultrathin lead citrate stained sections were examined in a JEOL-TEM-2000-FXII microscope. The study was conducted in an academic hospital.

Main results and the role of chance: Viability staining with CFSE/PI before vitrification revealed that all blastocysts biopsied on day5 had damaged cells at the position of cutting (range 4-10cells), while 95% of the day3 biopsied embryos that developed to the blastocyst stage had 0 cells damaged at the herniating site. Following vitrification and subsequent warming, additional PI stained cells (range 5-20) were evident in other parts of the day5 biopsied blastocysts and in similar incidence to vitrified blastocysts that were biopsied on day3. Cytoskeletal analysis by confocal laser scanning microscopy revealed that the majority of spindles examined in both fresh and vitrified biopsied embryos were normal. However in the vitrified groups a higher incidence of spindle abnormalities was observed which

was not significantly different between Day3 biopsied embryos (33/98 (33.7%) abnormally shaped spindles and 5/98 (5.1%) multipolar and monopolar spindles and day5 biopsied embryos (42/128 (32.8%) abnormally shaped spindles and 7/128 (5.5%) multipolar and monopolar spindles (p>0.05). Transmission electron microscopy (TEM) analysis revealed similar ultrastracture between the day 3 and day 5 biopsied embryos before vitrification. However, compared to fresh blastocysts vitrified blastocysts had more characteristic lipofuscin droplets (representative of apoptosis) and a higher number of vacuoles and distension of mitochondria.

Limitations, reasons for caution: The blastocysts used in this study were all diagnosed with either chromosomal abnormalities or single gene defects following PGT-A or PGT-M.

Wider implications of the findings: This is the first study to compare viability, ultrastructure and spindle/chromosome configurations in day3 and day5 biopsied embryos following vitrification. The similarities observed in ultrastucture reflect similar patterns of metabolism, while lipofuscins indicate 'rescue' processes for the embryos, which in their attempt to fully recover following vitrification, eliminate damaged/abnormal cells.

Trial registration number: not applicable

O-067 Smooth endoplasmic reticulum clusters in oocytes influence pronuclear behaviour and morphokinetics at early-cleavage stage but have no negative impact on embryonic and pregnancy outcomes

S. Ueno[1], T. Miki[2], U. Kazuo[1], T. Okimura[1], A. Yabuuchi[2], T. Kaobayashi[3], K. Kato[3]

[1]Kato Ladies Clinic, IVF Laboratrory, Tokyo, Japan ;
[2]Kato Ladies Clinic, R&D division, Tokyo, Japan ;
[3]Kato Ladies Clinic, Gynaecology, Tokyo, Japan

Study question: Do smooth endoplasmic reticulum clusters (sERCs) influence pronuclear behaviour at fertilisation, morphokinetics, blastocyst development, and live birth following single embryo transfer (SET)?

Summary answer: Smooth ERCs influence pronuclear behaviour at fertilisation and morphokinetics at early-cleavage stage, but have no adverse impact on embryonic and pregnancy outcomes.

What is known already: sERC-positive (sERC+) oocytes and/or cycles in which sERC+ oocytes were retrieved are reported to be associated with poor clinical outcomes following IVF-ET. However, the effects of sERCs on embryonic and pregnancy outcomes remain unclear. The endoplasmic reticulum (ER) is a major internal storage site of calcium ions, and the ions stored in the ER should be mobilized properly during fertilisation for further embryonic development. Therefore, it is hypothesized that sERCs may be associated with aberrant pronuclear (PN) behaviour at fertilisation and morphokinetics during embryo development; however, the number of studies supporting this hypothesis is limited.

Study design, size, duration: A retrospective study of 6,010 cycles (mean age: 38.3±3.5 years old), including 294 cycles with sERC+ cycles was conducted between 2014 and 2018. Study 1: PN size and behaviour at fertilisation, direct cleavage rate in 1st cytokinesis (DC-1), morphokinetics during embryo development, and blastocyst utilisation rates were compared between sERC+ and, sERC- oocytes obtained from sERC- cycle. Study 2: Live birth rates (LBRs) following SET were compared between sERC+ and, sERC- oocytes from sERC- cycle.

Participants/materials, setting, methods: Oocytes were inseminated by ICSI and were cultured in either a dry incubator (ASTEC, Japan) or a time-lapse incubator (Vitrolife, Sweden). Morhpokinetics were analysed using EmbryoViwer (Vitrolife). Wilcoxon rank sum test and chi-square test were used to compare the PN size, DC-1 rate, and morphokinetics between sERC+ and sERC- oocytes. Chi-square test and multivariate logistic regression analysis were used to compare blastocyst utilisation and LBRs at >22 weeks of pregnancy between sERC+ and sERC- oocytes.

Main results and the role of chance: Study 1: The time (hours) required from insemination to PN appearance (male: 4.27±1.28 vs. 4.49±1.47, female: 5.10±1.43 vs. 5.30±1.55), PN alignment (7.90±2.51 vs. 8.65±2.95), PN fading (22.3±3.7 vs. 23.4±4.2), 2-cell (25.1±4.2 vs. 26.1±4.3), 3-cell (35.1±5.4 vs. 35.6±6.2), and 4-cell (37.4±6.9 vs. 38.0±6.5) stages was significantly faster in the sERC+ oocytes than in the sERC- oocytes ($P < 0.05$). The difference in PN size (between male and female) immediately before PN fading was significantly larger in the sERC+ oocytes than in the sERC- oocytes (105.5 ± 106.1μm^2 vs, 72.8 ± 67.2μm^2, $P < 0.05$). However, there were no significant differences in DC-1 rates and the time from insemination to reaching the 5-cell, 8-cell, blastulation, and expanding blastocyst stages between sERC+ and sERC- oocytes. No correlation was observed between sERC+ status and blastocyst utilisation rate [sERC+ oocyes: 46.2%, 96/209, sERC- oocytes: 48.7%, 2,111/4,331, adjusted odds ratio: 1.01, 95% confidence interval (CI): 0.75-1.35]. Study 2: The LBRs following SET in sERC+ and sERC- oocytes were 21.7% (10/46) and 18.6% (546/2942), respectively. There was no significant correlation between the sERC+ status and LBR (adjusted odds ratio: 1.35, 95%CI: 0.79-2.42). Furthermore, all of the babies derived from sERC+ oocytes were healthy.

Limitations, reasons for caution: The retrospective design and small sample size are the major limitations. The rate of sERC+ oocytes was very low during the study period. Therefore, these were the only cases we could identify. Further studies are needed to explore the mechanism by which sERCs influence PN behaviour and morphokinetics.

Wider implications of the findings: Our results demonstrated that sERC did not adversely affect embryonic and pregnancy outcomes. Therefore, it was suggested that sERC+ oocytes could be used for IVF treatment. We also found that sERCs correlated with PN behaviour and morphokinetics in early-cleavage stage. Further detailed investigations are required to confirm these findings.

Trial registration number: not applocable

SELECTED ORAL COMMUNICATIONS

SESSION 18: CELLULAR AND MOLECULAR MARKERS OF OVARIAN AGEING

06 July 2020 Parallel 2 15:15 - 16:35

O-068 Which accumulation is better in poor ovarian responders stratified by POSEIDON, egg or blastocyst?

T.H. Chuang[1], J.Y. Hsieh[1], C.T. Kuo[1], M.J. Lee[1], H.L. Wang[1], H.H. Lai[1]

[1]Stork Ladies Clinic, Stork Fertility Center, Hsinchu, Taiwan R.O.C.

Study question: Which accumulation is better in poor ovarian responders stratified by POSEIDON, egg or blastocyst?

Summary answer: Both egg accumulation or blastocyst accumulation achieve comparable clinical outcomes in poor ovarian responders.

What is known already: The patients have poor responses to ovarian stimulation (POR) generally resulted in low quantity of retrieved oocytes, fewer available embryos, and thus reduced pregnancy rate. Attributing to the improvement of the vitrification technique in human eggs and embryos, accumulation of eggs/embryos becomes an effective and safe way to increase the number of available embryos and the opportunity of a successful pregnancy.

Study design, size, duration: In this retrospective study, 955 oocyte pick-up (OPU) cycles were involved from January 2017 to October 2019, consisting of 409 cycles from 110 patients with egg accumulation (EAc) and 546 cycles from 172 patients with blastocyst accumulation (BAc). The definition of POR was based on the POSEIDON criteria (Humaidan et al., 2016). These patients decided to undergo one of the accumulative strategies by themselves after consulting their doctors about the pros and cons.

Participants/materials, setting, methods: The inclusion criteria of patients were age ≥35 years, AMH <1.2 ng/mL, and retrieving more than one oocyte in each OPU cycle. The metaphase II (MII) oocytes were cryopreserved in the EAc group, and the blastocysts grading above BC according to Gardner system were cryopreserved in the BAc group via vitrification (Cryotech®, Japan). The clinical outcomes were calculated in the patients underwent frozen-thawed blastocyst transfer.

Main results and the role of chance: The mean retrieved MII oocytes per case (EAc: 8.2±4.2, BAc: 7.4±6.2, $p<0.05$) and the mean obtained blastocyst per case (EAc: 3.3±2.6, BAc: 2.9±2.6, $p<0.05$) were significantly higher in the EAc group. In contrast, significantly higher fertilization rate (EAc 71.7%, BAc: 76.0%, $p=0.03$) was observed in the BAc group. No difference was found in good blastocyst formation rate (EAc: 50.3%, BAc: 51.2%, $p=0.73$) between the two groups. Of reproductive outcomes, the biochemical pregnancy rate (BPR), clinical

pregnancy rate (CPR), and implantation rate (IR) between the EAc and the BAc groups were comparable: [BPR] 52.9% vs. 58.1% (p=0.60); [CPR] 37.1% vs. 27.9% (p=0.29); [IR] 22.0% vs. 26.0% (p=0.53). Of PGT-A transfer cycles, there was no significant difference between the two groups. ([IR] 40.0% vs. 37.7%, p=1.0)
Limitations, reasons for caution: The retrospective nature is the main limitation of this study.
Wider implications of the findings: Though the laboratory outcomes showed differences between the patients with embryo and egg accumulation, the clinical outcomes of cryotransfer displayed comparable in the two populations.
Trial registration number: not applicable

O-069 Human ovarian ageing can be caused by Reactive Oxygen Species (ROS)-induced damage in primordial follicles

M. Smits[1], R. Wüst[2], F. Dijk[3], S. Dorrestein[1], M. Kleijn[1], M. Goddijn[1], R. Houtkooper[4], S. Mastenbroek[1], G. Hamer[1]

[1]Amsterdam UMC- University of Amsterdam, Center for Reproductive Medicine, Amsterdam, The Netherlands ;
[2]VU University, Department of Human Movement Sciences, Amsterdam, The Netherlands ;
[3]Amsterdam UMC- University of Amsterdam, Pathology, Amsterdam, The Netherlands ;
[4]Amsterdam UMC- University of Amsterdam, Laboratory Genetic Metabolic Diseases, Amsterdam, The Netherlands

Study question: Can ovarian ageing be caused by life-long oxidative phosphorylation, and therefore reactive oxygen species exposure, in oocytes and granulosa cells?
Summary answer: Oxidative phosphorylation, and reactive oxygen species (ROS)-induced damage, are visible during all stages of folliculogenesis, suggesting life-long ROS-exposure could indeed contribute to ovarian ageing.
What is known already: Oocyte quality declines with increasing female age. The reason for this is unknown. Oogenesis mainly occurs before birth after which oocytes have to remain dormant in primordial follicles until they are ovulated, a process that may take decades. Damage caused by ROS released from mitochondria during oxidative phosphorylation might be involved in the decline in oocyte quality. Although based on little experimental evidence, the current thinking is that, to prevent generation of ROS, primordial follicles only use glycolysis for energy supply. We have now assessed mitochondrial activity and ROS-induced damage in oocytes and granulosa cells throughout all stages of folliculogenesis.
Study design, size, duration: Using the Dutch Pathology Registry (PALGA), we collected ovarian biopsies stored in the Netherlands between 1991 and 2018. Biopsies were excluded in case of ovarian malignancies, polycystic ovarian syndrome or preventive resection due to *BRCA* mutation carrier. In total, 39 ovarian biopsies of individual patients, ranging in age from 18 to 45 years were received, of which 34 contained at least one follicle.
Participants/materials, setting, methods: Ovarian biopsies were used for high resolution microscopic analysis of mitochondrial structure, activity and ROS-induced damage to proteins, lipids and DNA. Antibodies used were: TOMM20, anti-phosphorylated pyruvate dehydrogenase (PDHA), anti-3-Nitrotyrosin, anti-4-Hydroxynonenal and anti-8-Hydroxy-2'-deoxyguanosine. Deconvoluted Z-stack images of follicles at different developmental stages were taken on a Leica SP8 fluorescence microscope, and analyzed by Leica Application Suite X. IBM SPSS Statistics 25.0 was used for statistical analysis.
Main results and the role of chance: For the first time, we showed phosphorylated pyruvate dehydrogenase activity in oocytes and granulosa cells in all stages of follicular development: from primordial follicles to tertiary follicles. This indicates that pyruvate is actively converted into acetyl-CoA, and transported into the citric acid cycle, rather than used for glycolysis. We observed ROS-induced cellular damage in oocytes of primordial follicles, in women of all reproductive ages. No age-related differences in immunofluorescence intensity ratios between mitochondria (TOMM20 antibody intensity) and mitochondrial activity (phosphorylated PDHA antibody intensity) were observed. But ROS-induced damage in lipids and proteins seemed to show an increasing trend with age, although not statistically significant. The accumulation of ROS damage could impair oocyte quality, leading to decreased chances of becoming pregnant, and increased chances of pregnancy loss as seen in women of advanced maternal age.
Limitations, reasons for caution: Oxidative phosphorylation and ROS damage were demonstrated in all stages of follicle development, but sample size, in combination with the microscopy techniques used, limited our statistical analyses based on maternal age groups.
Wider implications of the findings: We demonstrated that oocytes and granulosa cells at all stages of folliculogenesis have active mitochondria and generate ROS, contributing to protein and lipid damage, which can accumulate during ageing. Future studies on the contribution of oxidative phosphorylation to the decline in fertility of women of advanced maternal age seem warranted.
Trial registration number: not applicable

O-070 Serum dehydroepiandrosterone sulphate (DHEA-S) concentration is a predictive factor for clinical pregnancy in women with poor ovarian response undergoing in vitro fertilization (IVF)

A. Fuentes[1], K. Sequeira[1], A. Muñoz[1], A. Tapia-Pizarro[1]

[1]IDIMI - Hospital San Borja Facultad de Medicina- Universidad de Chile, Reproduccion Humana, Santiago- RM, Chile

Study question: Is it possible to predict clinical pregnancy rate (CPR) in women with poor ovarian response (POR) undergoing IVF?
Summary answer: Serum Dehydroepiandosterone sulfate (DHEA-S) concentration showed to predict clinical pregnancy in women with POR undergoing IVF
What is known already: Serum DHEA-S levels have been shown to decrease with age. In parallel, the probability of pregnancy also decreases. The purpose of this study was to identify a minimum serum DHEA-S level that correlates with acceptable CPR in women with POR undergoing IVF
Study design, size, duration: Prospective cohort study involving 70 women followed at the tertiary referral center, IDIMI, Universidad de Chile, from 2017-2018
Participants/materials, setting, methods: A cohort of women with POR (n = 50) and a control group (n = 20) undergoing IVF were studied. Serum levels of DHEA-S, AMH, FSH, estradiol as well as Antral follicle count (AFC) on day 3 of ovarian stimulation were assessed. DHEA-S concentrations in follicular fluid at the time of oocyte pick-up were also measured. Clinical pregnancy outcomes were correlated with the assesed parameters. Correlations and ROC analyses were perfomed to predict clinical pregnancy
Main results and the role of chance: There was no difference between the two groups in day 3 FSH and estradiol. Mean age and duration of ovarian stimulation were significantly higher in women with POR than controls (35.7±0.55 *vs.* 32.84±1,19 and 11.28±0.27 *vs.* 10.31±0.36 respectively) while day 3 AFC, Serum DHEA-S, Follicle-to-Oocyte Index (FOI) and serum AMH concentrations were significantly lower in the POR group than control (6±0.36 *vs.* 12.47±1.73, 160.57±12.52 *vs.* 218. ±25.30, 0.59±0.66 *vs.* 1.42±0.22, and 0.76±0.14 *vs.* 2.50±0.72; respectively). Serum DHEA-S concentration strongly correlated with those in follicular fluid (Pearson index = 87.5%). The ROC analysis for DHEA-S *vs.* pregnancy showed an area under the curve of 81.1% with a sensitivity of 87.5% and a specificity of 80.3 % with a cutoff value of 221.4 µg/dL
Limitations, reasons for caution: This prospective pilot study significantly implicates endogenously circulating levels of DHEA-S in the clinical pregnancy rates. Although our study has a power of 81%, more systematic studies/RCTs with larger sample size are required to confirm circulating DHEA-S levels as an efficient and robust predictor of clinical pregnancy rates
Wider implications of the findings: This study underlines the significance of optimum levels of endogenous DHEA-S for successful implantation. Our results suggest that the so called adrenopause of any origin seems to be associated with poor results in IVF. This information can be crucial during the pre-IVF counseling of these women
Trial registration number: not applicable

O-071 Longevity pathways are involved in human ovarian ageing

G. Janssens[1], M. Smits[2], M. Goddijn[2], G. Hamer[2], R. Houtkooper[1], S. Mastenbroek[2]

[1]Amsterdam UMC- University of Amsterdam, Laboratory Genetic Metabolic Diseases, Amsterdam, The Netherlands ;
[2]Amsterdam UMC- University of Amsterdam, Center for Reproductive Medicine, Amsterdam, The Netherlands

Study question: Are gene expression pathways known to be involved in general aging, particularly longevity pathways, also involved in human ovarian ageing?
Summary answer: Growth, metabolism, and cell cycle progression related pathways that are known to be involved in general ageing appear to play a role in ovarian ageing.
What is known already: Oocyte quality declines with advancing maternal age, a process generally referred to as ovarian ageing. Genetic pathways that modulate the rate of general, somatic cell, ageing have been researched intensively. Pro-longevity genes slow down the process of ageing and increase life span, while anti-longevity genes accelerate ageing and therefore decrease life span. Ovarian ageing does not follow the same time line as general ageing. It is not known whether generally recognized longevity genes also play a role during ovarian ageing. Identification of ovarian ageing pathways can lead to new hypotheses and possible treatment options for subfertility caused by ovarian ageing.
Study design, size, duration: We analyzed a dataset of individual gene expression profiles of 38 Germinal Vesicle (GV) oocytes of 38 women aged between 25 and 43 years old. Correlations between female age (calendar age and biological age, i.e. dosage of follicle stimulating hormones, antral follicle count (AFC)) and longevity pathways were investigated using a database of known longevity pathways.
Participants/materials, setting, methods: Transcripts of 38 GV oocytes were used for individual gene expression analysis. R version 3.5.1 was used to process and analyze data. GeneAge database build 19 was used to obtain mouse ageing related genes. Human to mouse orthologs were obtained using the R package biomaRt. Correlations and significance between gene expression data and ages was tested for using Pearson's product moment correlation coefficient using ranked expression data. Distributions were compared using a two-sample Student's t-tests.
Main results and the role of chance: 46 anti-longevity genes showed a positive correlation with female calendar age and FSH dosage administered during ICSI treatment and a negative correlation with AFC. 84 pro-longevity genes were negatively correlated with calendar age and FSH dosage, while positively correlating with AFC.

In general, pro- and anti-longevity genes changed in opposing directions with advancing maternal age in oocytes in a manner that, in somatic cells, represents ageing and a limited life span, and in oocytes could reflect the potential or the quality of the oocyte.

Notably, the anti-longevity genes include many 'growth' related genes involved in the MTOR pathway, such as *EIF5A2*, *EIF3H*, *EIF4E*, and *MTOR*. The pro-longevity genes include many cell cycle progression related genes involved in DNA damage repair (e.g. *XRCC6, ERCC2,* and *MSH2*) or cell cycle checkpoint regulation (e.g. *ATM*, *BRCA1*, *TP53*, *TP63, TP73* and *BUB1B*).
Limitations, reasons for caution: Using mature oocytes instead of GV oocytes may potentially provide different results. No correction for multiple testing was carried out because a small set of longevity related genes were selected a priori for the analysis.
Wider implications of the findings: Growth, metabolism, and cell cycle progression related pathways that are known to be involved in general ageing appear to play a role in ovarian ageing. We suggest that interventions known to modulate these processes could benefit women suffering from ovarian ageing.
Trial registration number: not applicable

O-072 Investigating apoptotic, inflammatory and growth markers in the follicular fluid of poor responders undergoing natural cycle IVF treatment

N. Nitsos[1], K. Sfakianoudis[2], P. Tsioulou[3], A. Glava[3], E. Maziotis[3], P. Giannelou[3], S. Grigoriadis[3], A. Rapani[3], A. Nezos[3], K. Pantos[2], M. Koutsilieris[3], N. Vlahos[4], G. Mastorakos[5], M. Simopoulou[3]

[1]Genesis Athens Clinic, Microbiology Laboratory, Athens, Greece ; [2]Genesis Athens Clinic, Assisted Conception Unit, Athens, Greece ; [3]National and Kapodistrian University of Athens, Physiology, Athens, Greece ; [4]Aretaieion Hospital- Medical School- National and Kapodistrian University of Athens, Second Department of Obstetrics and Gynecology, Athens, Greece ; [5]Aretaieion Hospital- Medical School- National and Kapodistrian University of Athens, Unit of Endocrinology- Diabetes Melitus and Metabolism- 2nd Department of Obstetrics and Gynecology- Aretaieion Hospital- Medical School- National and Kapodistrian Uni,

Study question: Do poor responders present with different levels of cfDNA concentration and integrity, as well different levels of inflammatory and growth markers in follicular fluid?
Summary answer: Poor responders present with similar cfDNA levels and integrity, compared to normal responders in natural cycles, albeit with lower follicular fluid levels of G-CSF.
What is known already: Embryo developmental potential is associated with oocyte quality and maturation status. Follicular fluid includes a wide pallet of hormones, growth factors and members of the Transforming Growth Factor-beta superfamily, interleukins, cytokines, reactive oxygen species, anti-apoptotic factors, peptides, amino-acids, sugars, and prostanoids, in conjunction with circulating cell-free DNA. These markers observed in follicular fluid affect the ovarian folliculogenesis process, and subsequent embryo development and pregnancy outcome. A better understanding of the pathophysiological processes involved in poor ovarian response (POR) is of added value.
Study design, size, duration: A total of 88 patients undergoing IVF, were enrolled in this prospective single-center observational study, from September 2018 to July 2019. Forty-four of these patients were identified as poor responders according to Bologna Criteria, whereas the remaining 44 were classified as normal responders. All patients underwent natural cycles with fresh embryo transfers. Clinical pregnancy was similarly recorded.
Participants/materials, setting, methods: Follicular fluid was collected as part of the oocyte retrieval process. Levels of cfDNA were quantified via Q-PCR employing the ALU115 and ALU247 primers, associated with necrotic and apoptotic and necrotic events respectively. The Q247/Q115 ratio represents cfDNA integrity. Follicular fluid levels of inflammatory markers-Interleukin-15 (IL-15) and Corticotropin-Releasing Hormone (CRH)- and of growth factors – Insulin-like Growth Factor 1 (IGF-1), Vascular Endothelial Growth Factor (VEGF) and Granulocyte Colony-Stimulating Factor (G-CSF) were evaluated via ELISA.
Main results and the role of chance: In the normal responders group a positive correlation between CRH and IL-15 was established ($p<0.001$), as well as between G-CSF and progesterone ($p=0.03$). A negative correlation between E2 and cfDNA integrity was also observed ($p=0.005$). In the poor responders group a positive correlation was established between VEGF and ALU 115 ($p=0.006$) as well as ALU 247 ($p=0.01$). Negative correlation was established between VEGF and FSH ($p=0.02$). IGF-1 was negatively correlated with AMH ($p=0.04$) and CRH ($p=0.008$). A positive correlation CRH and IL-15 was also observed ($p=0.005$). Between the two groups no statistically significant difference was observed regarding the levels of IL-15, CRH, IGF-1 or VEGF. The levels of G-CSF were statistically significant higher in the normal responders' group when compared to the poor responders' group ($p=0.003$). No statistically significant difference was observed between the groups regarding cfDNA concentration or cfDNA integrity. Cycles that resulted in clinical pregnancy presented with a lower cfDNA integrity compared to the cycles not leading to clinical pregnancy both in the normal and in the poor responders' group (Normal: 0.07±0.04 vs 0.25±0.17, $p<0.001$; Poor: 0.10±0.06vs0.26±0.12 $p<0.001$ respectively). Cycles with successful blastocyst formation presented with higher cfDNA levels in the normal responders' group (0.38±0.26vs0.82±0.66 $p=0.03$).
Limitations, reasons for caution: Limitations of our study refer to the limited size of the studied population, as well as lack of data referring to the all-inclusive patients' history, namely body max index, exercise activity or smoking, which may be identified as possible sources affecting cfDNA levels.
Wider implications of the findings: Poor and normal responders present with similar levels of inflammatory, apoptotic or necrotic markers. Lower levels of G-CSF associated to poor responders indicate G-CSF's role in folliculogenesis/follicular maturation. Levels of cfDNA and integrity, correlated with clinical outcome, highlighting their role as possible biomarkers. A conclusive verdict requires larger studies.
Trial registration number: Not applicable

O-073 Transcriptome analysis of human granulosa cells after conventional controlled ovarian stimulation versus mild ovarian stimulation in poor ovarian responders

X.P. Liu[1], C.C. Zhou[1], J.J. Li[1], T.B. Wu[1], H.S. Mai[1], X.Y. Liang[1], R. Huang[1]

[1]Reproductive Medicine Center, 6th Affiliated Hospital-Sun Yat-sen University, Guangzhou, China

Study question: What is the difference on the transcriptome of human granulosa cells after mild ovarian stimulation and conventional controlled ovarian stimulation in poor responders?
Summary answer: Different stimulation protocols for poor responders induced alterations in the granulosa cells that may affect immune processes, cytokine interactions and the pathway of oocyte development.
What is known already: No consensus is available regarding the optimal decision between mild stimulation and conventional controlled ovarian stimulation (COS) protocols for poor responders. Currently, studies comparing the efficacy of COS versus mild stimulation have generally focused on clinical pregnancy outcomes. Until now, none of studies have discussed the impact of such two different stimulation regimens on the cellular physiology of follicular cells in poor responders. There is no referable evidence that based on follicular physiology to support which stimulation protocol is optimal for them.
Study design, size, duration: This is an experimental study which contained 48 poor responders according to Bologna criteria.
Participants/materials, setting, methods: Forty-eight patients who met the Bologna criteria of poor ovarian response were allocated into two groups as mild stimulation or COS. Twenty-seven patients allocated to the mild stimulation group, while 21 patients in the COS group. Granulosa cells are collected on the oocyte pick-up day, and RNA was extracted and sequenced using Illumina Hiseq technology. Some of the differently expression genes were validated by real-time quantitative PCR.
Main results and the role of chance: In summary, a total of 192 genes were up-regulated, and 233 genes were down-regulated, in the mild stimulation group compared with the conventional controlled stimulation group. Gene Ontology analysis and Kyoto Encyclopedia of Genes and Genomes analysis revealed that the differently expression genes between the two groups were mainly involved in cytokine-cytokine receptor interactions, TGF-beta signaling pathway, the biological function of regulation activity and immune response, which associated with the development of the follicle and the oocyte.
Limitations, reasons for caution: The sample size was relatively small in our study. There is a need for larger number of patients.
Wider implications of the findings: The two different ovarian stimulation protocols for poor responders cause dissimilar biological functions in granulosa cells, which have influence on the development of the oocytes and subsequent IVF outcome. Most importantly, our findings indicate that the mild ovarian stimulation may be more benefit to the competence of the oocytes.
Trial registration number: not applicable

SESSION 19: RIF AND ENDOMETRIAL FACTORS: DOES IT MATTER?

06 July 2020 Parallel 3 15:15 - 16:30

O-074 Efficacy of endometrial microbiome metagenomic analysis and analysis of infectious chronic endometritis on in vitro fertilization outcome in women with recurrent implantation failure

N. Iwami[1], M. Kawamata[1], N. Ozawa[1], T. Yamamoto[1], E. Watanabe[1], M. Mizuuchi[1], O. Moriwaka[1], H. Kamiya[1]

[1]Kamiya Ladies Clinic, Center of reproduction, Sapporo, Japan

Study question: Following results of endometrial microbiome metagenomic analysis (EMMA) and analysis of infectious chronic endometritis (ALICE), is there an effect post treatment for the patients with recurrent implantation failure (RIF)?
Summary answer: The clinical pregnancy rate of the patients who underwent EMMA/ALICE testing was significantly higher than that of the patients who did not undergo testing.
What is known already: Chronic endometritis (CE) is persistent endometrial inflammation mainly caused by bacterial infections. CE is found in about 30% of infertile women, and 60% of patients with RIF, so pathogenic flora identification is the first step of treatment. Using next generation sequencing (NGS) technology, EMMA/ALICE testing can determine the composition of the endometrial microbiome by analysing bacterial 16S ribosomal RNA with a focus on *Lactobacillus* population. *Lactobacillus*-dominated microbiota (LDM, defined as >90% *Lactobacillus* species) in the endometrium was reported to be associated with favorable reproductive outcome, while non-LDM (<90% *Lactobacillus* species) was found to decrease implantation, clinical pregnancy, and ongoing pregnancy.
Study design, size, duration: The prospective cohort study consisted of 134 women with RIF (defined as at least three previous failed *in vitro* fertilization (IVF)-embryo transfer (ET) attempts) from July in 2018 to October in 2019 at our infertility center. EMMA/ALICE testing were suggested to all patients who had failed ET three times or more. Ninety-eight patients underwent EMMA/ALICE (Study group) before additional transfer, 36 patients with history of RIF continued ET without both examinations (Control group).
Participants/materials, setting, methods: During the patients' luteal phase, endometrial biopsies were performed for EMMA/ALICE testing, and treatment was given based on the results. The primary outcome measure was the cumulative clinical pregnancy rate after two additional ET. Clinical pregnancy was defined by visualization of a gestational sac. Statistical analysis was performed using unpaired t-test and chi-square contingency.
Main results and the role of chance: Patients characteristics such as age, body mass index, duration of infertility, and anti-mullerian hormone (AMH) were comparable between the groups. The mean number of unsuccessful implantations were comparable between the groups (Study group: 5.33±3.03 vs. Control group: 5.22±2.60, P=0.841). The rate of the patients with the history of miscarriage was significantly higher in Study group than that of Control group (Study group: 48.0% vs. Control group: 19.4%, p<0.010). According to the results of EMMA, 44 patients (44.9%) with normal microbiota (LDM) didn't receive probiotic treatment. The other 54 patients (55.1%) received probiotic therapies. In addition, among non-LDM patients, abnormal microbiota was detected in 14 patients (14.3%) in EMMA, and ALICE detected significant amounts of pathogenic bacteria in other 6 patients. Those 20 patients had antibiotics corresponding to the detected bacteria as well as probiotic treatment. As results, the cumulative clinical pregnancy rate in Study group was significantly higher than in Control group (Study group: 54.1% vs. Control group: 27.8%, p<0.010). However, there was no significant difference in the ongoing pregnancy rate (Study group: 44.9% vs. Control group: 27.9%, p=0.073) and the miscarriage rate (Study group: 15% {8/53 cases} vs. Control group: 0% {0/10 cases}, p=0.332).
Limitations, reasons for caution: The main limitation of our study is the lack of randomization, although it is prospective. As the sample size is small, further prospective studies are needed to confirm the efficacy of EMMA/ALICE.
Wider implications of the findings: Dysbiotic microbiota could be found in patients more than half using the NGS technique. Personalized treatment recommendations based on the EMMA/ALICE results can improve IVF outcome of RIF and repeated pregnancy loss. Moreover, broad-spectrum antibiotics treatments can be avoided, reducing the physical and economic burdens on patients.
Trial registration number: Not applicable

O-075 Composition of the endometrial microbiome is associated to reproductive outcomes in IVF patients

I. Moreno[1], I. Garcia-grau[2], D. Bau[3], D. Perez-Vilarrolla[3], M. Gonzalez-Monfort[2], D. Valbuena[4], F. Vilella[5], C. Simon[6]

[1]Igenomix, Research, Boston, U.S.A. ;

[3]Igenomix, Bioinformatics Department, Valencia, Spain ;
[4]Igenomix, Clinical Department, Valencia, Spain ;
[5]Igenomix Foundation / INCLIVA, Research Department, Valencia, Spain ;
[6]Valencia University- Harvard University, Department of Obstetrics and Gynecology, Valencia- Boston, Spain

Study question: Is there an association between the composition of the endometrial microbiota and the reproductive outcomes in infertile patients undergoing in vitro fertilization (IVF)?
Summary answer: The composition of the endometrial microbiota investigated the cycle prior to embryo transfer differs between patients with successful versus unsuccessful clinical outcome.
What is known already: The investigation of bacterial communities in the female reproductive tract using molecular methods has revealed the existence of a continuum microbiota that extends from the vagina to the upper genital

tract. Despite similarities between vaginal and uterine microbiota, the endometrial and vaginal microbiota are different in 20% of patients. The analysis of bacterial composition in endometrial microbiota during the window of implantation has shown an association of absence of pathogens and high abundance of Lactobacilli with IVF success, while the presence of pathogenic bacteria -non-Lactobacilli dominated microbiota-, is associated with poor reproductive outcomes in assisted reproductive treatments (ART).

Study design, size, duration: This is a prospective observational multicenter study including a total 452 patients. The study was performed in 13 reproductive centres located in Europe, North America, South America and Asia. The duration of the study was 30 months and the recruitment period extended for 1.5 years starting from August 4, 2017.

Participants/materials, setting, methods: Patients undergoing IVF receiving personalized embryo transfer with frozen blastocysts in a hormonal replacement therapy in whom endometrial fluid was collected at the time of the ERA test the cycle prior to embryo transfer. Taxonomic data were generated by sequencing of the 16S rRNA gene using the Ion 16S metagenomics kit (Thermofisher) and analysed using compositional data to transform scale-invariant values and avoid bias derived of technical different between batches.

Main results and the role of chance: The interim analysis in 177 patients with different clinical outcomes including no pregnancy, (n=82), ongoing pregnancy + live birth (n=69), biochemical pregnancy (n=10), or clinical miscarriage (n=16) revealed differential compositional data of the endometrial microbiota collected in the cycle prior to the embryo transfer. Based on the analysis of bacterial genera with an abundance >2-fold that the average, 29 specific taxa were identified to discriminate between the microbiota profile of women who did not become pregnant and those whose transfers resulted in live births. When the compositional data were interrogated for taxa with >2-fold abundance and filtering from those genera most differentially represented between these two categories, *Citrobacter, Haemophilus, Kocuria, Gemella, Enterococcus, Gardnerella, Atopobium* and *Aeromonas* were differentially identified discriminating between the successful or unsuccessful outcome groups. Patients that did not become pregnant presented higher abundance of *Enterococcus* and *Haemophilus*; patients with biochemical pregnancies presented increased abundance of *Enterococcus, Gardnerella, Haemophilus* and *Kocuria;* while patients suffering clinical miscarriages presented higher abundance of *Enterococcus.* The confounding factors analysed to ruled out any bias of the reported results were body mass index, age of patient, endometrial receptivity analysis (ERA) results and preimplantation genetic diagnosis of embryos.

Limitations, reasons for caution: These are interim results from 177 out of 452 patients recruited. Because the endpoint of the study was live birth, final results will only be complete when all the babies will be born.

Wider implications of the findings: The differential endometrial microbiota composition associated to different clinical outcomes in patients undergoing IVF might have profound implications for understanding the microbiology of intrauterine environment and its implication in unknown causes of infertility and implantation failure.

Trial registration number: 03330444

O-076 Twelve-month follow-up results of a randomized controlled trial studying endometrial scratching in women with one failed IVF/ICSI cycle (the SCRaTCH trial)

Pieterse, ; Haaglanden Medical Centre, Ms. S. van der Meer,

Study question: Does mid-luteal endometrial scratching prior to the 2nd stimulation cycle increase live birth rates (LBR) in women with one failed IVF/ICSI cycle?

Summary answer: During follow-up, non-significant 4.0-4.7% increases in LBRs were observed for women that underwent scratching. These differences should be further explored as to their clinical significance.

What is known already: Previous trials on endometrial scratching have been reported to have methodological limitations and high risk of bias making it unclear whether this procedure improves pregnancy rates. Even the recent large PIP trial suffers from the fact that a very heterogeneous study population was included and the timing of scratching was not standardized. Moreover, previous trials only reported the results of a single transfer following randomization. An RCT in a more homogeneous population which standardizes timing and method of scratching, and with a follow-up of 12 months may provide the best information on the effectiveness of scratching.

Study design, size, duration: A multicenter, non-blinded, randomized controlled trial was conducted between January 2016 and July 2018 in the Netherlands. Women were allocated 1:1 to endometrial scratching or no intervention, using a web-based system that ensured allocation concealment. Using an expected difference in LBR after the IVF/ICSI cycle following randomization of 9% (39% vs. 30%, respectively), the sample size was set at 900 participants (80% power and two-sided alpha of 0.05).

Participants/materials, setting, methods: Participants with a failed first IVF/ICSI cycle (≥1 embryo transfer) were eligible. Endometrial scratching was performed using an endometrial biopsy catheter in the mid-luteal phase prior to ovarian stimulation. The primary outcome was LBR from the fresh embryo transfer post-randomization; secondary outcomes included cumulative pregnancy outcomes up to ongoing pregnancy (OP) (achieved within 12 months after randomization) leading to LB. This abstract reports the complete case results for the primary and secondary 12-month follow-up outcomes.

Main results and the role of chance: In total, 936 women were included (468 scratch/468 control). Baseline and infertility characteristics were comparable between the groups. The participation rate was 89% (936/1054 eligibles). A conservative approach was used, in which participants who were lost-to-follow-up were assumed not to have conceived.

The LBR after the post-randomization treatment (i.e. 2nd cycle) was 22.6% in the scratch and 18.6% in the control group (RR 1.21 [95%CI 0.94-1.56]) with a corresponding absolute risk difference (ARD) of 4.0% [95%CI -1.2% to +9.2%]. For the 12-month follow-up, the cumulative LBR was 42.1% vs. 37.4% (RR 1.13 [95%CI 0.96-1.32]) with a corresponding ARD of 4.7% [95%CI -1.7% to +11.1%].

Important strengths include the fairly homogeneous study population, standardized scratching method, 12-month follow-up period, large sample size and high participation rate. The 12-month follow-up period is unique and offers the possibility to study longer-term effects of endometrial scratching. The high participation rate is probably due to the fact that endometrial scratching is not offered as part of clinical care in the Netherlands. This decreases the risk for selection bias and improves the inference for the effect of endometrial scratching for daily practice.

Limitations, reasons for caution: This analysis was based on complete data from 97-99% of the participants, which means the final results (available March 2020) may differ slightly. Despite this high percentage of complete data, complete case analysis reduces precision and may introduce bias. Therefore, in the final dataset residual missing data will be imputed.

Wider implications of the findings: Twelve-month follow-up results showed that a non-significant LBR improvement of 4.0% after the post-randomization treatment in the scratch group is maintained, resulting in a non-significant 4.7% improvement after 12 months. Further analyses in this dataset and an international individual participant data-analysis (IPD) will focus on understanding these findings.

Trial registration number: This trial was prospectively registered in the Dutch Trial Register (Nederlands Trial Register) under number 'NL5193' (old number: 'NTR 5342')

O-077 Ovarian stimulation alters the cervical microbiota

S. Mackens[1], S. Vieira-Silva[2], S. Santos-Ribeiro[3], J. Centelles-Lodeiro[2], A. Racca[1], G. Falony[2], R. Tito[2], H. Tournaye[1], J. Raes[2], C. Blockeel[1]

[1]UZ Brussel, Centre for Reproductive Medicine, Brussel, Belgium ;
[2]Vlaams Instituut voor Biotechnologie VIB - KU Leuven, Center for Microbiology, Leuven, Belgium ;
[3]IVI RMA Lisbon, Reproductive Medicine, Lisbon, Portugal

Study question: Does ovarian stimulation (OS) have an impact on cervical microbiota composition and diversity?
Summary answer: OS significantly influences the cervical microbiota composition and increases its diversity.
What is known already: Disturbances of the female genital microbiota are associated with female sexual health complications such as an increased risk for sexually transmitted infections and with obstetrical complications such as preterm delivery. Recently, it has been suggested that women undergoing IVF/ICSI are particularly prone to genital dysbiosis and that an abnormal microbiota composition and an increased species diversity might affect post-treatment pregnancy rates. However, before introducing reproductive tract microbiota analyses in clinical practice to predict IVF/ICSI outcome, confounders need to be investigated more thorough. For example, the impact of OS remains to be elucidated.
Study design, size, duration: This analysis was part of a prospective observational cohort study investigating the potential effect of the female reproductive tract microbiota on IVF/ICSI outcomes and included 106 women each providing two samples between 2016 and 2019. Samples from the cervical microbiota were collected by swabbing at two different timepoints: prior to OS (baseline) and at the moment of oocyte retrieval (post-OS).
Participants/materials, setting, methods: Caucasian women, aged <40y, planned for a first or second IVF/ICSI cycle performing OS in an antagonist protocol followed by fresh single blastocyst transfer were included. Cervical microbiota samples were retrieved by swabbing, flash-frozen in liquid nitrogen and stored at -80°C. Microbiota profiles were obtained by amplicon sequencing (16SrRNA V4) using the gold-standard DADA2 pipeline. Correlations to microbiota profiles were performed by constrained principal coordinates analysis at genus level (cPCoA with Aitchinson distance).
Main results and the role of chance: OS led to a significant shift in cervical microbiota (n=106x2, paired cPCoA, R^2=0.006, p=0.016). Also, microbial diversity significantly increased during OS (n=106x2, paired t-test, t-ratio=4.80, p=5.4E-6). We evaluated whether the menstrual cycle phase at the moment of baseline sampling confounded this association between OS and the shift in diversity and observed that, in our dataset, this was not correlated (Kruskal-Wallis, p=0.72). The cervical microbiota profiles were typed into 4 different community-types (CTs), two of them having the characteristic dysbiotic high-species diversity. Focusing on 72 patients having achieved live birth (n=39) versus not having reached a +hCG (n=33) after a fresh embryo transfer, CTs were not significantly associated to outcome at both timepoints (Fisher's test, baseline p=0.63, post-OS p=0.27). However, CTs shifted significantly from baseline to post-OS (n=144, Fisher's test, p=0.03). In cervical microbial diversity, also no significant difference was observed between the two outcomes (live birth vs not pregnant), at baseline (n=72, Kruskal-Wallis, ES=0.16, p=0.18), nor after OS (n=72, Kruskal-Wallis, ES=0.13, p=0.28). However, an increase in diversity was confirmed for both outcome groups, with this increase being slightly higher for the negative outcome (n=33x2, paired t-test, t-Ratio=3.50, p=0.001) than for the live birth outcome (n=39x2, paired t-test, t-Ratio=3.11, p=0.004).
Limitations, reasons for caution: Human-associated microbial communities have a high inter-person variability and even with a reasonably scaled study of 106 women, statistical significance is difficult to reach. Caution is warranted as non-significant associations do not prove non-correlations.
Wider implications of the findings: Interest has increased in predicting IVF/ICSI outcome using reproductive tract microbiota analysis. The impact of potential confounders however needs to be assessed first. We found OS to be a significant driver of microbial compositional and diversity variation, labelling it as a potential confounder that deserves more attention in future research.
Trial registration number: NCT03105453

O-078 Uterine peristalsis during implantation period; experience of 4,800 patients with 3 or more failure of embryo transfers

H. Matsubayashi[1], K. Kitaya[1], K. Yamaguchi[1], Y. Ohara[2], M. Doshida[2], T. Takeuchi[2], T. Ishikawa[2]

[1]Reproduction Clinic Osaka, Obstetrics and Gynecology, Osaka, Japan ;
[2]Reproduction Clinic Tokyo, Obstetrics and Gynecology, Tokyo, Japan

Study question: Is uterine peristalsis frequently observed in patients with recurrent implantation failure?
Summary answer: Uterine peristalsis was frequently (47.2%) observed in patients with recurrent implantation failure mostly in the whole uterine cavity with "lower→upper→lower" direction.
What is known already: Uterine peristalsis caused by uterine contraction is thought to be one of the risk factor for implantation failure, because the uterus is quiescent at the time of implantation period.Previous studies suggested more than 2 or 3 waves/min may be a threshold for implantation failure. Although those reports focused on frequency and direction of the uterine contraction, there were no reports regarding intensity and location of the uterine contraction. Therefore, we investigated intensity and location as well as frequency and direction of the uterine contraction in the largest number of patients with recurrent failure of embryo transfers.
Study design, size, duration: Transvaginal ultrasonography scans of uterine peristalsis were performed at the mid luteal phase in 4,800 patients with 3 or more failure of embryo transfers in two clinics between 2013 and 2019. The transvaginal probe (6 to 10 MHz) was introduced into the vagina as gently as possible to avoid stimulating the uterine cervix. After scanning mid-sagittal plane of the uterus, the probe was fixed as steady as possible while 3 min, video was recorded simultaneously.
Participants/materials, setting, methods: The video images were analyzed at 10 time the normal speed using Quick Time Player by a single observer. Frequency, intensity, location and direction of the uterine contractile activity were recorded and evaluated. Intensity was divided into 3 categories; movement with the whole endometrium (strong), with the middle and the surface of the endometrium (medium), and just the surface of the endometrium (weak). Direction was complicated with many patterns (e.g., lower→upper→lower).
Main results and the role of chance: Of 4,800 patients (average age, 37.5), 2,534 (52.8%) did not show any uterine peristalsis, 2,266 (47.2%) had uterine peristalsis. In the peristalsis group, frequency was 57.1% for 1 to 3 (times/3 min), 28.6% for 4 to 6, 10.7% for 7 to 9, and 3.7% for 10 or more. Intensity was almost equal among 3 categories (strong 30.4%, medium 38.8%, weak 30.8%). Most uterine peristalsis was observed in the whole uterine cavity (82.8%), whereas those in the upper, middle and lower part of the uterus were 8.7%, 1.2% and 7.3%, respectively. In terms of direction, about half (52.1%) of uterine peristalsis was observed as "lower→upper→lower", followed by "upper→lower→upper" (15.8%), "lower→upper" (13.8%), "upper→lower" (13.3%), and unfocused (4.9%). Pregnancy outcome of patients (N=29) who had strong uterine peristalsis with 10 or more was retrospectively evaluated after taking piperidolate hydrochloride (150 mg/day). Patients with live birth or ongoing pregnancy with 28 weeks or more were 13 (44.8%), those with biochemical pregnancy or miscarriage were 7 (24.1%), and those without pregnancy were 9 (31.0%).
Limitations, reasons for caution: Since this is a retrospective observational study, a prospective randomized study is necessary to determine the cutoff value that should be treated for uterine peristalsis in patients with recurrent implantation failure.
Wider implications of the findings: These data suggest that uterine peristalsis was frequently (47.2%) observed in patients with recurrent implantation failure, mostly in the whole uterine cavity with direction as "lower→upper→lower". However, we have to determine the cutoff value that should be treated. Further studies will be required.

Study question: How do the rate and causes of aneuploidy within human oocytes change throughout the reproductive lifespan?
Summary answer: Distinct types of chromosomal errors drive aneuploidy in human oocytes in an age-dependent manner, thereby regulating reproductive capacity in young girls and older women.
What is known already: Aneuploidy affects an exceptionally high number of human conceptions, resulting in congenital disorders or pregnancy loss. Most focus has been on women of advanced maternal age by studying oocytes donated during fertility treatment. What is less appreciated is that aneuploidy rates in clinically-recognized pregnancies are also elevated in teenagers that are by default excluded from IVF based studies. We currently do not understand whether the elevation in teenagers is due to errors in oocytes, sperm, or embryonic mitoses. This study provides insight into the mechanisms behind the incidence of aneuploidy across the entire human reproductive lifespan.
Study design, size, duration: This is a multicenter study based on >3000 oocytes collected from 268 girls and women from two independent cohorts. Small antral follicles (cohort 1) were collected directly from ovarian tissue of unstimulated girls and women undergoing ovarian cortex cryopreservation prior to chemotherapy (9.1-38.8 years). Mature and immature oocytes (cohort 2) were collected from gonadotrophin-stimulated women being treated in *in-vitro* fertilization (IVF) clinics (20-43 years).
Participants/materials, setting, methods: Oocytes were obtained from women covering a majority of the reproductive lifespan (9-43 years) by *in-vitro* maturation of small antral follicles (cohort 1) or immature oocytes (cohort 2) to the mature meiosis II (MII) stage. The oocyte and polar body were isolated and underwent whole genome amplification, followed by both Next Generation Sequencing (NGS) and SNP array analysis. Chromosome segregation errors were identified by NGS based chromosome content.
Main results and the role of chance: The rate of chromosomal abnormalities in oocytes follows a U-shaped curve, suggesting that aneuploidies at both young and advanced ages are female in origin. Unexpectedly, specific segregation errors showed different age-dependencies, therefore providing a quantitative explanation for the U shape. Increased aneuploidy in young girls and women (<20) was preferentially associated with whole-chromosome non-disjunction (MI NDJ) events. Whereas women of advancing maternal age (≥33) showed centromeric or more extensive cohesion loss through premature separation of sister chromatids (PSSC) and reverse segregation (RS) events, respectively. These results were validated directly in human oocytes of two independent patient cohorts, as well as a third cohort of pre-implantation embryos.
Limitations, reasons for caution: None of our samples represent a completely 'normal' setting, due to either in-vitro maturation or hormone stimulation. However, the U-curve was reproducible in three independent datasets, including clinically relevant mature MII oocytes from gonadotrophin-stimulated women.
Wider implications of the findings: Our findings suggest that age-dependent chromosomal errors originating directly in oocytes may shape the curve of natural fertility in humans.
Trial registration number: not applicable

O-080 preimplantation genetic testing for aneuploidy: evaluation of age, indication and embryological parameters for detection of different types of aneuploidy

S. Ecemis[1], K. Boynukalin[2], M. Gultomruk[3], E. Turgut[4], M. Bahceci[4]

[1]Bahceci IVF Ankara Centre, Gynecology- Obstetrics and Infertility, Ankara, Turkey ;

[4]Bahceci IVF Fulya Centre, Gynecology- Obstetrics and Infertility, Istanbul, Turkey

Study question: Do any patient and embryo characteristics allow us to predict aneuploidy or the type of aneuploidy (single, double, segmental or complex)?
Summary answer: Female age was the sole significant factor affecting the ploidy status of the embryo. Clinical and embryological features did not reach to statistical significance.
What is known already: The correlation of morphology and morphokinetic parameters of embryos with embryo ploidy status have been evaluated in many studies. Still the evidence is scarce and correlation statement is moderate. The embryos those were generated from the same cohort of a patient might be affected by treatment related external factors in a same manner. The type of aneuploidy such as single (trisomy, monosomy, segmental), double (monosomy/monosomy, monosomy/trisomy, trisomy/trisomy, segmental/segmental, segmental/aneuploidy) or complex has not been studied in detail.
Study design, size, duration: This is a single center retrospective observational study performed between January 2016 and January 2019. The study includes the data analysis of 1793 blastocysts with conclusive comprehensive chromosome screening (CCS) by Next Generation Sequencing (NGS) of trophectoderm (TE) biopsies obtained from 591 patients. Female age under 35 years included in the study.
Participants/materials, setting, methods: PGT-A was offered to infertile couples with recurrent implantation failure(RIF) and repetitive miscarriages (RM), previous history of aneuploidy, severe male factor, and for patient anxiety. TE biopsy was performed on day 5 or day 6 to hatching blastocysts and Gardner classification was used as morphological grading. Correlations between patient, treatment and embryological parameters and euploidy status were tested in Generalized Linear Mixed Model using Binomial Distribution as Probability distribution.
Main results and the role of chance: The median female age of this patient population was 32 (30-33). Of the 1793 biopsied blastocysts, 800 were aneuploidy, 963 were euploid. Regarding the day of biopsy, the euploidy rate were significantly different between day 5 and day 6 biopsied embryos (830/1304(63.7%) vs 281/489(57.5%), p=0.016 respectively). Aneuploid blastocysts showed poor quality ICM [15.4%(105/682) vs 9.1%(101/1111); p<0.001] and TE [75%(512/682) vs 56.3%(626/1111); p<0.001]. The frequency of different abnormal chromosomal patterns as single, complex aneuploid and chaotic patterns were not related to the day of biopsy (p = 0.166) as well as to the ICM (p=0.12) and TE (p=0.89) score. We observed an increasing probability for aneuploidy with female age of 3% per year (p<0.015) even though the patient population was <35 years of age. No statistically significant relation was found between aneuploidy and the other clinical and laboratory findings.
Limitations, reasons for caution: The study is limited by its retrospective nature. Higher sample size or a prospective design within the morphokinetic parameters could be used in future studies to corroborate the current findings.

Wider implications of the findings: This study reports that conventional morphologic parameters are insufficient for predicting the euploid embryo and the type of aneuploidy. Also the patient characteristics other than female age are not predictive. infertility diagnosis or PGT-A indications does not characterize the ploidy status. Future research to identify non-invasive biomarkers should be performed.

Study question: Is the clinical outcome of mosaic embryos influenced by chromosomal constitution?
Summary answer: Reproductive potential of mosaic embryos is affected by the complexity of and the number of aneuploidy cells present in trophectoderm (TE) biopsy.
What is known already: Chromosomal mosaic embryos are characterized by the presence of chromosomally different cell lines within the same embryo. While the transfer of these embryos is now offered as an option for women who undergo in vitro fertilization (IVF), several concerns remain. For instance, the limited data on pregnancy outcome and the possibility that intra-biopsy mosaicism in the TE is a poor predictor of the ploidy status of the ICM. Therefore, some argue that mosaicism should be not reported until a clear classification of such embryos in relation with their reproductive potential has been defined.
Study design, size, duration: We collected the clinical outcomes of 822 mosaic embryos transferred in women underwent IVF between May 2016-May 2019. All embryos were cultured to blastocyst stage; trophectoderm (TE) biopsy was performed on Day-5 of development or Day6/7 for slow growing embryos. The clinical outcome obtained after transfer of mosaic embryos with different chromosomal constitution was compared with each other and with that obtained from a control group of 3781 euploid blastocysts.
Participants/materials, setting, methods: Preimplantation genetic testing (PGT) was performed using high resolution next generation sequencing (NGS) methodology. TE biopsies were classified as mosaic if they had 20%-80% abnormal cells. For statistical analysis mosaic embryos were divided in groups based on mosaic levels and chromosomal constitution detected in TE: single mosaic aneuploidy (monosomy/trisomy; SM), double mosaic chromosomes (monosomy/trisomy or combination, DM), complex mosaic aneuploidy (>2 different aneuploidies; CM) and mosaic segmental aneuploidy (single and double deletion/insertion >5Mb, MS).
Main results and the role of chance: The embryos were plotted in 10% increments, representing a progressive increase in the proportion of aneuploid cells in the TE, and linear regression showed a statistically significant decline in rates of implantation and ongoing pregnancy/birth (regression function with respective slopes -0.42 and -0.55, P=0.0381 and 0.0099). Regarding chromosomal constitution, MS had the best outcomes, followed by the group with one affected chromosome, followed by the group with two affected chromosomes, followed by the complex group (implantation P<0.0001, ongoing pregnancy/birth P<0.0001). MS showed a significantly poorer clinical outcomes compared to the euploid control group (implantation 51.3% vs 61.1%, P=0.0004; ongoing pregnancy/birth 42.6% vs 52.7%, P=0.0003).
Limitations, reasons for caution: Additional clinical data must be obtained to evaluate the contribution of each different chromosome before this approach can be evaluated as an additional tool to choose mosaic embryos for transfer.
Wider implications of the findings: The study provides the largest dataset of transferred mosaic embryo outcomes reported to date. This compiled analysis conclusively shows that embryos with different pattern of chromosomal mosaicism have a distinct set of clinical outcomes. This findings should be considered for genetic counseling.
Trial registration number: None

O-082 The application of more stringent parameters for mosaic classification in blastocysts-stage primplantation genetic testing for aneuploidies reduces false positive mosaic rates without comprising true detection

Study question: How do mosaic diagnostic thresholds setting affect the accuracy of Next Generation Sequencing (NGS)-based preimplantation genetic testing for aneuploidies (PGT-A)?
Summary answer: When single trophectoderm biopsy is tested, wide mosaicism thresholds (i.e.,20-80%) increase false positive calls compared to more stringent ones (i.e.,30-70%) without improving true detection rate.
What is known already: Highly sensitive NGS-based technologies for PGT-A allows precise identification of intermediate chromosome copy number alterations potentially associated to chromosomal mosaicism in trophectoderm biopsies. Nevertheless, differences in technical validation procedures and in detection thresholds employed for diagnostic calls could lead to incorrect classification of normal and abnormal embryos into the mosaic category. Overcalling mosaicism in trophectoderm biopsies lowers PGT-A accuracy, ultimately affecting patients treatment outcome from both a clinical and a psychological standpoint. In this study, we evaluated diagnostic predictivity of different mosaicism classification criteria by employing blinded analysis of chromosome copy number values (CNV) in multifocal blastocyst biopsies.
Study design, size, duration: The accuracy of different mosaicism diagnostic cut-offs was assessed comparing chromosomal CNV in intra-blastocysts multifocal biopsies. Enrolled embryos were donated for research between January and December 2019. The Institutional Review Board at the Near East University approved the study (project: YDUI20191170-849). Embryos showing euploid/aneuploid mosaicism in their clinical trophectoderm (TE) biopsy (n=36) and euploid embryos (n=23) were disaggregated into 5 portions: the inner cell mass (ICM) and 4 TE biopsies. Overall, 295 specimens were analysed.
Participants/materials, setting, methods: Fifty-nine donated blastocysts were warmed, allowed to re-expand and disaggregated in TE biopsies and ICM. PGT-A analysis was performed using Ion ReproSeq PGS kit and Ion S5 sequencer (ThermoFisher). Sequencing data were blindly analysed with Ion-Reporter software. Intra-blastocyst comparison of raw NGS data was performed employing different thresholds commonly used for mosaicism detection. CNV for each chromosome were reported as mosaic, according to 30-70% and 20-80% criteria. Categorical variables were compared using Fisher's exact test.
Main results and the role of chance: To minimize the impact of technical over biological variation, intermediate CNV were classified as confirmed mosaic according to the following criteria: 1) detection of the same mosaic alteration in at least 3 biopsies or in 1 additional biopsy over the 50% threshold, or 2) detection of a reciprocal mosaic pattern involving the same chromosome. If the same alteration was uniformly detected (>50%) in all biopsies, the embryo was classified as uniform aneuploid. When the high mosaicism threshold was considered (50-70%), the aneuploidy finding, mosaic or uniform, was confirmed in 82.5% of patterns (14/17; 95%CI=54.6-96.2). In particular, 35.3% of cases (6/17; 95%CI=3.0-16.8) were uniform aneuploid. For the low mosaicism category, 30-50%, putative mosaicism was confirmed in only 5.3% of the cases (3/57; 95%CI=1.10-14.62). When 20-50% threshold was applied, a significantly higher

number of false mosaic alterations were observed, and the confirmation rate dropped to 1.8% (n=3/168;95%CI=0.37-5.13; P<0.001). In particular, the inclusion of very-low mosaicism (20-30%) results only added false positive results but no true mosaic case (66.1%;n=111/168;95%CI=58.38-73.19;P<0.001). In the euploid embryos group, none of the results obtained in the 39 cases of 20-30% and in the 30-50% range were confirmed.

Limitations, reasons for caution: The study involved only blastocysts initially diagnosed as euploid or mosaic. Uniform aneuploid embryos were not evaluated at this stage. This approach involved the analysis of mosaicism thresholds at the embryo level and future studies will need to evaluate these criteria in relation to clinical predictive values following embryo transfers.

Wider implications of the findings: Based on an embryo re-biopsy model, single TE biopsy results showing low mosaicism, particularly the very-low range (20%-30%) shouldn't be considered as mosaicism diagnoses. The application of the lower stringency threshold for mosaic classification (i.e.,20%) leads to misclassification of embryos, increasing false positive calls and lowering accuracy of PGT-A analysis.

Trial registration number: N/A

O-083 Incidence of mosaic embryos in translocation carriers: Are translocation carriers more predisposed to generate mosaic embryos?

M. Cetinkaya[1], M.A. Tufekci[1], C. Cinar Yapan[1], S. Kahraman[1]

[1]Istanbul Memorial Hospital, Assisted Reproductive Technologies and Reproductive Genetics Center, Istanbul, Turkey

Study question: Is the mosaicism ratio influenced by the sex of the translocation carrier and the type of translocation in preimplantation genetic testing for structural rearrangements (PGT-SR)?

Summary answer: The mosaicism ratio is significantly higher in Robertsonian translocation carriers (RobTC) (7x) and in male translocation carriers (3x).

What is known already: Embryonic mosaicism is defined as the presence of karyotypically distinct cell lines within an embryo and can be detected with Next Generation Sequencing (NGS) at a 20-80% rate. High incidence of mosaicism has been reported in preimplantation embryos, with the blastocyst mosaicism being between 4-24% (Harton et al., 2017). Although mosaic embryos have a chance to implant (Munne et al., 2017; Spinella et al., 2018) their pregnancy rate is lower, with an increased miscarriage rate. However, female and male translocation carriers, whether Robertsonian or reciprocal, have not been yet analyzed regarding the incidence of generating mosaic embryos.

Study design, size, duration: This retrospective study was based on 143 PGT-SR cycles initiated between January 2017 and September 2019. A total number of 573 blastocysts were tested for PGT-SR by ReproSeq on Ion Torrent S5 (Thermo Fisher Scientific) following trophectoderm biopsy.

Participants/materials, setting, methods: The number of blastocysts tested from female and male translocation carriers were 284 and 289, respectively. The number of blastocysts tested from reciprocal translocation carriers was 471 whereas 102 were from RobTC. The mean female age in all groups was similar and statistically non-significant (32.8 and 31.2 for female and male and 33.3 and 31.7 for Robertsonian and reciprocal translocation carriers). Chi-square test was used for categorical group comparisons.

Main results and the role of chance: The overall mosaicism rate for PGT-A was 11% (8239 trophectoderm biopsies). The euploid/ balanced translocation rate of Robertsonian and reciprocal translocation carriers was 32.4% and 20.4%, respectively (p=0.008). The frequency of mosaic embryos generated by RobTC was seven times higher than carriers of reciprocal translocations (21.6% and 3.2%; p<0.0001).

Also, male translocation carriers in general were three times more prone to have mosaic embryos than female translocation carriers (9.3% and 3.5%; p=0.046). The euploid/ balanced translocation rate was identical for male and female translocation carriers (22.5%).

When the subgroups were analyzed, female RobTC were found to generate nearly seven times more mosaic embryos than female reciprocal translocation carriers (15.4% and 2.3%; p<0.001). Moreover, male RobTC engendered nearly six times more mosaic embryos than male reciprocal translocation carriers (23.7% and 4.2%; p<0.0001).

One possible mechanism to explain the increased mosaicism in RobTC may be the involvement of the centromere in balanced translocation carrier embryos. This involvement may lead to errors in mitotic divisions during embryo development. Embryos of RobTC have been shown to exhibit a mitotic interchromosomal effect that enhances genetic instability during early development (Alfarawati et al., 2012). Also, 30% of RobTC were diagnosed as having a severe male factor.

Limitations, reasons for caution: The limitation of our study was being a retrospective analysis. A prospective follow-up study with a larger sample size is needed to verify the outcome of this abstract.

Wider implications of the findings: As the possibility of finding an euploid or balanced carrier embryo is relatively lower for translocation carriers, the transfer of a mosaic embryo may be a realistic option. Higher incidence of mosaicism in Robertsonian/ male translocation carriers may provide an insight to understanding the mechanism of mosaicism in human embryos.

SESSION 21: IMPACT OF NEW TECHNOLOGIES ON HUMAN REPRODUCTION

06 July 2020 Parallel 5 15:15 - 16:30

O-084 A construct of mesenchymal stem cell-derived exosomes/ collagen scaffold promotes endometrium regeneration and fertility restoration through macrophage immunomodulation

L. Xin[1]

[1]Zhejiang University, School of Medicine, Hangzhou, China

Study question: Can a construct of mesenchymal stem cell-derived exosomes/collagen scaffold provide a new treatment for Asherman's syndrome?

Summary answer: A construct of mesenchymal stem cell-derived exosomes/ collagen scaffold promotes endometrium regeneration and fertility restoration through macrophage immunomodulation

What is known already: Endometrial traumas caused by recurrent curettage, caesarean section and myomectomy always result in intrauterine adhesions (IUAs) and infertility. Umbilical cord-derived mesenchymal stem cell (MSC)-based therapies have shown some promise achievements in the treatment of IUAs for their easy collection, high proliferation and low immunogenicity. However, the potential tumorigenicity, low infusion and low retention of MSCs are still controversial and the clinical application of MSCs is limited. In contrast, MSC-derived exosomes exhibit a similar function to their source cells and are expected to overcome these limitations.

Study design, size, duration: A total of approximately 200 SD rats were involved and received different treatments. Uteri were examined at 1,3,7, 30 and 60 days after surgery. We evaluated the effects of CS/Exos on the regeneration of damaged endometrium and the restoration of fertility, as well as exploring the healing mechanism from the aspect of macrophage immunomodulation by functional miRNAs *in vivo* and *in vitro*.

Participants/materials, setting, methods: we designed a construct of exosomes and a collagen scaffold (CS/Exos) for endometrium regeneration, and investigated the regeneration mechanism through macrophage immunomodulation. PCR,ELISA, IF, IHC, HE staining, Masson's staining and RNA-seq were involved.

Main results and the role of chance: The CS/Exos transplantation potently induced (i) endometrium regeneration, (ii) collagen remodeling, (iii) increased the expression of the estrogen receptor a/progesterone receptor, and (iv) restored fertility. Mechanistically, CS/Exos facilitated $CD163^+$ M2 macrophage polarization, reduced inflammation, and increased anti-inflammatory responses *in vivo* and *in vitro*. By RNA-seq, miRNAs enriched in exosomes were the main mediator for exosomes-induced macrophage polarization. Overall, we demonstrated that CS/Exos treatment facilitated endometrium regeneration and fertility restoration by immunomodulatory functions of miRNAs.

Limitations, reasons for caution: The results of this research are inadequate to apply directly in human because human uterine and rat uterus differ in structure and function. Further large animal experiments, such as monkeys, are needed.
Wider implications of the findings: Our research highlights the therapeutic prospects of CS/Exos for the management of IUAs.
Trial registration number: not applicable

O-085 Differentiation of stromal cells into theca cells: understanding theca cell formation in human ovaries

P. Asiabi[1], M.M. Dolmans[1], J. Ambroise[2], A. Camboni[1], C. Amorim[3], Andrade[1]

[1]Pôle de Recherche en Gynécologie- Institut de Recherche Expérimentale et Clinique, Université Catholique de Louvain- 1200, Brussels, Belgium ; [2]Centre de Technologies Moléculaires Appliquées- Institut de Recherche Expérimentale et Clinique-, Université Catholique de Louvain- 1200, Brussels, Belgium [3]Université Catholique de Louvain (UCL) -Institut de Recherche Expérimentale et Clinique Laboratoire de Gynécologie - 1200, Brussels, Belgium

Study question: Is there a subpopulation of precursor theca cells (PTCs) in human ovarian cortex or all can ovarian stromal cells differentiate into theca cells (TCs)?
Summary answer: Around 43% of ovarian stromal cells (SCs) can differentiate into TCs, which indicates the presence of PTCs in human ovaries.
What is known already: There are very few studies on the origin of TCs in mammalian ovaries. Progenitor TCs have been described in neonatal mice ovaries, which can differentiate into TCs under the influence of factors from oocytes and granulosa cells. On the other hand, studies in large animal models have reported that SCs isolated from the cortical ovarian layer can also differentiate into TCs with the right stimuli.
Study design, size, duration: After obtaining informed consent, ovarian biopsies were taken from eight menopausal women (53-74 years of age) undergoing laparoscopic surgery for gynecologic disease not related to the ovaries. SCs were isolated and then in vitro cultured either in basic medium (G1) or enriched with growth factors, follicle-stimulating hormone and luteinizing hormone (G2) for 8 days.
Participants/materials, setting, methods: To confirm whether SCs were able to differentiate into TCs, relative mRNA levels for LHCGR, StAR, CYP11A1, CYP17A1, HSD3B1 and 2 were assessed. Immunohistochemistry (IHC) was also performed for their protein detection and a specific marker for theca interna cells (CD13). Finally, we analyzed the ultrastructure of the cells before (D0) and after (D8) in vitro culture, and DHEA and progesterone levels in the medium using transmission electron microscopy and ELISA respectively.
Main results and the role of chance: Quantitative PCR results showed a significant ($p<0.05$) increase in mRNA levels of HSD3B2 in G1 and G2 and CYP17A1 in G1 after 8 days of in vitro culture. IHC results confirmed expression of each enzyme involved in the steroidogenic pathway at the protein stage. However, only G2 exhibited a significant proportion (43%) of CD13-positive cells compared to cells soon after isolation (0%) and in vitro-cultured in basic medium (0%). Ultrastructural analyses showed a distinct difference between the two groups versus D0. Linear trends displayed a significant rise ($q<0.001$) in dehydroepiandrosterone (DHEA) and progesterone concentrations in medium in G2 culture with time. Similarly, G1 exhibited a significant upturn ($q<0.001$) in DHEA, but not progesterone, which remained the same throughout the culture period. Statistical comparisons of progesterone and DHEA levels on day 8 for G1 versus G2 were $q<0.05$ and $q=0.33$ respectively.
Limitations, reasons for caution: While our results indicate the presence of PTCs in the human ovary, as after in vitro culture, 43% of cells express TC genes and proteins and are able to synthesize steroids. It is now necessary to identify specific markers for PTCs to confirm our findings.
Wider implications of the findings: Results from current experiments are a promising step towards understanding TC ontogenesis in the human ovary. Moreover, in vitro-generated human TCs can be used for studies on drug screening, as well as to understand TC-associated pathologies, such as androgen-secreting tumors and polycystic ovary syndrome.
Trial registration number: not applicable

O-086 Embryo development of reconstituted zygotes using haploid androgenotes obtained from ooplast-mediated male genome cloning

A. Petrini[1], P. Xie[1], A. Trout[1], R. Setton[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Is it feasible to clone the male genome by utilizing haploid androgenic blastomeres as male gametes to reconstitute diploid zygotes supporting full preimplantation development?
Summary answer: Haploid androgenotes are capable of complementing female pronuclei, allowing reconstitution of diploid zygotes that completed a normal preimplantation development comparable to normally fertilized conceptuses.
What is known already: In cases of severely impaired spermatogenesis in which only a limited number of gametes is available, or in cases of gametal heterozygosity for heritable diseases, male gamete cloning has been sought and attempted. Male genome cloning can be achieved through an ooplast-mediated approach that generates androgenic embryos, which cleave to the 2-, 4-, or 8-cell stage while maintaining the identical genotype as the injected spermatozoa and can function as a male gamete. In addition, the propagation of the male genome allows pre-fertilization genetic testing.
Study design, size, duration: Haploid male embryos were generated and allowed to cleave to duplicate the male genome. Resulting androgenotes were isolated immediately after first cleavage and treated with DNA polymerase inhibitor to pause cell cycle before the S phase. Monopronucleated recipient oocytes were fused with androgenotes to reconstitute diploid embryos. Constructs were maintained in culture up to 96h in a time-lapse system to assess all steps of preimplantation development. Piezo-actuated ICSI was performed on untreated oocytes as control.
Participants/materials, setting, methods: Metaphase II oocytes from B6D2F1 mice were treated with cytochalasin B and enucleated by excising the spindle herniation under OosightÔ visualization. Resulting ooplasts were injected with spermatozoa from the same strain and allowed to reach the 2-cell stage. Resulting androgenotes were exposed to 1.5 mM aphidicolin until reconstitution and fused with monopronucleated recipient oocytes from another cohort using Sendai virus. Cleavage parameters of resulting zygotes were obtained by time-lapse comparing to ICSI conceptuses as control.
Main results and the role of chance: A total of 59 oocytes were all successfully enucleated. The resulting 59 ooplasts were injected with sperm heads; 44 survived (75%), and all developed a single male pronucleus 4-6h post-ICSI. After culturing up to 16h, 42 (95%) constructs cleaved to the 2-cell stage, yielding 84 haploid androgenotes. Parthenogenic activation by calcium ionophore was successful in 93% of the recipient oocytes, confirmed by the extrusion of the second polar body and the appearance of a single female pronucleus. A total of 42 haploid androgenotes were subzonally inserted with Sendai virus and successfully fused with corresponding activated oocytes at a rate of 92.9%. Untreated oocytes were inseminated by piezo-actuated ICSI serving as control, yielding 30 zygotes. The cleavage of reconstructed embryos into the 2-cell stage (89.7%), 4-cell stage (87.2%), morula compaction (84.6%), and blastocyst formation (76.9%) was comparable to control ICSI conceptuses (86.7%, 83.3%, 80.0%, and 80.0%, respectively), with no noticeable morphokinetic differences.
Limitations, reasons for caution: While this approach is successful in a mouse model, its application to human reproduction requires serious consideration. Major concerns include the retention of imprinting of the male genome during the development of the pseudo-blastomere. Other biological hindrances include the role of the human sperm centrosome and heteroplasmy.
Wider implications of the findings: This technique offers the possibility of replicating a male gamete and may improve our understanding of reprogramming immature germ cells as gametes. Male genome cloning may benefit patients with heritable diseases who need pre-fertilization gamete screening or the use of genomic editing to provide healthy or genome-corrected functional pseudo-gametes.
Trial registration number: not applicable

O-087 Use of intraovarian platelet rich plasma does not increase the ovarian reserve markers,ovarian response or IVF outcome in Bologna poor responders.

S. Singh[1], S. Singh[1], N. Ashraf[1], R. Basheer[1], M. Ashraf[1]

[1]Craft Hospital And Research Center, Reproductive Medicine, Thrissur, India

Study question: Does administration of autologous intraovarian platelet rich plasma (PRP) increase the ovarian reserve markers,ovarian response or IVF outcome in Bologna poor ovarian responders (POR)?
Summary answer: There is no benefit of autologous intraovarian PRP in increasing AMH,AFC,ovarian response to ovarian stimulation or IVF outcome in Bologna POR women.
What is known already: Poor ovarian responders are the most difficult subgroup of patient to treat in ART.The challanges in treatment includes high risk of cycle cancellation,low number of oocytes/embryos and very low pregnancy rates.Many interventions have been tried in these women including androgen supplementation,LH supplementation,growth hormone etc,but none has been clearly shown to be beneficial in improving the take home baby rate.PRP has been utilised as a regenrative therapy by many specialities of medicine since it is rich in growth factors and cytokines.It's use in reproductive medicine has been tried in endometrial regeneration,but data in poor responders for improving treatment outcome is lacking.
Study design, size, duration: A prospective observational cohort pilot study was performed over a period of 18 months on 30 POR reproductive aged women diagnosed based on Bologna criteria at craft hospital,Kerala,India.All the women previously had atleast 1 failed IVF at our center and had details of previously performed ovarian reserve testing available within last 3 months.All the couples had detailed counselling about the experimental nature of the procedure and written consent was obtained.Internal ethical committee approval was taken.
Participants/materials, setting, methods: PRP prepared from autologus blood following standard protocols in mid-late follicular phase was injected under ultrasound guidance into the ovarian cortex under conscious sedation, using a 35 cm 17 G needle at 2 sites in each ovary. After a period of 2 months,antral follicle count (AFC) and anti-mullerian hormone (AMH) were reassesed and 2nd IVF was performed by antagonist protocol.The results of post-PRP values of AFC,AMH and IVF outcome were compared to the pre-PRP value.
Main results and the role of chance: A total of 30 POR women (mean age +/- SD: 38.7 +/- 4.6) were included in the study.The ovarian reserve markers and IVF outcome prior to administration of intraovarian PRP (pre-PRP group) was compared to the the parameters obtained after intraovarian PRP (post-PRP group) The pre-PRP and post-PRP group has similar AFC (4.2 +/- 2.6 vs 3.8+/- 1.8; p>0.05) and AMH (0.46 +/- 0.26 vs 0.49 +/- 0.22; p>0.05). When compared to the IVF cycle performed pre-PRP administration,the post-PRP group showed no difference in the number of growing follicles of >/= 14 mm (3.7 +/- 2.2 vs 4.0 +/- 2.4) , number of MII oocytes (3.2 +/- 1.2 vs 3.5 +/-1.7), fertilization rate (2.8 +/- 1.2 vs 2.6 +/- 1.7) and cleavage stage embryos (1.8. +/- 1.1 vs 2.0 +/- 1.4) respectively; p>0.05 for all). In 5 women (16.6%),cycle had to be cancelled due to lack of follicular growth after 5 days of gonadotrophin administration. 3 women (10%) did not have any embryos to be transferred and hence the cycle was cancelled.Embryo transfer was performed in total of 22 women.Clinical pregnancy rate of 13.3 % (4/30) was achieved with a live birth rate of 10% (3/10).
Limitations, reasons for caution: This study has limitation of being observational cohort study with the women serving as their own historical controls. The study also has a small smaple size.The data presented here were analysed 2 months after the administration of PRP.Whether waiting for a longer duration would have changed the outcome is not known.
Wider implications of the findings: Autologus intraovarian PRP administration has not been shown to improve AMH,AFC,ovarian response or IVF outcome in Bologna poor responder women.It's use should be restriced strictly to research settings to prevent women being exposed to this unnecessary intervention till further evidence to the contrary through well designed randomised controlled trials.
Trial registration number: Not applicable

O-088 Bone marrow derived stem cells restore ovarian function and fertility in premature ovarian insufficiency women. Interim report of a randomized trial: mobilization versus ovarian injection

N. Pellicer De Castellvi[1], S. Herraiz[2], M. Romeu[3], S. Martinez[3], A. Buigues[4], I. Gomez-Seguí[5], J. Martinez[6], A. Pellicer[7]

Study question: Could reproductive outcomes and menopausal symptoms of POI women be improved by autologous stem cell ovarian transplant (ASCOT) or Granulocyte-colony stimulating factor (G-CSF) stem cell-mobilization?
Summary answer: Both ASCOT and G-CSF mobilization promoted follicle growth and raised AFC in 60% POI women; obtaining after COS 4 MII-oocytes, 2 embryos, and 1 pregnancy.
What is known already: Premature ovarian insufficiency (POI) is characterized by oligo-amenorrhea due to follicular depletion in young women, where the only practical option is egg/embryo donation, as their spontaneous pregnancy rate is very low(<4%). We recently described that bone marrow derived stem cell (BMDSC) infusion promotes follicular growth by increasing ovarian vascularization, stromal cell proliferation, and reducing cell death in POI mice models and xenografted human ovarian tissue. Based on this, ASCOT technique has been already tested in poor responders improving ovarian function biomarkers (AMH and AFC) in 81.3% of women and allowing a total of 6 pregnancies and 3 healthy babies
Study design, size, duration: Randomized prospective pilot study started in 2018 at La Fe University Hospital, Valencia. The study involves 20 POI women, according to the following inclusion criteria: ≤38 years, ≥4months oligo/amenorrhea, serum FSH>25IU/l.

Patients were randomized into two study arms: 1) Mobilization of bone marrow stem cells to peripheral blood by a 5-day treatment with G-CSF (10ug/kg/day subcutaneous injection), where cells remain circulating; 2) ASCOT: after G-CSF mobilization, stem cells were collected and transplanted into one ovary.
Participants/materials, setting, methods: To date, 10 patients have been included, 4 of them were randomized to the G-CSF arm and 6 to the ASCOT. After intervention, patients were monitored during 6-month for endocrine function, serum levels of FSH, AMH and estradiol, antral follicle count (AFC) was assessed by ultrasound scan. Patients' basal levels were established before treatment.

When follicular growth was detected (AFC increased in at least 1 follicle) controlled ovarian stimulation was initiated following standard protocols.
Main results and the role of chance: Preliminary results in 10 patients, showed follicular development in both arms when compared to basal levels; these follicular growth waves were detected 90-140 days after treatments.

In the G-CSF group, AFC increased in 50% of recruited patients (2/4) while in the ASCOT this improvement was detected in 66.6% of women (4/6).

Statistically significant decrease of FSH levels was not recorded, but two women in the G-CSF group(50%) and 1 in the ASCOT(16%) showed a two-fold decrease, concluding the follow-up period(82.7±8.1 to 24.1±17.4 and 34.9 to 18.1; respectively).

After G-CSF mobilization, 2/4 women, initiated COS, with a total of 4 punctured follicles, 2 MII obtained and 1 embryo vitrified. Embryo transfer was performed but pregnancy was not achieved; this patient currently has regular menses after the follow-up period. In the ASCOT group, 4 of 6 patients initiated COS cycles. Oocyte pick-up was performed in 70% of initiated COS; where 3 MII and 1 GV were retrieved. One 3-day embryo was vitrified and transferred, having an ongoing pregnancy(20 weeks). These women were unable to undergo COS/oocyte pick-up before treatments due to absence of antral follicles.

Within menopausal symptoms, hot flashes and vaginal dryness improved in 50% of women, while 40% recovered menses (spotting).
Limitations, reasons for caution: These are descriptive preliminary results obtained in the first 10 recruited women that should be confirmed at the end of the trial. Our study lacks from a real control group, without treatment, though poor prognosis POI patients should not be left untreated, as their only reproductive option is egg donation.

Wider implications of the findings: ASCOT in POI women can be a potential therapy for women with no option of having offspring with their own oocytes. This study has shown a future use of stem cells in POI women, even without direct ovarian infusion, which suggest potential development of less invasive procedures in the future.
Trial registration number: NCT03535480

SELECTED ORAL COMMUNICATIONS

SESSION 22: UPDATES ON ART OUTCOMES, BARRIERS AND PREDICTIONS: AN INTERNATIONAL OVERVIEW

06 July 2020 Parallel 6 15:15 - 16:35

O-089 Predicting cumulative livebirth from the second complete cycle of IVF: a population-based study of 49,314 couples

M. Ratna[1], S. Bhattacharya[2], D. McLernon[1]

[1]University of Aberdeen, Institute of Applied Health Sciences, Aberdeen, United Kingdom ;
[2]University of Aberdeen, School of Medicine- Medical Sciences and Nutrition, Aberdeen, United Kingdom

Study question: Can we develop an IVF prediction model to estimate the chance of cumulative livebirth in couples embarking on a second complete cycle of IVF?
Summary answer: Yes, our prediction model can estimate individualised chances of cumulative livebirth over three additional complete cycles.
What is known already: Existing models can estimate the individualised cumulative chance of livebirth following one or more complete IVF cycles in couples embarking on their first IVF treatment. There are currently no prediction models in IVF which can estimate the individualised cumulative chance of livebirth over multiple complete cycles in women who decide to continue IVF after completing their first cycle. Existing cumulative prediction models also fail to account for couples who decide to stop treatment after a complete cycle. Models that do not adjust for discontinuation may give predictions that are too optimistic.
Study design, size, duration: For model development, a population-based cohort was used of 49314 women treated in IVF clinics across the UK from 1999 to 2008 using their own oocytes and their partners' sperm. Model external validation was performed on data collected from 36170 women who underwent treatment in UK IVF clinics from 2010 to 2017.
Participants/materials, setting, methods: All UK IVF treatments were obtained from the Human Fertilisation and Embryology Authority (HFEA) database. Using a discrete time logistic regression model, we predicted the cumulative probability of livebirth from the second to the fourth complete cycle. We adjusted for couple characteristics at the second cycle and outcome of first cycle. Inverse probability weighting was used to account for treatment discontinuation. Discrimination was assessed using c-statistic and calibration was assessed using calibration-in-the-large and calibration slope.
Main results and the role of chance: Of 49314 women, 12408 (25.2%) had a livebirth after their second complete cycle. Cumulatively, 17394 (35.3%) had a livebirth over three further complete cycles. Women who had a livebirth in their first complete cycle had over twice the odds of a livebirth compared to women who did not get pregnant in their first complete cycle (Odds Ratio: 2.18 (95% Confidence Interval: 2.15, 2.21)).

As an example, consider a 32-year-old woman with two years of unexplained infertility who had a livebirth after her first complete cycle. If she starts her second complete cycle one year later, she has a 48% predicted chance of a second livebirth resulting from this second complete cycle. Over three complete cycles her cumulative predicted chance of livebirth is 75%. For a woman with similar characteristics who suffered a pregnancy loss in her first complete cycle the cumulative predicted chance of livebirth is 72% while for a woman who did not get pregnant it is 66%.

The c-statistic for the development and validation cohorts were 0.647 (0.641, 0.652) and 0.626 (0.612, 0.632) respectively. Both calibration-in-the-large (Intercept: 0.0351 (0.0149, 0.0553)) and calibration slope (0.804 (0.769, 0.840)) showed under-prediction in validation cohort. However, after recalibration the fit was much improved.
Limitations, reasons for caution: We were unable to adjust for some potentially important predictors, e.g. body mass index (BMI), smoking and alcohol intake in women, as well as measures of ovarian reserve such as antral follicle count. These were not available in the linked HFEA dataset.
Wider implications of the findings: This is the first model to estimate the overall chance of a livebirth over three further cycles for a couple who have already undergone a complete IVF cycle. The model can be used as a counselling tool to help couples make an informed decision regarding further treatment.

O-090 Assisted reproductive technology in Africa: a five-year analysis of data from the African Network and Registry

L. Potgieter[1], P. Archary[1], I. Smit[1], O. Ashiru[2], E. Gwet-Bell[3], S. Dyer[1]

[1]Groote Schuur Hospital, Obstetrics and Gynaecology, Cape Town, South Africa ;
[2]Medical ART Centre, Not applicable, Lagos, Nigeria ;
[3]Clinique Médicale Odyssée, Not applicable, Douala, Cameroon

Study question: What were utilization, outcomes and practices of assisted reproductive technology (ART) in Africa between 2013 and 2017?
Summary answer: Utilization remained low; fresh autologous cycles predominated, with favorable pregnancy rates but accompanied by high rate of multiples and low reporting of delivery outcomes.
What is known already: Global access to infertility treatment requires global understanding of regional realities, challenges and differences. Many African countries, the majority of which are low and lower-middle income countries, carry a triple burden of infertility, namely high infertility disease prevalence, negative socio-cultural consequences, and poor access to effective treatment. Tubal and severe male factor are the leading causes of infertility in Africa, often requiring ART. Availability of ART has been low and treatment outcomes and practices were not monitored regionally prior to 2013. The African Network and Registry for ART (ANARA) commenced data monitoring in 2013 with increasing participation.
Study design, size, duration: Retrospective registry data pertaining to the years 2013 - 2017 were collected cross-sectionally over a period of three years. All ART centres known to exist on the African continent were invited to participate through mailing campaigns, and in conjunction with local workshops and conference presentations. ANARA online software or standardized data forms adjusted from the International Committee for Monitoring ART were used for data collection. Both retrospective summary and cycle-based data were collected and analysed.
Participants/materials, setting, methods: Centre participation and data submission were voluntary. Data sets were received and if necessary, transferred to standard data forms. All data were checked for mathematical errors and corrected as far as possible but not further validated. Data were pooled by year, country and then at regional (Africa-wide) level; and analyzed using descriptive statistics. Most results and trends were reported at regional level only, with the exception of number of procedures and ART utilization.
Main results and the role of chance: Registry participation increased from 40 ART centres in 13 countries in 2013 to 47 centres in 17 countries in 2017. Data are based on 153 461 procedures. Fresh autologous IVF/ICSI predominated in over 70% of procedures, with autologous frozen embryo transfer and fresh and frozen oocyte donation accounting for 17% and 7% respectively. ICSI was performed in over 90% of autologous cycles. Fresh embryo transfer was favoured overall.

The transfer of two and three embryos predominated for all years and all procedures. This practice remained constant with no observable increase in single embryo transfers. There was however a trend towards fewer transfers of four and more embryos. The majority of autologous cycles were conducted in women younger than 35.

During the period of observation, the average pregnancy rate per aspiration was 33% for fresh IVF/ICSI, while the pregnancy rate per thaw in frozen autologous cycles fluctuated between 25% and 39%. These rates were accompanied by a mean multiple delivery rate of 27% and 23% respectively. Overall, only 61% of pregnancies were followed up to delivery.

The evaluation of cycle-based data demonstrated a profound difference between elective and non-elective single embryo transfer in terms of pregnancy rates (47% vs 22%).

Limitations, reasons for caution: Registry participation varied, limiting data representation in some countries and for the continent overall. There were large variations regarding completeness of data. Means to validate data have not yet been established.
Wider implications of the findings: ART monitoring has been successfully initiated in Africa. Efforts are now directed at expanding registry participation, increasing capacity for the collection of prospective cycle-based data with use of appropriate software, and improving pregnancy follow up. Registry data are essential for improvement strategies regarding access to and quality of care.
Trial registration number: Not applicable

O-091 Pregnancy outcomes and lifetime fecundity – a nationwide, registry-based cohort study

A.M. Kolte[1], D. Westergaard[2], Ø. Lidegaard[3], S. Brunak[2], H.S. Nielsen[4]

[1]Copenhagen University Hospital Rigshospitalet, Recurrent Pregnancy Loss Unit- Fertility Clinic 4071, Copenhagen, Denmark ;
[2]University of Copenhagen, Novo Nordisk Foundation Center for Protein Research, Copenhagen, Denmark ;
[3]Copenhagen University Hospital Rigshospitalet, Dept. Gynaecology 4231, Copenhagen, Denmark ;
[4]Copenhagen University Hospital Hvidovre, Dept. Gynaecology and Obstetrics, Hvidovre, Denmark

Study question: How do different pregnancy outcomes and maternal age at first pregnancy influence the predicted total number of live born children (lifetime fecundity)?
Summary answer: A first ectopic pregnancy or pregnancy loss significantly reduced lifetime fecundity. Recurrent pregnancy loss (≥3 consecutive losses) also reduced lifetime fecundity.
What is known already: Several studies have investigated the impact of pregnancy loss, ectopic pregnancies, molar pregnancies and still birth on the next pregnancy. To our knowledge, no large-scale studies have described the effect of prior pregnancy outcomes on lifetime fecundity.
Study design, size, duration: Nationwide register-based cohort study comprising 458,475 women with at least one pregnancy in the Danish Medical Birth Registry or the Danish National Patient Registry from 1977 until 2017.
Participants/materials, setting, methods: We investigated lifetime fecundity in all women who lived in Denmark between their 20th and 45th birthday who had been pregnant at least once. Analyses were based on age at first pregnancy, outcome of the first pregnancy (live birth, ectopic pregnancy, pregnancy loss, still birth or molar pregnancy) and number of pregnancy losses, both total number and maximum number of consecutive pregnancy losses. Lifetime fecundity was estimated using a Generalized Linear Mixed Model.
Main results and the role of chance: Any adverse outcome in the first pregnancy significantly reduced lifetime fecundity compared to live birth. A first ectopic pregnancy had the largest effect (1.16 children on average, 1.11-1.22, 95% CI) compared to a woman with a first live (1.95 children on average, 1.86-2.03, 95% CI), both with the first pregnancy at age 30. Recurrent pregnancy loss (≥3 consecutive losses) also decreased lifetime fecundity significantly (1.57 children on average, 1.5-1.65, 95% CI) compared to women with no pregnancy losses (1.92 children on average, 1.83-1.97, 95% CI). Conversely, the total number of pregnancy losses among women <35 year at first pregnancy had no impact. Sex of the first-born child did not impact lifetime fecundity.
Limitations, reasons for caution: It is a limitation that pregnancy losses handled outside of hospitals are not registered in the Danish registries. Other factors other than pregnancy history likely also influence lifetime fecundity.
Wider implications of the findings: In this unique dataset, we show that adverse pregnancy outcomes have a significant impact on lifetime fecundity. This highlights the importance of taking prior pregnancy outcomes into account in family planning, and the necessity of more research into the pathophysiology of ectopic pregnancies and recurrent pregnancy loss.
Trial registration number: N/A

O-092 Is the number of oocytes retrieved associated with time to conception leading to live birth? A population-based analysis of 221,073 cycles

Y.J. Law[1], N. Zhang[1], R. Paul[1], O. Fitzgerald[1], K. Harris[1], G. Chambers[1], C. Venetis[1]

[1]University of New South Wales, Centre for Big Data Research in Health, Sydney, Australia

Study question: Does retrieving a higher number of oocytes after ovarian stimulation prolong the time to conception leading to live birth in women of different ages?
Summary answer: Retrieval of higher numbers of oocytes does not prolong, but rather, shortens the time to conception leading to live birth in women of all ages.
What is known already: Higher numbers of oocytes retrieved have been shown to be independently associated with more euploid embryos, subsequently leading to higher cumulative live birth rates. However, the euploidy rate (euploid/total embryos available) may vary depending on the number of oocytes retrieved and female age. With more oocytes and eventually embryos available for transfer, particularly in older women, there may be a lower chance of selecting a euploid embryo and therefore, an increased time to conception leading to live birth (TCLB). Whether the number of oocytes retrieved is associated with TCLB has never been investigated.
Study design, size, duration: This is a large retrospective population-based cohort study using data from the Australian and New Zealand Assisted Reproduction Database. Overall, 116,579 women undergoing 221,037 autologous aspiration cycles between January 2009 to December 2015 were included in the analysis. All fresh and frozen embryo transfers resulting from the associated aspiration cycle were included in the analysis until one live birth occurred or all embryos were used. Cycles with no oocytes retrieved were excluded from this analysis.
Participants/materials, setting, methods: Time to conception leading to live birth was assessed in two ways: the number of days (from oocyte pick-up to the date of confirmation of pregnancy) and the number of intended embryo transfers needed to achieve a live birth. Competing risks regression analysis and cumulative incidence functions were used to evaluate the association between oocyte yield and the TLCB. All analyses were also stratified by female age while controlling for important confounders.
Main results and the role of chance: Utilising time in days as the time variable, the number of oocytes retrieved remained a significant positive predictor of TCLB after adjusting for female age, parity, type of embryo transferred, cycle count, insemination method and type of infertility. Compared to the reference group of 10-14 oocytes retrieved, the subdistribution hazard ratio (SHR) of achieving a conception leading to a live birth increased with the number of oocytes retrieved across all age groups. Indicatively, for women aged 35-39, the SHRs (95% CIs) were 1-3 oocytes: 0.44 (0.42-0.47), 4-9 oocytes: 0.71 (0.69-0.73), 10-14 oocytes: 1.00, 15-19 oocytes: 1.16 (1.12-1.20), 20-24 oocytes: 1.35 (1.29-1.41), ≥25 oocytes: 1.41 (1.33-1.50). When the number of intended embryo transfers was used as the time variable, SHRs (95% CIs) were 1-3 oocytes: 0.46 (0.43-0.48), 4-9 oocytes: 0.72 (0.71-0.74), 10-14 oocytes: 1.00, 15-19 oocytes: 1.14 (1.11-1.18), 20-24 oocytes: 1.32 (1.26-1.37), ≥25 oocytes: 1.37 (1.30-1.44). The cumulative incidence curves for all female age subgroups supported that with higher number of oocytes there is a higher cumulative incidence of conception leading to live birth at all time points (either using days or intended embryo transfers as the time variable). A sensitivity analysis including only term live births also yielded similar results.
Limitations, reasons for caution: This study is based on retrospective observational data, thus not all confounders or clinical decisions may be accounted for. Furthermore, causality should not be inferred using these data.
Wider implications of the findings: This study demonstrates that retrieval of higher numbers of oocytes not only does not prolong the TCLB, but instead, seems to lead to higher cumulative incidence of conception leading to live birth in all female age groups. This information is important in informing future clinical decisions and furthering patient education.

O-093 Variability and ovarian dysfunction of the menstrual cycle – a prospective analysis of the German Natural Family Planning database including 43,999 menstrual cycles

P. Herrmann[1], T. Freundl-Schuett[2,3], L.M. Wallwiener[3], P. Frank-Herrmann[1,3], T. Strowitzki[1,3], A. Freis[1,3]

[1]Universitäts-Frauenklinik, Department of Gynecologic Endocrinology and Fertility Disorders, Heidelberg, Germany ;
[2]Heinrich Heine University Duesseldorf, Department of Obstetrics and Gynaecology, Duesseldorf, Germany ;
[3]German Society of Gynecological Endocrinology and Fertility Medicine DGGEF e.V., Section Natural Fertility, Heidelberg, Germany

Study question: To evaluate if individual variability of cycle length and ovulation, as well as the presence of luteal phase deficiency are more frequent than currently assumed

Summary answer: Intraindividual cycle length as well as fertility parameters differ distinctly subject to age, emphasizing the importance of individual assessment during the ongoing cycle.

What is known already: As the chances to conceive spontaneously vary dramatically during the menstrual cycle, determination of peak fertility remains crucial for couples trying to conceive. Recent reviews and guidelines have shown that there is still a lack of knowledge concerning the spontaneous menstrual cycle. Moreover, the American Society for Reproductive Medicine scrutinizes the clinical relevance of luteal phase deficiency in the etiology of infertility. The symptothermal method combines observation of the periovulatory temperature rise and cervical mucus changes and determines ovulation, as well as the onset and the end of the fertile phase according to the double-check principle.

Study design, size, duration: 43,999 menstrual cycle charts of 1923 women aiming for conception or contraception were collected prospectively between 1985-2019. Ovulation and the fertile window were determined applying the Sensiplan method, using estrogen- as well as progesterone-parameters and an evidenced symptothermal algorithm based on the extended Holt-rules. Ovulation was determined as the day before temperature rise. Luteal phase deficiency (LPD) was defined as hyperthermic phase < 10 days and anovulation as the presence of a monophasic temperature curve.

Participants/materials, setting, methods: Patterns of menstrual cycles (MC; n=12,612 cycles of 1051 women) were analyzed after excluding the use of oral contraception within the last three months. We included women aged 18 - 44 years who contributed data consisting of 12 cycle charts. Women after breast feeding, birth or miscarriage were included as soon as the first ovulatory cycle with sufficient luteal phase was detected. Statistical analysis was performed using single factor variance analysis, chi-squared-tests and logistic regression.

Main results and the role of chance: Mean cycle length (CL) was 29.7±7.6 days (d). 62.5% of women had cycle length variation (CLV) of >7d within 12 cycles. Respective to age, women aged 35-39 years (y) presented with the lowest amount of CLV>7d (52.2%), whereas women aged 18-24y showed CLV in 67.0%. Ovulation occurred most frequently on d15 (12.8%). 54.8% of women had a difference of >7d between the earliest and the latest day of ovulation, with a significant decrease subject to age (18-24y: 62.2%; 25-29y: 56.5%; 30-34y 58.2%; 35-39y: 40.5%; 40-44y: 30.2%, p<0.001). Average luteal phase length was 12.1±2.3d. 11.2% of MC presented with luteal phase deficiency (LPD). 17.6% of women had ≥3 cycles with LPD, whereas 46.9% did not show any LPD. Presence of LPD decreased according to age: 14.4% (18-24y) vs. 8.3% (35-39y) (OR=0.983, 95%CI: 0.972-0.994, p=0.002). Incidence of LPD rose constantly if ovulation occurred later (OR=1.084, 95%CI: 1.074-1.095, p<0.001). Cycles with an ovulation later than d22 showed LPD in 25.8%. Anovulation occurred in 2.6% of MC, irrespective of age. In cycles consisting of <25d or >35d, relative amount of anovulatory cycles increased up to 8.6% and 6.9%, respectively. Ovulatory cycles with sufficient luteal phase occurred in 61.0% (CL<25d), 88.9% (CL=25-35d) and 82.0% (CL>35d).

Limitations, reasons for caution: Data regarding possible comorbidities, such as hyperprolactinemia, were not collected. However, to reduce the impact of possible confounders, only women who contributed at least 12 cycles were included.

Wider implications of the findings: Individual assessment of the current fertile window is crucial for couples trying to conceive. Our data demonstrate that current innovations (such as the majority of mobile apps) claiming to support conception using a rudimentary calendar method based on previous cycles are not suitable to reliably indicate the fertile days.

O-094 Motivational factors and barriers for infertile patients and their partners to seek consultation and treatment

A. Domar[1], R. Vassena[2], M. Dixon[3], M. Costa[4], E. Vegni[5], J Guiglotto[6], M. Markert[7], J. Boivin[8]

[6]W2O Group, Marketing Research & Strategic Insights, Philadelphia, U.S.A. ;
[7]Ferring Pharmaceuticals, Health Economics & Outcomes Research, Copenhagen, Denmark ;
[8]Cardiff University, School of Psychology, Cardiff, United Kingdom

Study question: What are the key drivers and barriers for infertile patients and their partners to see an infertility specialist and subsequently undergo treatment?

Summary answer: Patients waited three years seeking infertility diagnosis. There were significant differences in perceived healthcare provider services among respondents seeking treatment versus not seeking treatment.

What is known already: Individuals and couples frequently wait years prior to seeking out medical advice and treatment for infertility, decreasing their chances of treatment success. The causes of delays to diagnosis, treatment and pregnancy are not well established amongst patients or their partners.

Study design, size, duration: An online, international, 30-minute quantitative survey collected data from 15th March–17th May 2019. The study included 1,944 respondents across nine countries: United States, Canada, United Kingdom, France, Germany, Italy, Spain, Australia and China. The survey was developed in English and translated to local language. All translations were validated by national linguists.

Participants/materials, setting, methods: The survey assessed average time to treatment, patient and partner perspectives on the treatment journey, and drivers for, and barriers to, infertility treatment. Participants were either (a) infertile patients (N=1037) or (b) partners to infertile patients (N=907; but not necessarily partners of the patient sample), who were at different stages of the treatment journey. Average age was 35.8 (SD=9.66) years, 56% (N=1095) were female, 67% (N=1119) were married and 91% (N=1773) were heterosexual.

Main results and the role of chance: Across countries, average time to diagnosis was 3.2 years (SD=2.4), followed by an average of 2.0 years (SD=2.1) attempting natural conception before consultation, and an average of 1.6 years (SD=1.4) of treatment before successful couples achieved pregnancy.

The most frequently reported driver for considering treatment in respondents with a consultation (N=1025) was an equal desire within couples to have a child (41%), followed by a willingness to do anything to become parents (38%). Among partners (N=356), 28% cited transparency of information from health care professionals about treatment expectations as an important driver. Of respondents not seeking consultation following diagnosis (N=352), the most frequent reason was perceived cost (38%).

Post consultation, only 32% of respondents not seeking treatment (N=207) reported that their healthcare professional offered services, such as supportive services, compared to 61% of respondents seeking treatment (p<0.001). Similarly, 37% of respondents not seeking treatment agreed that their practitioner had offered mental health services, compared to 62% among those receiving treatment (p<0.001). The most frequently reported barriers for those not seeking treatment were cost (42%, N=87) and determination to conceive naturally (31%, N=64). Of the 95 couples who discontinued treatment, 35% (N=33) discontinued due to financial impact.

Limitations, reasons for caution: This study was an anonymous, quantitative online questionnaire, there was no response validation by healthcare professionals, with potential to be a non-representative sample. Additionally, respondents were unable to ask clarifying questions. Recruitment of individual participants meant it was not possible to run sub-analyses of patient-partner pairs.

Wider implications of the findings: Respondents delayed consultation and treatment for years, which can negatively impact chances of pregnancy. Motivational coherence in the wish for a child was a key driver for treatment. Costs were a main barrier. There were large differences in perceived supportive

service offerings among respondents seeking treatment versus not seeking treatment.

O-096 Organoids as 3D models for endometrium and endometriosis

H. Vankelecom[1]

[1]*Cluster of Stem Cell and Developmental Biology, Development and Regeneration, Leuven, Belgium*

Abstract text

The endometrium is the first contact site of the embryo and crucial for human reproduction. Mechanisms underlying the tissue's monthly remodeling during the menstrual cycle and its embryo receptivity remain far from understood, as well as how these processes go awry during endometrium pathology. This limited understanding is primarily due to a lack of research models reliably recapitulating endometrium biology and disease in nature and heterogeneity.

Organoid technology provides an innovative tool to grow mini-tissues in culture. We established 3D organoid models from both healthy and diseased endometrium which reproduce key features of the original epithelium. The organoids show long-term expansion capacity while remaining genomically, transcriptomically and functionally stable. The endometrium-derived organoids phenocopy physiological responses to reproductive hormones and mimic the menstrual cycle in a dish. The organoids derived from endometriosis (as well as endometrial cancer) recapitulate characteristics of the patients' diseased tissue and faithfully capture the clinical heterogeneity of the disease. Finally, the endometrial disease organoids reproduce the original lesion when transplanted in immunodeficient mice.

Taken together, we created new organoid models that provide powerful and innovative tools to decipher the mechanisms underlying endometrium biology and pathology, and at the same time serve as screening platform to test (new) drugs, even in a patient-personalized manner.

O-097 Educate, assess and counsel – who, how and when?

A.N. Andersen[1]

[1]*Copenhagen University Hospital, The Fertility Clinic- section 4071, Copenhagen, Denmark*

Abstract text

The United Nations definition of reproductive health from 1995 stated that people should have "the capability to reproduce and to decide if, when and how often to do so". This was written at a time where focus was on contraception, but the wise phrasings also remains relevant considering today´s challenges in human reproduction, with low total fertility rates (TFR) around 1.5 in Europe. The question today is how we can assist more women and men to fulfil their reproductive life-plans in terms of number and spacing of children.

The lecture will propose a 3-step strategy. **A)** Women and men below 20 years evidently should have their main focus on contraception, but public campaigns and school education should create an initial awareness their fertility and avoidance of sexually transmitted diseases **B)** In the age groups 20 to 30 there should still be a focus on public campaigns, but another effort could be to "integrate pro-fertility thinking" into family planning. To phrase Seifer et al. (2015) by "putting family back into family planning". In family planning individual assessment and counselling is part of the consultation, and it could include simple tools for self-assessment of reproductive risks, like the FertiSTAT colour-coded sheet **C)** In the age of 30 society could offer nulliparous women and men pro-fertility-focussed individualized assessment, education and counselling. Thirty is the age where many nulliparous women really gets motivated for individual pro-fertility guidance.

The lecture will focus on point C, the approach offered in the Fertility Assessment and Counselling Clinic (FAC) that has initially been outlined by Hvidman et al. in 2015. In short, it offers a free 30 minutes consultations with specialist in Reproductive Medicine for singles and couples. Women have assessment of risk factors for impaired fertility graded in green, yellow and red scores, including measurements of antral follicle counts and pelvic pathology by ultrasound, and a blood sample for AMH. The consultations always include review of educational graphs on age and female fertility. Men are reviewed for known risk factors for male subfertility, and a sperm analysis is made "on-site". Couples with known infertility are NOT seen at the FAC clinic, which use the facilities of the Fertility Clinic, but operates separately. Individuals do not need any referral and the activity is funded by the public regional health system. During the last 8 years the clinic has had a total of around 4.000 consultations.

The mean female age is around 33 years. Lower in couples and higher in single women. The main motive for seeking the consultation was that 70% of the females wanted an estimate on how long they could postpone childbearing. Around 40% are single women and 30% use contraception. Follow-up studies have shown that both women and men remembered the consultation several years and that the score sheets to some extend can predict natural conceptions. Many women saw the consultation as a catalyst for change, in general towards advancing their attempts to conceive. The men felt empowered after the fertility counseling because they were equipped with concrete information that could inform their parenthood plans and decisions.

We argue that 30 years is the time where nulliparous women a) consider themselves susceptible to the condition of not being able to achieve their desired family size and b) still have 5 years ahead without major decline in age-related subfertility and c) believes that specific action to become pregnant can help them.

O-098 Getting fertility education on the national curriculum

A. Balen[1]

[1]*The Leeds Centre for Reproductive Medicine, Professor of Reproductive Medicine and Surgery, Leeds, United Kingdom*

Abstract text

Getting fertility education on the national curriculum

Professor Adam Balen

Professor of Reproductive Medicine, Leeds Teaching Hospitals, UK

In 2016, when I was chair of the British Fertility Society I founded the Fertility Education Initiative(FEI) with aim of improving people's knowledge of fertility and reproductive health in the UK. We brought a number of partner organisations to the project, including the RCOG, Faculty of Sexual and Reproductive Healthcare, Sex Education Forum, Sexpression, Teenage Pregnancy Knowledge Exchange, Fertility Network UK, Fertility Fest and Public Health England. Key members of the national committee are the deputy chairs Professor Joyce Harper (Institute for Women's Health, University College London) and Professor Jacky Boivin (School of Psychology, Cardiff University).

We first held a "Fertility Health Summit" which created a lot of publicity in the national media. Our vision is to ensure that people have a greater understanding and awareness about fertility and reproductive health, so they can make an informed choice about their own fertility journey, or that of others they may have an impact on.

In brief, our three key aims are:

1. Understanding human fertility:
   a) Human Reproduction
   b) Male and female reproductive health, including the reproductive life cycle; fertility and infertility; signs, symptoms and preventable causes of fertility issue; and planning for a healthy pregnancy
2. Understanding modern families:
   a) Societal and cultural variations in family building
   b) Routes to parenthood; for heterosexual, LGBTQ+ and single people with and without fertility issues; assisted conception techniques for family building; other routes to parenthood (such as adoption, fostering, step-families); and living a life without children
3. Understanding current reproductive technologies: To help educate people about what reproductive technologies can and cannot do and how they might impact on how human beings are made in the future.

We are developing age-appropriate educational material, some of which is already available on the BFS website and a series of animations, The first Your Fertility Matters https://youtu.be/ETwDCKBaYd4 and the second Fertility Technologies Shaping Modern Families https://youtu.be/dOi08g3CLOc covering modern ways of forming families and routes to parenthood for heterosexual, LGBTQ+ and single people with and without fertility issues.

In 2019, the draft statutory guidance on sex education (now known as Relationship and Sex Education, RSE) and health education was presented to the UK government for debate. This followed a highly publicised public consultation that we contributed to on behalf of the Fertility Education Initiative. We were delighted that the new guidance includes the need to educate young people about 'the facts about reproductive health, including fertility and the potential impact of lifestyle on fertility for men and women'. The bulk of the guidance naturally deals with general health and wellbeing, the foundation of healthy relationships and all aspects of physical, emotional, mental, sexual and reproductive health and wellbeing. There is also reference to understanding the various forms of sexuality and sexual relationships and 'that others' families, either in school or in the wider world, sometimes look different from their family, but that they should respect those differences and know that other children's families are also characterised by love and care'. There is emphasis on age-appropriate information and when specific topics should be discussed.

The inclusion of information on fertility in the guide is a huge step forward for fertility education, which until now has been largely overlooked, poorly taught and not even properly covered in most biology syllabi, let alone PHSE (personal, social, health and economic education) or RSE lessons.

[2]*University of Florence, Experimental and Clincal Biomedical Sciences, Florence, Italy ;*
[3]*University of Florence, Experimental and Clinical Medicine, Florence, Italy ;*
[4]*University of Florence, Experimental and Clinical Medicine, Florence, Italy*

Abstract text

In order to fertilize and support embryo development, spermatozoa require several functional attributes, most of which cannot be revealed by a routine semen analysis. Indeed, semen analysis reveals only two functional sperm properties needed for fertilization, progressive motility and normal morphology. In vivo, spermatozoa must penetrate cervical mucus, undergo the complex process of capacitation, develop a special type of motility known as hyperactivation necessary to penetrate oocyte vestments, undergo acrosome reaction, fuse with the oolemma and, finally, deliver an intact DNA to the oocyte in order to achieve syngamy. Each of these functions requires the endowment of molecules, receptors, pathways activation, second messengers as well as morphological characteristics of the spermatozoa. Many of these features have been disclosed in the last years, but more research efforts are needed in order to fully understand the complexity of the fertilization process. Based on this knowledge, in the last three decades, tests have been developed to evaluate the sperm ability to accomplish many of the functions required for a correct fertilization, including the integrity of DNA. Some of these tests have potential clinical value both for natural and assisted reproduction, as they predict sperm fertilizing ability and ability to support development of embryos characterized by better quality and implantation with good sensitivity and specificity. However, some of these texts are complex, poorly standardized, expensive and require equipment that may not be present in laboratories for routine semen analysis. Hopefully, progresses in technology will lead to development of easy to perform and inexpensive tests.

O-100 Routine and new diagnostic approaches for male infertility: Are new genetic markers near primetime?

D.J. Lamb[1]

[1]*Weill Cornell Medicine, Urology, New York, USA*

SELECTED ORAL COMMUNICATIONS

SESSION 26: THE DAY AFTER. FERTILITY PRESERVATION AND EMBRYO TRANSFER IN PATIENTS WITH CANCER DIAGNOSIS.

06 July 2020 Parallel 5 17:00 - 18:00

O-101 Fertility preservation in men affected by cancer: a retrospective analysis of their experiences around fertility counseling and evaluation of needs regarding additional support tools.

V. Ehrbar[1], G. Sartorius[1], C. Urech[1], C. Rochlitz[2], S. Tschudin[1]

[1]*University Hospital Basel, Gyn. Socialmedicine and Psychosomatics, Basel, Switzerland ;*
[2]*University Hospital Basel, Medical Oncology, Basel, Switzerland*

Study question: What are the needs of male cancer patients regarding an online information tool based on their experience with fertility preservation?
Summary answer: Male cancer patients consider counselling by professionals regarding fertility preservation as very helpful and would favor complementing support tools.
What is known already: Impairment of fertility is a common sequela of the nowadays available and often highly efficient options to treat cancer. Thus, discussing fertility preservation (FP) with all young cancer patients before start of treatment is crucial. The few existing studies in male cancer patients show that appropriate information about FP increases counseling satisfaction and prevents regrets about decisions regarding FP. According to research in female cancer patients, online decision aids are a helpful and efficient complement to fertility counseling. Support tools for men, however, are scarce and predominantly in English. Little is known about their needs regarding this kind of support.
Study design, size, duration: The study consisted of a quantitative and a qualitative part, i.e a retrospective questionnaire-based cross-sectional survey followed by focus groups. Recruitment was ongoing for 30 months in three fertility centers in Switzerland. Participants had a history of cancer within the last five years and were invited regardless of their decision regarding FP.
Participants/materials, setting, methods: Participants (N=72) completed the online questionnaire specifically developed for the given context. The survey consisted of questions about the experiences and needs of male cancer patients regarding counseling and regarding information provision concerning FP. Subsequently three focus groups (N=12) were conducted, where the topics covered by the survey were discussed more profoundly.
Main results and the role of chance: Mean age of the participants of the online survey was 32.94 (SD 8.38), most of them are living in a relationship

(70.8%) and 30.6% have at least one child. Predominant type of cancer was testicular cancer (55.6%), followed by lymphomas (16.7%) and leukemia (13.9%). All but two participants decided to undergo FP by semen cryopreservation. The moment, when they were informed about FP was for 68.1% of the participants before start of cancer treatment and for 29.2% during treatment, respectively; whereas 2.8% did not recall having been informed at any time. The professional who provided the information was predominantly an oncologist (41.9%) or urologist (30.6%). Participants rated the significance of the counseling as very high with a mean of 4.2 (maximum of 5) and experienced the professionals as supportive (4.37 out of 5). Analysis of the focus groups showed that support tools such as the existing decision aids for women would be welcome. The majority of the participants (70.8%) stated that they would use such a tool, which should ideally comprise structured information provision, patient stories, and deeper insights in topics such as sexuality, fertility as well as contact information to peers and professionals.

Limitations, reasons for caution: Participants answered the questionnaire retrospectively; therefore, a recall bias needs to be considered. The final sample of participants consisted uniquely of patients who got a referral to fertility counselling. Consequently, these results are not generalizable for all male cancer patients.

Wider implications of the findings: These data complement the preexisting studies focusing on female cancer patient's needs regarding FP and support by a male perspective. They highlight that male patients would profit from a support tool, as well. In general, more research is required in the specific domain of psychological impact on male patients.

Trial registration number: NCT03876366

O-102 Single men's attitudes towards posthumous reproduction does not necessarily match accepted social trends.

A. Stein[1], E. Altman[1], M. Rotlevi[1], A. Deutsch[1], Y. Shufaro[2]

[1]Beilinson Medical Center, Sperm bamk and Male infertility, Petah Tikva, Israel ; [2]Beilinson Medical Center, Infertility and IVF Unit, Petah Tikva, Israel

Study question: What's the attitude of single men cryopreserving sperm in the face of serious morbidity/mortality risks to the use of their sperm for posthumous reproduction?

Summary answer: Most of the single men who cryopreserved their sperm in face of a mortality/morbidity risk object to posthumous reproduction using their sperm.

What is known already: Requests for posthumous reproduction are growing, raising an ethical debate and prolonged litigation, especially when written instructions were not left by the patients. The issue of the progenitors' intention to procreate (or not) after death is the key to ethically based decision making. In the Israeli society procreation is a very strong value, so in the absence of written instructions the patients' relatives often claim for posthumous reproduction based on the presumed will of the deceased in accordance to the mainstream social trend.

Study design, size, duration: Prior to sperm cryopreservation, single men were asked to sign a structured form declaring their consent or refusal for usage of their cryopreserved sperm in case of future mortality. Addressing this issue and signing the form after counselling is a mandatory requirement for sperm cryopreservation. Adolescent patients signed the form with their parent / guardian. The patients were from different religious and cultural origins.

Participants/materials, setting, methods: Five-hundred-thirty-four single man; 401 adults and 133 adolescents, referred for sperm cryopreservation prior to medical/surgical treatment in a tertiary hospital. All the adolescents and 296/401 (74%) adults were diagnosed with malignant disorders. The remaining 105 adults were facing fertility endangering procedures. The choices in the form were to destroy the sperm or to allow posthumous use by a female partner or other people of their choice.

Main results and the role of chance: Five hundred thirty four single men signed the form providing instructions in case of mortality. One hundred thirty three were 13-18 years old (age 15.9 ± 1.16 years) and the rest (401) were adults (age 27.4 ± 8.06 years).

Out of the adult group 5 patients (1.2%) authorized their sibling to use their sperm, 23 (5.7%) willed their sperm to their informal female partners, and 16 (4.0%) permitted their parents to use their sperm posthumously. The significant rest 357 (89.0 %) ordered to destroy their cryopreserved sperm in case of their expiry.

Out of 133 adolescence, four (3%) gave consent to their parents to use their sperm in case of death, while 97% (129 cases) ordered to discard their sperm in such a case.

Limitations, reasons for caution: Despite the size of the group and the social diversity of its members, the findings might still reflect a local reality.

Wider implications of the findings: These results indicate that despite the value of parenthood in the Israeli society, most single men cryopreserving sperm in face of morbidity/mortality danger do so for their own future live parenthood are not interested in posthumous reproduction

Trial registration number: Not applicable.

O-103 Considerations regarding (non-)use of frozen oocytes or embryos for embryo transfer after fertility preservation in young breast cancer survivors.

E. Butalid[1], I. Vriens[2], R. Van Golde[3], J. Derhaag[4], B. Van Bree[3], C. De Die - Smulders[5], V. Tjan- Heijnen[2], L. Van Osch[5]

[1]MUMC+, Obstetrics and Gynaecology, Utrecht, The Netherlands ; [2]MUMC+, Oncology, Maastricht, The Netherlands ; [3]MUMC+, Obstetrics and Gynaecology, Maastricht, The Netherlands ; [4]MUMC+, Embryology, Maastricht, The Netherlands ; [5]MUMC+, Genetics, Maastricht, The Netherlands

Study question: What are female breast cancer survivors' considerations regarding (non)use of frozen oocytes or embryos for embryo transfer after fertility preservation prior to breast cancer treatment?

Summary answer: Most women report a strong intrinsic motivation to pursue natural conception. Time pressure to become pregnant was the most mentioned consideration to perform embryo transfer.

What is known already: Fertility preservation is used in young women undergoing chemotherapy for early-stage breast cancer. Several groups have reported on the return rate of women for their cryopreserved oocytes or embryos after fertility preservation, varying from 0% to 33%. Insight into the women's underlying reproductive considerations and their preferred mode of conception in this specific situation, are, however largely lacking.

Study design, size, duration: This qualitative study investigated women's deliberation of reproductive options after fertility preservation and breast cancer treatment. Interviews were planned until saturation of themes had been achieved. Sixteen women and three male partners took part in semi-structured interviews between August 2017 and August 2018.

Participants/materials, setting, methods: Interviews were conducted with women who had oocytes or embryos cryopreserved prior to breast cancer treatment, at the Maastricht University Medical Center between October 2008 and March 2015. To achieve heterogeneity, women who had had embryo transfer, who had tried to conceive without embryo transfer and who had not tried to become pregnant after breast cancer diagnosis were included. Grounded theory approach was used for analysis.

Main results and the role of chance: Mean age at breast cancer diagnosis was 29.5 years (range 23-38). Mean time after diagnosis was 4.6 years (range 2-8). There was a strong intrinsic motivation to pursue natural conception, which was strengthened by psychological, practical and physical considerations. Reported psychological considerations included that trying spontaneously felt more relaxed and would save 'the back-up option' (i.e. the frozen oocytes or embryos). A practical consideration was that hospital visits or medicines were not needed. Time pressure to become pregnant quickly was a major issue among women who considered embryo transfer, which was considered as a faster method. Time pressure was experienced due to interruption of adjuvant endocrine therapy or the feeling that conception was already delayed because of breast cancer treatment. The wish to use pre-implantation diagnosis (PGD) treatment for hereditary breast cancer disease was another consideration to opt for embryo transfer. Furthermore, women considered the physician's advice as a strong influence to choose for either mode of conception. Women did not have any regret regarding the fertility preservation procedure and regarded the presence of oocytes or embryos as a back-up plan as psychologically reassuring.

Limitations, reasons for caution: During the study participants were in different phases of family planning. This possibly is causing recall bias in the reporting of original considerations. Some already completed their family for some years. Others were still using adjuvant endocrine therapy and may not oversee future considerations.

Wider implications of the findings: The lack of regret and the psychological reassurance of a back-up plan could be supportive for women who opt for fertility preservation. Since time pressure and PGD were the most reported considerations for embryo transfer, well-thought-out counseling about the mode of conception should be done by a reproductive specialist.
Trial registration number: n/a

O-104 Development and testing of an online fertility preservation decision aid for female cancer patients

M. Van den Berg[1], C. Beerendonk[1], A. Bos[2], M. Boshuizen[3], D. Determann[3], R. Van Eekeren[4], C. Lok[5], E. Schaake[6], E. Witteveen[7], M. Wondergem[8], D. Braat[1], R. Hermens[9]

[1]Radboud University Medical Centre, Obstetrics and Gynaecology, Nijmegen, The Netherlands ; [2]University medical center Utrecht, Obstetrics and Gynaecology, Utrecht, The Netherlands ;
[3]Patientplus, Medical writer, Utrecht, The Netherlands ;
[4]Rijnstate hospital, Surgical oncology, Arnhem, The Netherlands ;
[5]Antoni van Leeuwenhoek, Gynaecology, Amsterdam, The Netherlands ;
[6]Antoni van Leeuwenhoek, Radiotherapy, Amsterdam, The Netherlands ;
[7]University medical center Utrecht, Medical oncology, Utrecht, The Netherlands ;
[8]Amsterdam UMC- locatie VU, Hematology, Amsterdam, The Netherlands ;
[9]Radboud University Medical Centre, IQ Healthcare, Nijmegen, The Netherlands

Study question: What are female cancer patients' experiences with an online developed fertility preservation decision aid (DA) tailored to cancer type and associated cancer treatments?
Summary answer: Female cancer patients considered the DA very helpful in decision-making, particularly the personalized information and the value clarification sheet for recognizing personal values in decision-making.
What is known already: Decision-making regarding future fertility is very difficult and complex for female cancer patients. The decision has to be made in a very short time frame in a period with great emotional distress. As a consequence, patients experience decisional conflict regarding this decision. To support female cancer patients and to decrease their decisional conflict, fertility preservation (FP) DAs are being developed. However, in order to make a well-informed decision, patients need personalized information tailored to their cancer type and treatment. DAs that provide information based on cancer type and treatment are not available yet.
Study design, size, duration: The DA was systematically developed by a multidisciplinary steering group in 2019 using recommendations published by Coulter and the International Patient Decision Aid Standards. Patients' and professionals' needs in decision-making were identified by in-depth interviews with female cancer survivors and oncofertility professionals. Patients' experiences with the DA were evaluated with semi-structured interviews with female cancer survivors by using the think aloud method and by questioning the acceptability, usability, comprehensibility, and readability of the DA.
Participants/materials, setting, methods: The DA steering group (N=21) consisted of representatives of healthcare professionals working in female oncofertility care throughout the Netherlands, patient association representatives (adolescent and young adult, breast, gynaecological and haematological cancer), researchers with expertise in shared decision-making and medical writers. After an iterative process of reviewing and revising with the steering group, the DA was evaluated with female cancer survivors recruited from a tertiary hospital and patients' associations.
Main results and the role of chance: Patients and professionals expressed a need for information tailored to cancer type with associated cancer treatments and infertility risks in the DA. Furthermore, the following information was considered important: infertility risks associated with cancer treatment; burden/risks and pregnancy chances of fertility preservation treatment; consequences of the decision for future fertility; and patients' personal values in decision-making. These preferences complemented with the national fertility preservation guideline formed the basis for the development of the DA.

Several face-to-face and online meetings were held with the steering group to discuss and review the structure and content. After reaching consensus, 17 female cancer survivors and patients' representatives were interviewed while using the DA.

Patients were satisfied with the content and lay-out of the DA and considered it very helpful in decision-making. In particular, the cancer-specific information and the value clarification sheet for recognizing their personal values was of great value. All patients would have liked to use the DA if this was available. To improve the DA, the following was suggested: clarify navigation through DA, make tables and graphs more readable, personalize DA more by letting choose which FP options to read about, and emphasize that the DA does not replace oncofertility consultations.
Limitations, reasons for caution: Bias could have occurred because most interviewed patients had a strong wish to conceive prior to decision-making. Patients who have doubts about their wish to conceive and refrain from a treatment may make their decisions based on different information and values.
Wider implications of the findings: After revising the DA according to the improvement suggestions, the tool is ready for implementation into routine clinical practice. Future studies should evaluate if the DA reduces decisional conflict and decision regret regarding fertility preservation decision-making.

Abstract text

The mRNA translational program and the control of nuclear and cytoplasmic events 20/02/2020: Changed by ESHRE Chairs

After a prolonged phase of growth and accumulation of cytoplasmic and nuclear components, a fully-grown mammalian oocyte undergoes a series of more rapid changes in preparation for fertilization and acquisition of totipotency. All these changes are thought to be essential to produce a "good quality egg" that supports embryo development after fertilization. Although the events associated with nuclear maturation are relatively well described and linked to generation of an egg of the correct ploidy, much less is known about the molecular changes in the cytoplasm of an oocyte. To investigate these processes, we have focused on the program of maternal mRNA translation taking place during meiotic maturation and at the oocyte-to-zygote transition. Since transcription is silent at these stages, gene expression is entirely dependent on RNA translation. Taking advantage of a novel RNAseq strategy to quantify mRNA translation, we have generated a blueprint with genome-wide resolution of the changes in translation during both mouse oocyte growth and meiotic maturation. Analysis of these data show that a switch in the pattern of maternal mRNA translation takes place at the time of oocyte reentry into the meiotic cell cycle. Translation of mRNAs coding for proteins required during oocyte growth, including those involved in ribosome and mitochondrial biogenesis, ceases. Conversely, translation of mRNAs for cell cycle components, for chromatin remodeling, and for the transcription machinery that will be used in the embryo becomes activated. Preliminary data show that similar regulation occurs in human oocytes although with different timing. Translational inhibition of specific mRNAs including those coding for the histone variant H3.3 causes delayed developmental defects in the zygote and in the early embryo. In the same vein, defective translation of cell critical cycle components yields aneuploid oocytes and compromised pregnancy. We show that oocyte manipulations known to decrease oocyte quality, including denudation or disruption of endocrine or paracrine signaling in the somatic compartment, also affect the program of maternal mRNA

translation. Remarkably, preliminary data strongly suggest that translation of maternal mRNAs is also disrupted in oocytes during maternal aging. Taken together, these data demonstrate that execution of the maternal mRNA translation program during oocyte maturation is essential to produce a good quality egg and suggest that translational defects are a cause of the compromised developmental competence observed during maternal aging. Supported by NIH P50 HD055764 and R01 GM116926.

O-107 Dynamics of the epigenetic landscape in blastocyst development and stem cell models

P. Rugg-Gunn[1]

[1]*Babraham Institute, Epigenetics, Cambridge, United Kingdom*

Abstract text

Epigenetic processes are essential for regulating the spatiotemporal patterns of gene expression in development. Upon fertilisation, terminally differentiated gametes undergo extensive and genome-wide epigenetic reprogramming as they become totipotent zygotes. These events establish distinctive chromatin states and are thought to enable the efficient activation of zygotic transcription. As the embryo develops, differences in chromatin patterns are established between embryonic and extraembryonic tissues that reinforce lineage specification decisions. Excitingly, the recent development of genome-wide, epigenetic profiling methods that can examine low cell numbers, including single cells, have opened up the possibility of directly investigating the links between chromatin states and lineage specification and also the molecular basis for proposed mechanisms such as lineage priming.

Another exciting development in the field, and one that complements our expanding knowledge of human embryos, is the progress that has been made in using human pluripotent stem cells (hPSCs) as in vitro models to understand the early stages of human embryo development. Recent work has captured hPSCs in multiple states that are broadly termed naïve and primed. Both cell states can self-renew, but are functionally and molecularly distinct. Naïve hPSCs largely recapitulate the transcriptome and epigenome of pre-implantation embryos, and primed hPSCs are similar to early post-implantation embryos. This is an important distinction because these two developmental stages differ enormously in gene regulation and in epigenetic hallmarks such as X-inactivation status and DNA methylation. The research in my laboratory is focused on understanding the mechanisms of epigenetic and gene regulatory changes as hPSCs transition between the two states, with the aim of applying that information to more precisely control cell fate decisions and to better understand human development. Some of our work has also uncovered major differences in developmental strategies that exist between humans and other species in the control of epigenetic events, such as X-chromosome regulation. I will discuss our recent progress on these topics in my seminar.

O-111 Development and evaluation of a preconception health online learning module for nurses in primary care

K. Hammarberg[1]

[1]*Monash University, School of Public Health and Preventive Medicine, Melbourne, Australia*

Abstract text

It has long been known that a woman's health and health behaviours during pregnancy are crucial for pregnancy health and the health of the newborn. There is now growing evidence that poor maternal and paternal health before conception can result in difficulties conceiving, pregnancy complications, impaired fetal growth, poor birth outcomes, and short and longer-term health problems for children [1].

Nurses and midwives who provide primary health care are ideally placed to opportunistically discuss pregnancy intention and promote preconception health with people of reproductive age. However, we have established in two separate studies conducted in collaboration with nurses and midwives, that although nurses and midwives believe it is part of their role to promote fertility and preconception health in their practice, they rarely do so because they lack the knowledge, skills, and resources to initiate conversations about optimising health before conception [2, 3]. Almost all nurses and midwives in these studies agreed that more information and education about preconception health would increase their confidence to discuss it with their patients.

'Your Fertility' is an Australian government funded fertility and health promotion program. In collaboration with the Australian Primary Health Care Nurses Association (APNA), and using co-design where nurses and midwives contributed to the development work, members of 'Your Fertility' developed an evidence-based online learning module to assist nurses and midwives working in primary health care settings promote preconception health in their practice. We are currently conducting an evaluation where participants complete a brief online survey before and after completing the learning module. This will allow us to assess if the online learning module improves knowledge about and attitudes towards promoting preconception health in clinical practice. The second survey will also include questions about participants' perceptions of the acceptability, salience, and comprehensibility of the learning module.

In my presentation I will describe the development and evaluation of this preconception health online learning module for nurses in primary care.

O-112 The midwife-led development of e-based pre-conception care programme

I. Delbaere[1]

[1]*VIVES University of Applied Sciences, Health care, Kortrijk, Belgium*

Abstract text

As in most European countries, a large proportion of Flemish women start to late with the intake of folic acid preconceptionally. A study of Hoppenbrouwers et al. addressing this issue, was the motivation for the Flemish Minister of Welfare, Public Health and Family to launch a website on preconception care 'gezondzwangerworden.be' (getting pregnant healthy) in 2015.

For the preparation of this website, preconceptional and prenatal guidelines were assessed by means of AGREE II. Topics for the website were selected by an internal committee of 5 experts and an external committee of 16 experts. Content was developed, based on guidelines and content validation was carried out by 40 experts.

When the website was launched, there was press communication and professional societies of midwives, obstetricians and family medicine were informed. Unfortunately, there were no resources for large communication strategies. Nevertheless, the website is visited by a growing number of couples and health care providers (currently 800 visitors daily). However, the intended effect on folic acid intake remains unclear.

Recently, the website was transformed formally. An included lifestyle test enhances interaction with visitors and enables tailored advise. Although this website with preconception advise includes information about the effect of age on fertility, this is not the most optimal platform to increase fertility awareness, in that couples visiting the website mostly already decided to start a family. In order to inform people about the impact of age on fertility, we developed an interactive tool 'klaarvoorkinderen.be' (ready for children). The aim of this tool is to encourage individuals and couples to reflect about parenthood on the one hand and to inform them on the other hand. The tool was developed in cooperation with professionals of different disciplines and was finetuned after focus group discussions with the target audience. Within these focus groups in different age groups, men and women were involved, as well as people with a desire to start a family and people who did not want children.

In Europe, a growing number of e-based preconception tools with evidence-based information is now available to inform the public about optimal preparation for a healthy pregnancy. These websites can be useful for healthcare providers as well, as a tool of guidance in preconception consultations.

SELECTED ORAL COMMUNICATIONS

SESSION 31: PREDICTIVE ALGORITHMS IN CLINICAL EMBRYOLOGY

07 July 2020 Parallel 1 10:00 - 11:30

O-113 Compared to traditional statistics, using machine learning algorithms increases prediction of euploidy in human embryos from weak (61%) to acceptable (72%)

S. De Gheselle[1], **J. Chambost**[2], **K. Declerck**[1], **C. Jacques**[2], **I. De Croo**[1], **C. Hickman**[2], **K. Tilleman**[1]

[1]*Ghent University Hospital, Department for Reproductive Medicine, Gent, Belgium ;* [2]*Apricity, Apricity, Paris, France*

Study question: To compare the ploidy prediction capability of traditional statistics versus machine learning when assessing human embryo morphokinetics.

Summary answer: Compared to traditional statistics, using deep learning algorithms increases prediction of euploidy in human embryos from 61% to 72%.

What is known already: Use of traditional statistics to predict PGT outcome using embryo morphokinetics has been attempted by various groups, with conflicting results as to whether it is possible to find significant morphokinetic markers to predict ploidy status of embryos. Conflicting results may be due to differences in approach. The main limitation is that regression analysis cannot exploit interconnections between predictors, whilst artificial intelligence approaches can. To our knowledge, this is the first attempt to compare the efficacy of prediction of traditional statistics with machine learning approaches in IVF. Moreover, there are limited studies using machine learning predictors to assess morphokinetic parameters.

Study design, size, duration: Traditional statistics and machine learning methods were used to assess the same retrospective dataset, (Jan2016-Dec2019) consisting of 445 biopsied embryos (129cycles) analysed for morphokinetic development using time-lapse imaging (EmbryoScope™). Trophectoderm biopsy was performed on day5 (D5) or 6 (D6). PGT for structural rearrangements or aneuploidy screening was performed by Next Generation Sequencing(NGS). The embryos were classified as either euploid [n=222 (178 D5, 44 D6)] or as displaying a chromosomal anomaly [n=223 (168 D5, 55 D6)].

Participants/materials, setting, methods: Input included morphokinetics (17 absolute and 7 time-interval timepoints), patient (such as age) and cycle (number of injected oocytes, 2pn fertilized, embryos biopsied) characteristics. Multiple logistic regression (MLR) analysis was performed on log-transformed morphokinetics parameters (SPSS) and on the entire dataset. For Machine learning; a random forest model (RFM) was used (80% of the dataset as training set and 20% as testing set). ROC analysis was performed to analyse the performance of the two approaches.

Main results and the role of chance: Using MLR (data displayed as geometric mean), only the following inputs were significantly different in embryos displaying a chromosomal numerical and/or structural anomaly versus embryos with an euploid profile respectively: t9+[72.61h versus 70.96h;p=0.007], tSC [82.60h versus 83.17h;p=0.05], tM [92.26h versus 92.47h;p=0.047], the time interval for the duration of compaction (tcomp) [8.32h versus 7.56h;p=0.043] and patient age (33.8 ± 4.6y vs 32.5 ± 4.0 years;p=0.031) achieving an AUC of 61% (CI: 56%-67%).

Using machine-learning, it was found that each absolute time point needed to be normalized by its previous morphokinetic parameter to reduce redundancy. The ranking of importance in predicting ploidy was tsC, t9+, t7, age, tM, t3, t6 and tPB2 (importance greater than 0.05). The following parameters approached significance (tB, tPNf, tSB, importance greater than 0.04). The remaining parameters, on their own, were not significantly predictive of ploidy. The top 7 parameters explained only 37% of the ploidy prediction, emphasizing the importance of using multiple datapoints for prediction of ploidy. This may explain discrepancies between previous papers in attempting to find a relationship between morphokinetics and ploidy.

Machine learning achieved an AUC of 72% (CI: 68%-77%) in the testing data set which was significantly higher than achieved with traditional statistics.

Limitations, reasons for caution: Dataset derived from a single clinic: generalization of results for other clinics was not assessed. Future work will include deep learning methodology on larger datasets with more diverse datapoints, using a data sharing hub, increasing data size, complexity and diversity to optimize the capabilities of machine learning in ploidy prediction.

Wider implications of the findings: Machine-learning raised the accuracy from 61% (weak) to 72% (acceptable) compared to MLR. Given the vast amount of variables impacting ART outcomes, traditional statistical methods should be replaced with machine learning and artificial intelligence approaches, becoming the new established standard for modelling prediction in ART.

Trial registration number: BC-07095

O-114 A universal algorithm is available in last generation time-lapse incubators: embryo score provided by the KIDScoreD5 is strongly correlated with chromosomal status and clinical outcomes.

L. Bori[1], F. Meseguer[1], M.A. Valera Cerdá[1], L. Alegre[2], A. Tejera[2], J. Remohí[3], M. Meseguer[2]

[1]IVIRMA, Research laboratory, Valencia, Spain ;
[2]IVIRMA, IVF laboratory, Valencia, Spain ;
[3]IVIRMA, Co-President, Valencia, Spain

Study question: Is the inbuilt software in EmbryoScope and EmbryoScopePlus systems useful to identify embryos with normal chromosomal status and high potential to achieve a live birth?
Summary answer: The embryo score provided by KIDScoreD5 algorithm is highly different depending on chromosomal status and the likelihood of achieving a pregnancy and a live birth.
What is known already: Time-lapse technology has allowed embryologists to develop selection algorithms with morphological and morphokinetic parameters. Numerous models have been described, but no one has yet been sufficiently consolidated for universal use. The EmbryoScope and EmbryoScopePlus systems include a selection method, KIDScoreD5, which classifies the embryos in categories based on cleavage time points and blastocyst appearance. The version 2 (v2) considers PN, t2, t3, t4, t5, tB and trophectoderm quality. Later, the Inner Cell Mass quality was added in version 3 (v3). To our knowledge, this is the first time that these newest versions are validated with such a large sample size.
Study design, size, duration: This retrospective analysis including 22,461 embryos from 2017 to 2019 was performed in IVI Valencia. Embryos were cultured in the time-lapse systems EmbryoScope and EmbryoScopePlus and routinely evaluated by senior embryologists according to the ASEBIR criteria. The EmbryoViewer software automatically detected morphological and morphokinetic parameters. If some error occurred, it was manually modified. Then, embryos were graded using the KIDScoreD5 algorithm in different scores from low to high quality (1-9.9).
Participants/materials, setting, methods: The KIDScoreD5 algorithm was tested with 7,857 embryos for v2 and 14,604 for v3. The embryo score was compared with the morphological grade assigned by embryologists, from A to D and excluded embryos. The correlation between the score of 3,311 embryos that underwent preimplantation genetic testing with their normal or abnormal chromosomal status was also studied. Finally, the association between the embryo score and clinical outcomes was analyzed in 3,296 Known Implantation Data (KID) embryos.
Main results and the role of chance: The comparison between the embryo score provided by the KIDScoreD5 and the category assigned by embryologists showed a direct association*. The means in V3 were 8.2 ± 1.2 for A; 5.7 ± 1.4 for B; 3.6 ± 1.2 for C, 2.2 ± 1.0 for D and 1.8 ± 0.7 for excluded embryos. Regarding the chromosomal status, embryos with normal content had significantly* higher score than abnormal ones. The score means and standard deviations for the newest version were 4.6 ± 1.8 for abnormal embryos and 5.3 ± 1.9 for normal ones. Embryos with higher marks achieved significantly* more implantation rate and live birth rate in both versions. Following results belong to V3 and are presented per quartiles of similar sample size. The implantation rates were 41.0% for score < 5.3, 54.2% for score 5.4-6.4, 59.3% for score 6.5-7.4 and 67.9% for score >7.5. The live birth rates were 20.2% for score < 5.3, 25.1% for score 5.4-6.4, 40.3% for score 6.5-7.4 and 48.6% for score >7.5. In addition, V3 was capable of distinguishing between implanted and non-implanted good quality blastocysts (A+B)*. The score means were 6.8 ± 1.5 for implanted good quality embryos and 6.4 ± 1.6 for non-implanted ones.
*p<.05
Limitations, reasons for caution: This project is limited by its retrospective and single-center nature. Multicenter validation would be necessary to corroborate the universal use of the KIDScoreD5 algorithm included in last generation time-lapse incubators.
Wider implications of the findings: This study showed the capability of the KIDScoreD5 in distinguishing between potential embryos with similar morphological characteristics. Therefore, embryo score could help embryologists to make decisions. Recently, time-lapse technology has taken a step forward towards automated annotations. The combination of universal selection models and automatism could improve the embryo selection.
Trial registration number: not applicable

O-115 Artificial Intelligence (AI) system combining both images and non-image inputs can improve the accuracy of human embryo viability prediction

I. Miyatsuka[1], K. Shimizu[1], T. Trisitichoke[1], A. My, Le[1], N. Enatsu[2], M. Inubushi[2]

[1]NextGeM Inc., Data science, Tokyo, Japan ;
[2]Hanabusa Women's Clinic, Reproductive Medicine, Kobe-Hyogo, Japan

Study question: Can an ensemble artificial intelligence (AI) system which uses both images and non-image features enhance the accuracy of embryos viability prediction?
Summary answer: Compared to conventional embryologist morphology assessments and image-based AI algorithms, predicting embryo viability using ensemble AI models yielded 30% and 4% improvement in accuracy respectively.
What is known already: Recent studies have demonstrated the ability of AI and computer vision to outperform traditional morphological assessments at predicting the likelihood of clinical pregnancy using images of human embryos. Existing algorithms, however, focus exclusively on using embryo images while neglect other non-image inputs such as patients inspection history and embryos hormonal profiles. An ensemble AI model which allows for mixed inputs can simultaneously evaluate both image and non-image data, thus enhancing the accuracy of identifying embryo viability by positive fetal heartbeat.
Study design, size, duration: A retrospective analysis using 19,342 static Day-5 blastocyst images with related inspection histories from 9,961 infertile patients undergoing IVF or ICSI treatment at Hanabusa Women's Clinic between January 2011 and August 2019 was conducted. Hormonal profiles are available for 1,358 embryos. Since the ensemble AI model requires both patients inspection histories and embryos hormonal profiles as inputs, development of such models was restricted to this subset of 1,358 embryos.
Participants/materials, setting, methods: All 19,342 blastocyst images are from single embryo transfer with known pregnancy outcomes. Images were converted into grayscale and rescaled into a resolution of 800x600 pixels. Two types of algorithms were evaluated: an image-only model and an ensemble model which combines deep learning algorithms for image inputs and machine-learning algorithms for non-image inputs. Due to limited sample size (1,358), predictive accuracy for the ensemble model was evaluated by the 10-fold cross-validation method.
Main results and the role of chance: Out of 19,342 Day-5 blastocysts (7,717 with fetal heartbeat), 1,358 embryos containing all the required image and non-image inputs are reserved for testing purpose. The remaining 17,984 images were split into training (~90%) and validation (~10%) sets for the development of an image-only AI model. The ensemble AI model, on the other hand, were trained and tested using only 1,358 embryos in the testing dataset.

Accuracy is used as the main measure to evaluate the performance of AI algorithms and defined as the percentage of both viable and non-viable embryos correctly identified by the AI models.

All blastocyst images were graded by experienced embryologists according to the Gardner scoring system. The prediction accuracy of the embryologist morphology assessment is calculated as the percentage of grade 3-6 embryos which resulted in positive pregnancy with fetal heartbeat and is set as the benchmark rate at 49.8%.

The accuracy rate achieved by the image-only AI model was 62.7%. The accuracy rate achieved by the ensemble AI model was 65.2%, representing an improvement in prediction accuracy of 4% when evaluating against image-only AI model and 30% when evaluating against the visual inspection method performed by embryologists.
Limitations, reasons for caution: Samples were collected from one clinic which can limit our results' reproducibility. The accuracy of the ensemble AI model is limited by the small number of embryos that we used. Non-image features in the current model do not include information related to male factor data and the embryo culture process.
Wider implications of the findings: Even with limited training dataset, our results indicate that we can improve the accuracy of predicting good-quality embryos by incorporating relevant non-image features. Future models may allow for embryo quality prediction at even earlier embryonic stages prior to syngamy.

[6]Safe Fertility Center, IVF Laboratory, Bangkok, Thailand

Study question: Can computer vision image annotation techniques be used alongside machine learning to provide reliable blastocyst evaluation that is robust to different camera or microscope types?
Summary answer: AI that combines automated embryo annotation, trained on optical microscope images alone, generalises to yield high accuracy and consistency for time-lapse derived images.
What is known already: Recent studies have shown that AI and computer vision can improve embryo selection and accurately predict clinical pregnancy from images of human embryos at a fixed time point (e.g. Day 5). These results are expanded to consider techniques that are robust to camera and microscope type, and objective focal length, including snapshots taken from cameras used in time-lapse incubators. Computer vision detection and segmentation techniques are able to improve the distribution of AI ranking scores, showing consistent accuracy when using EmbryoScope or (preliminary) GERI time-lapse incubator data, with only 2.2% sample deviation of accuracy across six different focal lengths.
Study design, size, duration: The original Life Whisperer model (VerMilyea et al, 2020), was retrained using extensive image augmentation, 2,530 non-time-lapse incubator microscope images of Day 5 blastocyst embryos, and related clinical pregnancy outcomes, from four US laboratories, two Australian laboratories and one New Zealand laboratory. The AI includes embryo-detection and segmentation to maximize generalizability across different imaging modalities. The AI was applied to double-blind datasets of optical microscope, EmbryoScope (Malaysia/Thailand) and GERI images from the US.
Participants/materials, setting, methods: 3,470 separate optical microscope, 221 EmbryoScope, and 38 GERI images from patients undergoing fertility treatment at 12 IVF laboratories in five countries were used to train, validate and test the AI accuracy, distribution, robustness to camera/microscope type, and objective focal length. Only images of Day 5 blastocysts for which pregnancy (heartbeat at first scan) outcome was known, were used. This study was determined exempt from IRB review by Sterling IRB, USA (#6467).
Main results and the role of chance: This is the first study to show that AI trained on standard Day 5 microscope images can generalize to time-lapse incubator images, demonstrating the robust and camera agnostic nature of this approach.

The AI accuracy for prediction of clinical pregnancy (fetal heartbeat) was 65.4% when averaged over a blind test set of Day 5 blastocyst images from 10 IVF clinics in four countries. The sensitivity of the AI was 86.2%, while the specificity varied depending on the curation of the dataset. New blinded datasets of Day 5 single images of blastocyst stage embryos from the EmbryoScope and GERI time-lapse systems were then assessed with the AI. The AI generalized well to the time-lapse derived images and consistent overall accuracy (59.1%) was achieved, with a sensitivity of 77.9%. Multiple focal lengths were also considered and showed only a 2.2% deviation of accuracy. Together these results suggest that this method of pre-processing and automated annotation, as well as AI trained on a globally diverse dataset, creates a generalizable AI that is robust to camera type and focal setting.
Limitations, reasons for caution: The GERI data set is small and therefore analysis of the distribution of scores from this set should be expanded. Additional consideration of camera effects and focal lengths from both EmbryoScope and GERI devices across a wider range of clinics should also be considered.
Wider implications of the findings: Constructing AI that is robust to image variation represents an advancement in the computer vision field. Applying these techniques to blastocyst-stage embryos demonstrates that AI can be robust and generalizable to different clinical environments. This suggests that AI in the clinical embryology setting is practical and scalable, regardless of hardware.
Trial registration number: Not Applicable

O-117 Automated evaluation system based on artificial intelligence and visualization technology can effectively improve the accuracy of blastocyst evaluation

S. Wang[1], L. Chen[1], C. Zhou[2], D. Zhang[2], H. Sun[1]

[1]The Affiliated Drumtower Hospital, Reproductive Medicine Center, Nanjing-Jiangsu, China ;
[2]GrowthEngine Information Technology Co.- Ltd., artificial intelligence laboratory, Beijing, China

Study question: In deep learning based human blastocyst image classification, where are the essential features from?
Summary answer: In deep learning based human blastocyst image classification, the essential features are from trophectoderm(TE) , inner cell mass(ICM) and zona pellucida(ZP).
What is known already: Deep learning is a kind of algorithms that use artificial neural networks as a framework to learn features from data. Deep convolutional neural networks have rapidly become dominant in medical image automatic analysis. There have been related automatic grading studies in the field of reproduction, but features used in deep leaning based medical image classification basis have not been explained.
Study design, size, duration: This study retrospectively analyzed the image of 1025 blastocysts from March 2017 to August 2018 at the center for Reproductive Medicine of Affiliated Drum Tower Hospital of Nanjing University Medical School in China.By mapping different grading to good quality blastocysts(graded 4 or higher,ICM or TE is not C)and poor quality blastocysts(graded less than 4,or ICM or TE is C).We randomly divided the images into training(80%), validation(10%) and test(10%) set.
Participants/materials, setting, methods: 10957 images of blastocysts were obtained by excluding images of incomplete or fuzzy embryos.The embryo classification model based on the convolutional neural network VGG-16 was on the training set based on transfer learning. Receiver operating characteristic (ROC) Curve and Area Under Curve (AUC) are used as performance measure of the classification model. Grad-cam algorithm is used to visualize the classification features of the model, and it is displayed in the form of thermal diagram.
Main results and the role of chance: An independent test set of 1,104 images of blastocysts acquired at 116±1h after fertilization was used to evaluate the quality assessment model of blastocysts, which achieve an accuracy rate of 91.74%. The AUC of the image classification model of blastocyst can reach 0.970. Using Grad-cam algorithm to visualize all blastocyst stage embryo images on the test set, it was found that key features relied on by the classification model were on TE, ICM, and ZP.
Limitations, reasons for caution: In order to further verify the features relied on in image classification of the model, multi-center blastocyst images are needed.
Wider implications of the findings: Automatic evaluation of blastocyst images helps to reduce the variability of embryologist assessments. Using visualization techniques to explain classification features can help embryologists understand the principles and functions of deep learning, and to promote the development of deep learning technology in clinical application.
Trial registration number: H2019011

O-118 The migration speed of nucleolar precursor bodies in pronuclei is a predictor of human embryo development

T. Inoue[1,2], S. Taguchi[2], M. Uemura[3], K. Miyazaki[2], Y. Yamashita[2]

[1]Hyogo College of Medicine, Department of Emergency- Disaster and Critical Care Medicine, Nishinomiya- Hyogo, Japan ;
[2]Umeda Fertility Clinic, Department of Gynecology, Osaka, Japan ;
[3]Kobe Gakuin University, Faculty of Rehabilitation, Kobe, Japan

Study question: Does the migration speed of nucleolar precursor bodies (NPBs) in male and female pronuclei (mPN and fPN) affect human embryo development?
Summary answer: In the zygote, having potential to develop into a blastocyst/baby, the migration speed of NPBs was faster, which is a novel predictor of embryo development.
What is known already: NPBs are not considered as simple nucleolar components transmitted from an oocyte to an embryo, and they could participate in genome remodeling during embryo development. In the zygote, pericentromeric, and centromeric heterochromatin surrounds most NPBs in a ring-like shape. NPBs are essential only shortly after fertilization, suggesting that they

might actively participate in centromeric chromatin establishment. Several studies have shown that NPBs are dynamic, and the characteristic NPB pattern may change within a short time during the syngamy process on time-lapse imaging. However, the relationship between NPB migration speed and embryo development is unclear.

Study design, size, duration: After ICSI, migration of 262 NPBs from 47 zygotes (12 patients) were analyzed, and embryonic development was prospectively observed until blastocyst (blastocyst: *n*=25, arrest: *n*=22). The relationship between NPB migration and live birth was retrospectively analyzed from take-home-baby (*n*=10) and negative-clinical-pregnancy patients (*n*=15) in frozen-thawed single ICSI-derived blastocyst transfer cycles. The zygotes were cultured in a time-lapse incubator (Geri+; CO_2, 6%; O_2, 5% at 37°C and 80±20% humidity), and images were recorded every 5 minutes.

Participants/materials, setting, methods: The mPN and fPN were identified by appearance location in a zygote (fPN appearance: just below polar bodies). The central coordinates of mPN, fPN, and 2–5 NPBs/PN were measured by Kinovea (motion capture software). Their central coordinates were confirmed/revised every image and were decided. The migration distance of NPBs between two sequential images was calculated as the standard of central coordinates of PN. Thereafter, the migration speed of NPBs was calculated.

Main results and the role of chance: The migration speed of NPBs was significantly faster in the blastocyst developed group than in the arrested group (mPN: 4.61±1.26 vs. 3.37±0.87 μm/h, *P*<0.001, fPN: 4.06±1.15 vs. 3.34±0.97 μm/h, *P*=0.024). The migration speed of NPBs in mPN was correlated with that of NPBs in fPN (*r*=0.65, *P*<0.001). The timing of blastocyst formation was correlated with the migration speed of NPBs in mPN (*r*=−0.546, *P*<0.002) and had a correlation tendency with that of NPBs in fPN (*r*=−0.367, *P*=0.05). In the arrested group, 68.2% embryos arrested until day 3. In univariate logistic analysis, the blastulation was related to the migration speed of NPBs in mPN and fPN, tPNf, tPNf-tPNa, t2, t2-tPNf, t3-t2, t3-tPNf, t5-t4, and t5-tPNf. In multivariate logistic analysis, the factor associated with blastocyst development was the migration speed of NPBs in mPN (OR: 5.14, 95%CI: 1.20–21.90, *P*=0.027). The migration speed of NPBs in mPN in take-home-baby patients was significantly faster than that in negative-clinical-pregnancy patients (4.64±0.67 vs. 3.75±0.79 μm/h, *P*=0.008). In contrast, the speed in fPN was not significantly different between both groups (4.30±1.24 vs. 3.80±0.92 μm/h, *P*=0.254). The migration speed of NPBs in mPN was correlated with that of NPBs in fPN (*r*=0.603, *P*=0.001).

Limitations, reasons for caution: We could not analyze the migration of NPBs in the z-axis direction. When NPBs were large in number or drastically moved, NPB tracking could not be performed. Although our results did not completely explain the relationship between NPB migration and embryo development, the findings should help in elucidating the relationship.

Wider implications of the findings: The migration speed of NPBs is a novel predictor of blastocyst development. NPB migration speed may add clinical value for embryo selection, which may be associated with live birth, and consequently, the time to live birth could be shorter. The predictor could be an attractive marker for non-invasive embryo selection.

Study question: Which GnRH antagonist protocol maximises ongoing pregnancy rate (OPR) when considering the type of GnRH antagonist, the protocol of initiation, and use of pre-treatment or not?

Summary answer: In pairwise and network meta-analysis of combined studies with GnRH antagonists (ganirelix and/or cetrorelix), OPR was maximised without pre-treatment and after a fixed protocol.

What is known already: Several GnRH antagonist protocols are currently used for ovarian stimulation in the context of assisted reproductive technologies (ART). These are based on the use of the most commonly available GnRH antagonists (cetrorelix and ganirelix), in either a fixed or flexible modality and with or without pre-treatment with oral contraceptive pills (OCPs). However, the effectiveness and safety of the type of GnRH antagonist (cetrorelix or ganirelix), type of protocol (fixed day 5/6 or flexible protocol) and the type of pre-treatment (no pre-treatment [NP] or pre-treatment with OCPs, estrogens, progestins) have not been properly evaluated.

Study design, size, duration: A systematic literature search was performed on 8th December 2018 in MEDLINE, EMBASE, CENTRAL, SCOPUS and Web of Science, according to PRISMA guidelines. Qualitative and quantitative syntheses of all direct (pairwise) comparative data were performed using the random-effects model. A frequentist network meta-analysis was also performed to leverage the power of data from randomized studies that compared various GnRH antagonist protocols with the long agonist protocol, while checking whether the underlying methodological assumptions hold.

Participants/materials, setting, methods: Randomized controlled trials performed on women undergoing controlled ovarian stimulation (COS) for ART treatment that compared different GnRH antagonist protocols (direct data) or a GnRH antagonist protocol with a long GnRH agonist protocol (indirect data) were included. Studies with a day 2/3/4 fixed antagonist protocol were excluded. The effect size of choice for dichotomous outcomes was the relative risk (RR) and uncertainty around these estimates was expressed using 95% confidence intervals (CI).

Main results and the role of chance: The searches resulted in 7,042 studies. Seventy-two studies were included in the systematic review and sixty-nine in the network meta-analysis. Studies were of low-to-moderate quality. There was no difference in clinical pregnancy rates when comparing cetrorelix with ganirelix (RR: 0.99, 95% CI: 0.74 to 1.33; I2=0%; 2 RCTs; 258 participants; low-quality evidence). OPR was not reported for this comparison. Lower OPR was observed after a flexible protocol compared with the fixed day 5/6 protocol (RR: 0.74, 95% CI: 0.58 to 0.96, I2=0%; 5 RCTs; 703 participants; moderate quality evidence) and after OCP pre-treatment compared with NP (RR: 0.79, 95% CI: 0.64 to 0.97; I2=0%; 4 RCTs, n=1,244 participants; moderate quality evidence).

Network meta-analysis of 41 RCTs (n=8,009 women) showed that the use of the fixed-OCP protocol resulted in a significantly lower OPR compared with fixed-NP protocol (RR: 0.84, 95% CI: 0.71 to 0.99; moderate-quality evidence). A flexible-NP protocol may result in lower OPR compared with the fixed-NP protocol; however, this was not statistically significant (RR: 0.85, 95% CI: 0.72 to 1.00; moderate-quality evidence). By comparing all available protocols, the surface under the cumulative ranking suggested that the fixed-NP protocol is most likely to result in the highest OPR.

Limitations, reasons for caution: Limited data for some subgroups (pre-treatment with estrogens or progestins and type of ovarian response) and for live birth; heterogeneity in the criteria used for flexible protocols; limited data directly comparing cetrorelix with ganirelix and, therefore, limited evidence to consider them as equivalent in combined studies comparing GnRH antagonist protocols.

Wider implications of the findings: In the general population, the fixed day 5/6 antagonist protocol without any pre-treatment should be considered the

optimal antagonist protocol. More trials are required to compare the effectiveness of ganirelix and cetrorelix separately, and identify the optimal protocol in women with high or low response.
Trial registration number: Merck KGaA, Darmstadt, Germany

O-120 Influence of the duration of GnRH-antagonist ovarian-stimulation protocol on IVF outcomes in patients with anovulation, endometriosis, premature ovarian failure (POF) and idiopathic infertility.

J. Gómez[1], J.V. Martínez-Sanchis[2], I. Iniesta Mirón[2], P.J. Fernández-Colom[3], J.M. Rubio Rubio[4]

[1]Hospital Universitari i Politècnic La Fe, Laboratory of Human Assisted Reproduction, Valencia, Spain ;
[2]Hospital Universitari i Politècnic La Fe, Laboratory of Reproduction, Valencia, Spain ;
[3]Hospital Universitari i Politécnic La Fe, Laboratory of Reproduction, Valencia, Spain ;
[4]Hospital Universitari i Politecnic La Fe, Laboratory of Reproduction, Valencia, Spain

Study question: To evaluate the effect of the length of ovarian-stimulation protocol on oocyte maturation, fertilization, clinical pregnancy, miscarriage and live births in four different infertile pathologies.
Summary answer: Duration of GnRH-antagonist-ovarian-stimulation protocol had an effect on oocyte-maturation rate in all groups and also pregnancies, live-births and miscarriages in endometriosis and idiopathic infertility patients.
What is known already: In last years, Gonadotropin-Releasing Hormone (GnRH)-antagonist protocols have become in first choice for ovarian-stimulation in infertile women due to its shorter stimulation duration and lower associated risk to suffer an ovarian hyperstimulation syndrome (OHSS). It has been demonstrated that follicular growth, oocyte maturation and endometrial development are affected by the length of gonadotropin stimulation. Very short or long exposure to gonadotropins could have a detrimental effect on oocyte maturity stage and endometrial receptivity, leading to poor embryo development and lower pregnancy rates. There is a lack of studies which evaluate these correlations taking into account the type of female infertility.
Study design, size, duration: Retrospective study which included a total of 3589 ICSI-cycles from January 2015 to December 2019. All patients were stimulated by similar GnRH-antagonist stimulation protocol for different period of time depending on patient's characteristics. Patients were distributed in four groups according to two selection criteria: female infertility pathology (1.Anovulation (n=492); 2.Endometriosis (n=449); 3.POF (n=722); 4.Idiopathic (n=1926) and three different time slots of ovarian-stimulation (≤ 8 days; 9-10 days and ≥ 11 days) into each group.
Participants/materials, setting, methods: Mean age of all patients were 34.47 which ranged from 19 to 40 years old. GnRH-antagonist protocol (Orgalutrant or Cetrotide) was combined to recombinant Follicle-Stimulating Hormone (FSH: ranged 150-300 IU) and human Menopausal Gonadotrophin, (hMG: 6500 IU). Oocyte retrieval was scheduled 36 hours (h) following human Chorionic Gonadotropin (hCG) and inseminated by ICSI at 39-40 h. Embryo transfers were performed on day 2 or 3 taking into account good-scored embryos based on morphological parameters.
Main results and the role of chance: We found a significant increase in oocyte maturation rate in all studied groups with longer periods of ovarian stimulation (1.Anovulation (P-value: 0.016): ≤ 8 days: 72.22^{a}±19.51; 9-10 days: 75.22^{ab}±12.90; ≥ 11 days: 78,86^{b}±13,79; Endometriosis (P-value: 0.011): ≤ 8 days: 71.81^{a}±24.11; 9-10 days: 78.05^{b}±14.04; ≥ 11 days: 80,00^{b}±14.17; 3.POF (P-value: 0.049): ≤ 8 days: 75.18^{a}±28.46; 9-10 days: 75.18^{a}±15.33; ≥ 11 days: 79.64^{b}±11.82; 4.Idiophaty (P-value<0.001): ≤ 8 days: 72.91^{a}±10.53; 9-10 days: 76.37^{b}±6.50; ≥ 11 days: 78.94^{c}±7.48), regardless type of infertility. Fertilization rate was similar in all group and periods of stimulation. Clinical pregnancy rate showed significant differences in Endometriosis-group (2) reaching the highest value (37.12±4.52; P-value:0.013) when patients were stimulated for 9-10 days compared to ≤8 days: 17.86±5.50 and ≥ 11 days: 22.63±38.38. Similar trend was observed in pregnancy rate in POF-group-(3) whereas Anovulation-(1) and Idiopathic-(4)-groups showed a slight increase with shorter stimulation periods (≤8 days) but there were not significant differences. Live birth rate was significant higher (28.41±35.02; P-value:0.011) in Endometriosis-group-(2) when ovarian-stimulation period was 9-10 days whereas in Idiopathic-group-(4) was reached with time slots ≤8 days (27.94±27.16; P-value:0.006). Finally, miscarriage rate was statistically significant lower (14.00±34.24; P-value:0.049) in Idiopathic-group (4) with shorter stimulation periods (≤8 days).
Limitations, reasons for caution: Reduced number of ICSI-cycles in some of studied groups. Baseline levels of FSH and Estradiol (E2) hormones should be included.
Wider implications of the findings: To perform a prospective and randomize study including baseline levels of FSH and E2 in order to standardize the optimal time slot of GnRH-antagonist-stimulation for patients with different types of infertility.
Trial registration number: k

O-121 Comparison of different progestin regimens for pituitary suppression during ovarian stimulation for assisted reproductive technology, a systematic review

B. Ata[1], E. Turkgeldi[2], P. Alexandru[2], S. Guler Cekic[2], S. Yildiz[2]

[1]Koc University, Obstetrics & Gynecology, Istanbul, Turkey ;
[2]Koc University Hospital, Obstetrics and Gynecology, Istanbul, Turkey

Study question: Do progestins differ in preventing premature ovulation during ovarian stimulation for assisted reproductive technology?
Summary answer: All progestins seem to effectively prevent premature ovulation in ART cycles. Low-quality evidence suggests that progestins can effectively prevent premature ovulation in ART cycles.
What is known already: Progesterone secreted by corpus luteum in normal menstrual cycle supresses luteinizing hormone (LH) secretion from the pituitary during the luteal phase. Studies showed that progestins can also supress LH in freeze all assisted reproduction technology (ART) cycles. It is important to inhibit pituitary LH secretion before oocyte pick up and generally gonadotropin (GnRH) antagonists are used to inhibit the LH surge. Progestins are as effective as GnRH antagonists in supressing pituitary LH secretion.
Study design, size, duration: This is a a systematic review of studies comparing the effectiveness of progestins in preventing premature ovulation during ovarian stimulation for ART. We searched several electronic databases, trial registers, and websites from the date of inception until June 1, 2019 for studies, which compared; i) two different progestins or ii) two different doses of the same progestin for pituitary suppression in ART. Only studies published in English as a full text article were included.
Participants/materials, setting, methods: Five randomized trials and cohort studies involving a total of 2404 women., which compared; i) two different progestins or ii) two different doses of the same progestin were included. The primary outcome was live birth rate (LBR) per woman. Secondary outcomes were live birth or ongoing pregnancy (LB/OP) per woman and per embryo transfer (ET), ongoing pregnancy, clinical pregnancy, positive pregnancy test, numbers of oocytes and metaphase-two oocytes, duration of stimulation and gonadotropin consumption.
Main results and the role of chance: Medroxyprogesterone acetate (MPA), dydrogesterone (DYG) and micronized progesterone (MIP) were compared in combinations of two in these studies. None of the studies compared all three progestins together. Three studies compared two different progestins: MPA versus DYG, DYG versus MIP and MPA versus MIP; two studies compared two different dosages of the same progestin 4 versus 10 mg of MPA and 100 mg versus 200 mg of MIP. The primary outcome was not reported in most studies however there were no differences between progestins for secondary outcomes. All progestins seem to effectively prevent premature ovulation in ART cycles. Lower doses of the same progestins were also similarly effective with higher doses.
Limitations, reasons for caution: The presence of a limited number of trials/studies, most of which are not randomized nor accounts for every woman starting stimulation are drawbacks, preventing definitive conclusions on the subject.
Wider implications of the findings: Progestins in general can become a reasonable alternative to GnRH analogues in ART cycles when a fresh embryo transfer is not intended.
Trial registration number: not applicable

O-122 Superiority of cumulative live birth rates after GnRH antagonist cycles relates to ovarian response: a cycle-specific analysis of data from a Japanese national registry

S.C. Jwa[1], M. Takamura[1], A. Kuwahara[2], T. Kajihara[1], O. Ishihara[1]

[1]Saitama Medical University, Department of Obstetrics and Gynecology, Saitama, Japan ;
[2]Graduate School of Biomedical Sciences- Tokushima University, Department of Obstetrics and Gynecology, Tokushima, Japan

Study question: Are cumulative live birth rates (CLBRs) in different ovarian stimulation protocols for assisted reproductive technology (ART) similar in groups with different ovarian responses?
Summary answer: Mild ovarian stimulation (clomiphene citrate [CC] and letrozole) achieves similar or superior CLBRs to GnRH antagonist protocols with suboptimal egg retrieval cycles (< 10 oocytes).
What is known already: CLBR is regarded as the most relevant outcome of IVF and has a strong relationship with the number of oocytes retrieved. To maximize CLBRs per oocyte retrieval, GnRH antagonist protocols are adopted for normal to high responders. However, there have been few reports on selection of ovarian stimulation protocols for suboptimal or poor responders in terms of CLBR.
Study design, size, duration: This is a large retrospective cycle-specific analysis of data from the Japanese ART registry, which includes all ART treatment cycles in Japan. A total of 20,4675 fresh autologous cycles performed in 2014 and 2015 and subsequent 179,313 frozen embryo transfer cycles up to December 2016 were included in the analysis.
Participants/materials, setting, methods: The cycles analyzed were as follows: GnRH agonist (n=66,962), GnRH antagonist (n=56,027) and mild ovarian stimulation using CC alone (n=30,098), CC + gonadotropin (Gn) (n=41,991), letrozole alone (n=4,363), and letrozole + Gn (n=5,234). CLBR per oocyte retrieval was defined as at least one liveborn baby from one fresh and subsequent frozen cycles. Odds ratios (ORs) for cumulative live birth were calculated using generalized linear model.
Main results and the role of chance: The overall CLBR was 27.6%; the highest being with GnRH antagonist protocols (31.2%), followed by GnRH agonist protocols (30.1%), and mild ovarian stimulation protocols (22.6%–24.4%). Compared with GnRH antagonist protocol, all other ovarian stimulation protocols achieved significantly lower overall adjusted ORs for cumulative live birth per oocyte retrieved. Stratification by number of oocytes retrieved revealed that, among high responders (>15 oocytes), GnRH agonist protocols still had significantly less chance of achieving cumulative live birth than GnRH antagonist protocols (adjusted OR, 0.72, 95% CI, 0.68–0.77). Among normal responders (10–15 oocytes), adjusted ORs of CC + Gn and GnRH agonist protocols did not differ significantly from those of GnRH antagonist protocols (adjusted ORs of CC + Gn, 1.04, 95% CI, 0.95–1.14, adjusted ORs of GnRH agonist protocols, 0.96, 95% CI, 0.91–1.01). However, adjusted ORs of mild ovarian stimulation using CC alone (adjusted OR, 1.43, 95% CI, 1.32–1.54), CC + Gn (adjusted OR, 1.07, 95% CI, 1.02–1.12), letrozole (adjusted OR, 1.35, 95% CI, 1.14–1.61) and letrozole + Gn (adjusted OR, 1.43, 95% CI, 1.27–1.61) showed higher ORs than those of GnRH antagonist protocols in suboptimal (<10 oocytes) and poor (<5 oocytes) responders.
Limitations, reasons for caution: Because the registry provides anonymous cycle-specific data, we could not distinguish women who received multiple fresh cycles during the study period. Further, indications for selecting specific ovarian stimulation protocols vary across clinics, potentially causing residual confounding. The registry lacks important confounders such as parity and indicators of ovarian reserve.
Wider implications of the findings: Our results suggest that for patients expected suboptimal or poor ovarian response, mild ovarian stimulation using CC or letrozole may be an alternative option for selecting ovarian stimulation in ART to achieve similar or superior CLBRs to GnRH antagonist protocols.
Trial registration number: This study was supported by Health and Labour Sciences Research Grants.

O-123 Development and validation of a gonadotropin dose-selection model for individualized ovarian stimulation in IVF/ICSI: an individual participant data meta-analysis (IPD-MA).

N. Schouten[1], R. Wang[2], M. Eijkemans[1], B.W. Mol[2], H. Torrance[1], T. Van Tilborg[1], F. Broekmans[1], ORT iOS IPD-MA study group.(3)

Study question: Can a gonadotropin dose-selection model be developed and validated that will help guide ovarian stimulation by maximizing safety without negatively impacting pregnancy/live birth rates?
Summary answer: Development and validation of a gonadotropin dosing-selection model results in a moderately to fairly accurate prediction of treatment effectiveness and safety.
What is known already: Many studies addressed the effect of individualized gonadotropin dosing in IVF/ICSI using ovarian reserve tests (ORTs) including anti-Müllerian hormone (AMH), antral follicle count (AFC) and basal follicle-stimulating hormone (bFSH). A Cochrane review reported no evidence that individualized dosing is effective at increasing ongoing pregnancy/live birth rates (OPR/LB), but may reduce the incidence of ovarian hyperstimulation syndrome (OHSS). Individual patient data meta-analysis (IPD-MA) can be used to develop/validate a universal prediction model to help choose the optimal dose that will maximize safety without a negative impact on OPR/LB and reduce costs by preventing OHSS and use of ineffective high gonadotropin doses.
Study design, size, duration: For this IPD-MA, electronical databases were systematically searched for dosing randomized controlled trials (RCTs) in women undergoing IVF/ICSI. Women were categorized as predicted low, normal or high responders based on ORTs. RCTs comparing different ovarian stimulation doses (standard, adjusted or individualized) were included if the outcomes of interest were reported: OPR/LB and/or (interventions to prevent) OHSS. Eligibility assessment was conducted by two independent reviewers. Corresponding authors of eligible studies were invited to join this collaboration.
Participants/materials, setting, methods: After transfer of the IPD, data were cleaned and inconsistencies were resolved with the corresponding authors. Missing data were imputed 100 times with multiple imputation by chained equations for systematically and sporadically missing multilevel data. Models were developed with logistic regression. Predictor variables were selected after pooling and backwards selection (using $p < 0.3$) and by using background literature. Internal-external cross validation was used to assess prediction model performance.
Main results and the role of chance: A total of 14 RCTs reporting on 3,455 women were included: 762 had an OPR/LB and 171 had a safety event (severe or moderate OHSS or OHSS preventive interventions). Candidate predictor variables were age, body mass index (BMI), AFC, AMH, bFSH, parity, cycle length, duration of infertility, smoking, GnRH-agonist or GnRH-antagonist use and IVF/ICSI. For age and BMI, restricted cubic splines were used. Selected predictor variables for the chance of OPR/LB (the effectiveness prediction model) were age, BMI, AFC and IVF/ICSI. Age, AMH and bFSH were selected as predictors for safety (the safety prediction model). Starting gonadotropin dose (range 75-600 IU) was forced in both models. Internal-external cross validation resulted in 14 area under the receiver operating characteristic curve (AUC) values and confidence intervals (CIs) for the effectiveness prediction model and 10 AUCs and CIs for the safety prediction model. These AUCs were summarized in a meta-analysis forest plot. The resulting overall AUC for the effectiveness model was 0.60 (95% CI of 0.55-0.65), which can be classified as moderately accurate. The resulting overall AUC for the safety model was 0.71 (95% CI of 0.64-0.79), which can be classified as fairly accurate. Heterogeneity was low in both analyses: I^2 was 0%.
Limitations, reasons for caution: Two participating groups are in the process of data transfer/cleaning, therefore these preliminary results may not reflect the final results. In the following months, predictions from these models have to

be combined to develop the clinically adaptable gonadotropin dosing tool. We expect to present this dosing tool at ESHRE.
Wider implications of the findings: This tool may aid in choosing the optimal gonadotropin stimulation dose per individual by minimizing safety risks and maintaining effectiveness in terms of OPR/LB rates. This could potentially reduce treatment costs, by preventing prescription of high gonadotropin doses in low responders and preventing OHSS in high responders.
Trial registration number: CRD42019115489

O-124 Natural micronized progesterone versus a GnRH antagonist in egg-donation cycles. An extended experience.

J.C. Castillo[1], J. Guerrero[1], R. Delgado[2], B. Moliner[1], L. Lydia[1], J. Ten[1], A. Fuentes[1], A. Bernabeu[1], J. Llacer[1], R. Bernabeu[1]

[1]Instituto Bernabeu, Assisted Reproduction Unit, Alicante, Spain ; [2]ACCUNA, Assisted Reproduction Unit, Alicante, Spain

Study question: Is oral natural micronized progesterone equivalent compared to a GnRH antagonist with respect to the oocyte yield retrieved in egg-donation cycles?
Summary answer: Oral natural micronized progesterone is comparable to a GnRH antagonist in terms of total number of oocytes and mature oocytes (MII) retrieved in egg-donation cycles.
What is known already: Studies in own eggs IVF cycles shows that exogenous oral natural micronized progesterone is capable of blocking the LH surge without compromising oocyte competence. The strategy may be also suitable for egg donors (cost effective, patient friendly, oral administration). However, scarce and conflicting evidence is available with regards to its performance in the context of ovarian stimulation in egg donors. The aim of this study is to evaluate the efficacy of oral progesterone compared to a GnRH antagonist protocol in terms of oocyte yield at egg retrieval in a large sample of egg-donation cycles.
Study design, size, duration: Retrospective analysis of egg-donation cycles (n=1090) performed between January 2019 to December 2019 to assess the performance of oral natural micronized progesterone (Progeffik® 200 mg/d) versus cetrorelix (Cetrotide® 0.25 mg/day) in ovarian stimulation cycles triggered with triptoreline acetate (Decapeptyl® 0.2 mg). The clinical outcomes per embryo transfer in matched recipients (n=598) receiving a fresh embryo transfer were also assessed.
Participants/materials, setting, methods: All participants received urinary FSH (Fostipur® 150-225 IU/d s.c.). The oral progesterone group (n=583) concomitantly received 200 mg/d micronized progesterone per os. The GnRH antagonist group (n=507) received cetrorelix 0 25 mg/d beginning with a leading follicle of 14 mm. Triptorelin 0.2 mg induced the final follicular maturation. Egg collection was performed 36 hours after triggering. The main outcome was the total number of oocytes and the number of MII retrieved at egg retrieval.
Main results and the role of chance: Overall, baseline and cycle characteristics were similar between progesterone and antagonist groups with regards to age: 25.2 (SD 4.4) vs 25.6 (SD 4.3) years old, AFC: 18.1 (SD 6.4) vs 18.5 (SD 7.4), BMI: 22.4 (SD 2.6) vs 22.8 (SD 2.7) kg/m^2; total dose of gonadotropins: 2088 (SD 817) vs 2086 (SD 633) IU and duration of stimulation: 9.8 (SD 1.4) vs 9.9 (SD 1.3) days; respectively. The total number and MII of collected eggs were no different: 15.8 (SD 7.5) vs 15.2 (SD 7.6), p=0.9 and 13.4 (SD 6.9) vs 12.9 (SD 7.1), p=0.7 in the progesterone versus GnRH antagonist group, respectively. In matched recipients, mean number of MII assigned were 9.5 (SD 1.3) vs 9.9 (SD 1.7) coming from the progesterone vs antagonist group, respectively (p=0.009). Fertilization rate was 78% in progesterone versus 75% in the antagonist group (p=0.001). Biochemical pregnancy rate was 64 versus 65% (p=0.7); clinical pregnancy rate 55.9 versus 56% (p=0.9) and ongoing pregnancy rate 47.7 versus 48%, (p=0.9).
Limitations, reasons for caution: Retrospective design. Without a formal sample size, findings after fertilization should be interpreted with caution. Additionally, changes in the laboratory were introduced in second half 2019, when the vast majority of cases received progesterone for LH peak prevention. Prospective, preimplantation genetic testing for aneuploidies studies on the topic are warranted.
Wider implications of the findings: These data, from a retrospective study design, suggest that exogenous progesterone is capable to block the LH surge without compromising oocyte yield or competence. This cost/effective, patient-friendly, oral administration approach may provide conveniences for egg donors thus, facilitating egg donation programs.

O-125 Live Births With a Novel ROSI Technique Using Elongating Spermatids for Non Obstructive Azoospermia Patients: A European Cohort Study

R. Pabuccu[1], S. Sertyel[2], E. Pabuccu[1], K. Aydos[3], A.H. Haliloglu[4], D. Demirkıran[2], G. Keles[5], A. Tanaka[6]

[1]Ufuk University School of Medicine, Obstetrics and Gynecology, Ankara, Turkey ; [2]Centrum Clinic Assisted Reproduction Center, IVF and Andrology, Ankara, Turkey ; [3]Ankara University School of Medicine, Urology, Ankara, Turkey ; [4]Ufuk University School of Medicine, Urology, Ankara, Turkey ; [5]Centrum Clinic Assisted Reproduction Center, IVF Section, Ankara, Turkey ; [6]Saint Mother Hospital., IVF Unit, Fukuoka, Japan

Study question: Can elongating spermatids be used for novel round spermatid injection (ROSI) technique in non-obstructive azoospermia (NOA) patients when no sperms are retrieved during a micro testicular sperm extraction (mTESE) procedure?
Summary answer: A novel ROSI technique using elongating (Sb2) spermatids and electrical oocyte activation reveals promising reproductive outcomes for NOA cases with a failed mTESE
What is known already: NOA is one of the leading causes of male infertility and nearly one half of all mTESE procedures fail to reveal mature spermatozoa for ICSI. For these cases, previously different stages of spermatids have been proposed for ICSI, however, with unsatisfactory reproductive outcomes. Recently, healthy live births were reported following a novel ROSI technique without major adverse events (Tanaka et al., 2018). In brief, selection of spermatids after mTESE, followed by disruption of the cell membrane, separation of the nucleus and intra cytoplasmic injection of the nucleus into electrically-activated oocytes are the basic steps.
Study design, size, duration: A cohort study was performed in a private IVF center from February 2018-December 2019. After urology consultation, all NOA cases underwent mTESE procedure on the day of oocyte pick-up (OPU). Testicular tissue was examined to collect spermatozoa forms when available. Otherwise, elongating (Sb2) spermatids were investigated to be used for the novel ROSI technique. After standard incubation, cleavage stage embryos (day 3) or blastocysts were transferred in either a fresh or frozen-thaw cycle.
Participants/materials, setting, methods: Signed informed consent was obtained from all patients. After mTESE, testicular tissue was evaluated under an inverted microscope with contrast system to classify spermatids if no spermatozoa were seen. After selecting Sb2 forms, elongated spermatid injection was applied, using the novel technology previously described for ROSI. After enzymatic digestion of the testicular tissue, spermatids were isolated, cell membranes were disrupted and finally the nucleus with the remaining cytoplasmic part was injected into electrically-activated oocytes.
Main results and the role of chance: A total of 472 couples underwent 904 cycles using elongating (Sb2) spermatids for the ROSI technique. Cases with the retrieval of mature spermatozoa and elongated spermatids were excluded from the present analysis. The mean age of women and men were 33.5±5 and 37±5, respectively. The mean number of oocytes was 6.6±4. The fertilization and cleavage rates were 49.9% (3024/6052) and 42.5% (2577/6052) respectively. The blastulation rate was 38.9 % (1005/2577). The number of cycles reaching a transfer was 78%. The number of positive hCG tests per ET was 14.2 % (102/714) and the number of ongoing pregnancies beyond 20 weeks was 9.6 % (69/714). A total of 8 live births have been recorded until now from this series, and pregnancies are still undergoing. The total live birth rate from the series will be reported during the conference.

Limitations, reasons for caution: The selection of early spermatogenic cells demands expertise as these cells could be indistinguishable from other round shape cells. Moreover, these cells do not properly trigger oocyte activation, thus electrical stimulation is needed for fertilization. Although early spermatogenic cells are haploid, genetic as well as epigenetic alterations might be possible.
Wider implications of the findings: The novel ROSI technique enables a proportion of males, for whom sperm donation or adoption until now was the only option, to father their own offspring. The present results support that elongating spermatids as an advanced form of round spermatids can be used for ICSI, resulting in healthy offspring.

O-126 The added value of enzymatic digestion to mechanical mincing in testicular sperm retrieval in non-obstructive azoospermia

V. Vloeberghs[1], A. Racca[1], B. Popovic-Todorovic[1], I. Mateizel[2], G. Verheyen[2], H. Tournaye[1]

[1]UZ Brussel, Obstetrics-Gynaecology, Jette- Brussels, Belgium ;
[2]UZ Brussel, Centre for Reproductive Medicine, Jette- Brussels, Belgium

Study question: To evaluate the added benefit of enzymatic digestionto mechanical mincing in testicular sperm retrieval for patients with non-obstructive azoospermia (NOA).
Summary answer: Enzymatic digestion increases the sperm retrieval from testicular biopsies of NOA patients by 32.3%.
What is known already: Although there is increasing evidence that the surgical technique to recover testicular sperm in NOA makes little difference as long as multiple biopsies are taken, the debate on which is the best technique continues. Few studies focus on the role of the lab and even fewer evaluated the benefit of enzymatic tissue digestion in order to improve sperm retrieval rates. Research in this domain has been flawed by heterogeneity of either the NOA diagnosis or the selected patient study population.
Study design, size, duration: A retrospective single-centre cohort study from 2004 till 2017 included all patients who underwent their first diagnostic or therapeutic testicular sperm extraction (TESE) by open biopsy. They all had normal standard genetic workup and subsequent histological confirmation of NOA. Patients who had a history of previous TESE or histological diagnosis of hypospermatogenesis were excluded. Primary outcome was sperm retrieval for either cryopreservation or intracytoplasmic sperm injection (ICSI).
Participants/materials, setting, methods: Up to 6 biopsies were obtained from each testis. In cases with no or insufficient number/quality spermatozoa observed during 30 min after mechanical mincing, enzymatic treatment of residual tissue pieces was performed with collagenase type IV. The results were divided according to the biopsy type (diagnostic or therapeutic). In order to evaluate which factors predicted sperm retrieval, multivariable regression analysis was performed adjusting for the following confounding factors: age, FSH level, testicular volume and histology.
Main results and the role of chance: In total, 425 patients were included. Overall, in 69/425 (16.2%) men, spermatozoa for cryopreservation or ICSI were found after mechanical mincing. In 115/356 (32.3%) patients who had no sperm following mincing, spermatozoa were found after enzymatic digestion. In order to reduce bias in sperm retrieval rate when TESE is scheduled on the day of ICSI (therapeutic) or prior to planning ICSI (diagnostic), these two patient populations were analyzed:316 (74.4%) in the diagnostic and 109 (25.6%) in therapeutic testicular biopsy group. There was no difference in mean age (34.9 vs. 35.9 years), mean volume of testicles (10.9 vs. 10.2 ml), histological diagnosis (Sertoli Cell only 56.1 vs. 56%; maturation arrest 21.8 vs. 21.2%; sclerosis and/or atrophy 19.9 vs. 18.4%) between the diagnostic vs. therapeutic group. FSH was significantly higher in the diagnostic group compared to the therapeutic group (22.3 vs. 18.5 IU/l, p=0.008). Sperm retrieval was significantly higher in the therapeutic vs. diagnostic group both after mincing (24.8% vs. 13.9%, p=0.007) and enzymatic digestion (43.1% vs. 21.5%, p< 0.001%). Multivariable logistic regression analysis showed that enzymatic digestion remained a significant predictor of sperm retrieval, when adjusting for potential confounders.
Limitations, reasons for caution: The main limitation of the study is its inherent retrospective design.
Wider implications of the findings: Enzymatic digestion in addition to mechanical mincing increases sperm retrieval substantially in NOA patients following either a diagnostic or a therapeutic TESE.
Trial registration number: Not Applicable

O-127 Ooplasm-Mediated Sperm Nuclear Decondensation for Heritable Genome Editing of the Mammalian Male Gamete

M.S. Wang[1], P. Xie[1], A. Trout[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can we identify a method to access the DNA of spermatozoa and allow gene editing by CRISPR-Cas9?
Summary answer: An ooplasm-mediated approach is effective in allowing sperm decondensation for CRISPR access and successful genome editing in the mouse.
What is known already: Previous studies on heritable genome editing (HGE) have been carried out at the zygote phase; however, they faced the difficulties of mosaicism and embryo research ethics. These issues may be resolved by first editing the DNA of the gametes. The challenge with spermatozoa, however, resides largely in their distinct structure—they contain tightly packed chromatin, carry no DNA repair mechanisms, and are highly susceptible to damage. Our previous attempts to directly edit spermatozoa DNA required considerable resources but yielded limited results. We hypothesize that an alternative cellular environment may be necessary to allow proper male genome editing.
Study design, size, duration: Over a period of 3 months, 88 oocytes were divided into two groups. One group was used for ooplasm-mediated sperm decondensation (OMSD) to produce haploid embryos containing only DNA from the male. The control group consisted of embryos produced through standard ICSI, following the established HGE approach. Both groups were treated with a CRISPR solution designed to knock out Tyr to create an albino phenotype. Gene editing success was then compared between the groups.
Participants/materials, setting, methods: Oocytes and sperm were collected from B6D2F1 mice. OMSD oocytes were enucleated and allowed 2 hours to rest. All oocytes then underwent ICSI with the addition of a CRISPR-Cas9 solution containing pre-complexed Cas9 protein and Tyr knockout gRNA. Embryos were incubated for 24 hours, and then cryopreserved. Later, DNA was extracted and amplified for T7E1 analysis of the target site.
Main results and the role of chance: Of the 88 oocytes, 31 were enucleated for the OMSD condition, while 57 constituted the control. After undergoing ICSI with CRISPR solution, 74% (23/31) of the OMSD oocytes survived compared to 75% (43/57) of the control. Of those, 43% (10/23) of the experimental group developed to the 2-cell stage, while 70% (30/43) of the control progressed (p<0.05). After extraction, a 423-bp region around the CRISPR target site was amplified. A total of 35 embryos produced a sufficient concentration of DNA, while 3 OMSD and 2 control embryos failed to amplify. Gene modification at the target site was confirmed in 29% (2/7) of OMSD embryos and 36% (10/28) of the control group. We achieved successful genome editing of spermatozoa DNA through the use of ooplasm-mediated sperm decondensation at a comparable rate to zygotic heritable genome editing. It is important to note that these results are likely to be underestimated, since any embryos with completely uniform modifications may not be detected by T7E1.
Limitations, reasons for caution: Currently, sample size is limited. Refining of experimental techniques is needed to improve survival and development rates, and DNA sequencing of blastomeres will provide a more accurate evaluation of editing efficiency. Additionally, off-target effects, mosaicism, epigenetic modifications, and birth rate have yet to be evaluated.
Wider implications of the findings: Once editing efficiency is optimized, individual pseudo-blastomeres of OMSD embryos can be used in place of spermatozoa to fertilize oocytes. Subsequently, the pre- and post-implantation development of offspring that contain the intended genetic modifications can be studied. Our model, if reproduced in human, may prevent the inheritance of paternal mutations.
Trial registration number: not applicable

O-128 A Novel Microfluidics Method for Reliable and Efficient Sperm Sex Selection

R. Elias[1], S. Cheung[1], A. Parrella[1], P. Xie[1], D. Keating[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can selection of Y-specific spermatozoa be achieved through ATP content modulation in a microfluidics system?

Summary answer: Ligand activation on the sperm flagellum decreased motility of the female spermatozoa and ensured expedited Y-bearing spermatozoa selection in a microfluidics chamber.

What is known already: Several techniques have been proposed to successfully select for X- or Y-bearing spermatozoa, such as centrifugation methods, layering techniques, electrophoresis, and flow cytometry. At our clinic, we have been able to carry out sex selection with an 80% success rate with the use of a proprietary density gradient technique that requires over 3 hours of processing. However, it has recently been proposed that modulation of the Toll-like receptor 7/8 (TLR7/8) on the X-bearing sperm flagellum impairs motility and may therefore be effective in sex selection techniques.

Study design, size, duration: In the last 5 years, we processed ejaculates from 98 consenting couples undergoing treatment at our center with a custom multilayer density gradient. The proportion of X- and Y-bearing spermatozoa before and after selection was assessed by fluorescent in situ hybridization (FISH). Cycle pregnancy outcomes and offspring sex were recorded. To expedite our selection process while maintaining sex enrichment, we tested a new method utilizing TLR7/8 ligand activation together with microfluidics.

Participants/materials, setting, methods: A total of 98 couples were treated at our center (IRB 1306014043) in 120 cycles. A proprietary multilayer density gradient method was used to select for sex-specific spermatozoa. We confirmed successful selection by FISH analysis on at least 1,000 cells/specimen. Pregnancy outcomes and offspring sex were assessed and compared. In a new selection technique, we incubated spermatozoa for 45 minutes in HTF medium containing 0.3μM of the TLR7/8 ligand, prior to microfluidics processing.

Main results and the role of chance: Of the couples (maternal age, 36.8±4yrs; paternal age, 39.6±5yrs) included, 53.1% wanted a female child, while 46.9% desired a male child. The initial sperm concentration was 65.4±26x10^6/ml, with 47.7±5% motility, normal morphology, and average sperm aneuploidy of 3.3±4%. After multilayer density gradient selection, sperm concentration decreased to 24.3±14x10^6/ml, while motility rose to 94.5±3% (P<0.0001).

Of the 52 couples who wanted a female child, FISH assessment confirmed a spermatozoa enrichment of 80%, and over 80% of couples obtained a female embryo as assessed by PGT-A. The clinical pregnancy rate for these couples was 25.7% (18/70), with a delivery rate of 61.1% (11/18) of the desired sex; the remaining pregnancies are ongoing.

For 46 couples who desired male offspring, FISH analysis confirmed a successful enrichment for Y-bearing spermatozoa, and over 80% of couples obtained a male embryo. The clinical pregnancy rate for these couples was 28.0% (14/50), and the delivery rate was 57.1% (8/14) of the desired sex; the remaining pregnancies are ongoing. To test our new method, in a separate non-clinical investigation, four additional sperm specimens were processed by the proposed ligand activation technique, yielding >80% enrichment, confirmed by FISH, that was comparable to the more time-consuming multilayer density gradient technique.

Limitations, reasons for caution: Although the TLR7/8 ligand mechanism is not absolutely clear, its effect on the flagellum is reversible and therefore does not affect acrosomal function or viability. Nevertheless, the capacity of spermatozoa selected by this technique to support embryonic development needs further investigation.

Wider implications of the findings: We were able to enhance the proportion of female and male embryos with our current multilayer density gradient technique requiring >3 hours. However, the proposed method incorporating ligand activation and microfluidics would lower this processing time to <1 hour. We are refining this method in order to achieve >80% selection.

Trial registration number: not applicable

O-129 Effect of microfluidic sperm separation versus standard sperm washing processes on fertilization rates, blastocyst development and euploidy rates among all infertility patients

G. Adaniya, E.L.D.- H.C.L.D.- Ph[1], C. Leisinger[2], M. Freeman[3], E. Behnke[4], M. Aguirre[5], T. VerMilyea[6], M. Schiewe[7]

[1]Ovation Fertility, IVF Laboratory, Carmel- IN, U.S.A. ;
[2]Ovation Fertility, IVF Laboratory, Baton Rouge- LA, U.S.A. ;
[3]Ovation Fertility, IVF Laboratory, Nashville- TN, U.S.A. ;
[4]Ovation Fertility, IVF Laboratory, Cincinnati- OH, U.S.A. ;
[5]Ovation Fertility, IVF Laboratory, Las Vegas- NV, U.S.A. ;
[6]Ovation Fertility, IVF Laboratory, Austin- TX, U.S.A. ;
[7]Ovation Fertility, IVF Laboratory, Newport Beach- CA, U.S.A.

Study question: Our goal was to determine if the ZyMōt microfluidic sperm separation device effectively improved ICSI sperm selection and subsequent embryo development applied to a general IVF patient population.

Summary answer: Utilization of a ZyMōt device to process all IVF semen samples (untested for Sperm DNA Fragmentation, SDF) revealed no overall benefit to embryo outcomes.

What is known already: The natural sperm filtering actions of cervical/uterine crypts has been mimicked by a new microfluidic sperm separation device (ZyMōt). Its microporous filter and channels help separate the most motile sperm with normal morphology without centrifugation. In turn, not only does the ZyMōt device claim to reduce procedure-induced reactive oxygen species (ROS) associated with causing SDF, it selectively isolates healthier, progressively motile sperm with lower SDF. Pilot studies suggest that the higher chromatin integrity (i.e., lower SDF) attained for IVF use improves fertilization, embryo morphology and blastocyst euploidy rates. We aimed to test the ZyMōt's proposed developmental benefits.

Study design, size, duration: A prospective, randomized, multicenter, sibling oocyte study was conducted with 86 consenting patients possessing ≥10 oocytes. Non-DFI tested ejaculates underwent a split processing treatment: 1) Control washing procedures (density gradient separation or swim-up) or 2) Treatment - ZyMōt swim out. Each sample was then used to inseminate an equal number of sibling oocytes. Resulting blastocyst were biopsied and NGS tested. Euploid (non-mosaic) embryo selection for ET was randomized. Chi-squared analysis was performed to assess differences($p<0.05$).

Participants/materials, setting, methods: Upon informed consent, partner sperm was processed in parallel by 1) either density gradient centrifugation (DGC) at OF-IN(n=26), OF-OH(n=19) and OF-LA(n=18) or a swim-up wash procedure (OF-TN,n=23); or 2) a 0.85μ ZyMōt device. After removal of cumulus/coronal cells by hyaluronidase, half of the mature oocytes were randomly allocated to ICSI with Control sperm and the other half with ZyMōt sperm. Fertilization, embryo culture and biopsy were performed using the clinic's standard protocols.

Main results and the role of chance:

Table. ICSI cycle embryo development outcomes following standard sperm washing procedures (Control) or the use of a microfluidic sperm separation device (ZyMōt)

Treatment:	ZyMōt	Control
Number of Oocytes	787	777
Fertilization rate (% 2PN)	604 (76.7%)	592 (76.2%)
Blastocyst rate (%>2BB)	296 (49.0%)	282 (47.6%)
Euploidy rate	165/283 (58.3%)	151/265 (57.0%)
Mosaicism rate	25/283 (8.8%)	31/265 (11.7%)

There were no statistical differences observed between the ZyMōt or Control sperm processing methods. Although some normal variation between labs was observed, there were also no differences between the control DGC and swim-up methods. Clinical pregnancy outcomes are still being evaluated, but preliminary results reveal no advantage to the ZyMōt treatment. To date, intrauterine

pregnancies are trending upward(p>0.1) for the Control groups (21 of 30, 70%) in contrast to 18 of 37 (48.6%) in the ZyMōt group.
Limitations, reasons for caution: Male factor patients with known elevated SDF were not selected for this multi-center trial. Therefore, we can not speak to the potential improvements ZyMōt may elicit. However, it is possible that selection of normal, progressive sperm for ICSI, plus the repair capacity of oocytes, is sufficient to promote normal development.
Wider implications of the findings: We do believe the ZyMōt device may have a useful application in infertile men with elevated SDF, yet it is equally possible that an ICSI sperm selection alone allows for the immobilization and injection of highly progressive, morphologically normal sperm as seen in this study of typical infertility patients.
Trial registration number: OF191218B

O-130 Testicular cell communication mediated by extracellular vesicles

E. Fok[1], K.H.K. Choy[1], S.Y. Chan[1], W. Lam[1]

[1]The Chinese University of Hong Kong, School of Biomedical Sciences- Faculty of Medicine, Hong Kong, Hong Kong

Study question: Is extracellular vesicle (EV) presence in the mouse testis? If yes, do these testicular EVs mediate cell communication in mouse testis?
Summary answer: EVs were present in mouse testis. Testicular EVs were uptake by both germ cells and somatic cells and they carry novel small RNA cargos.
What is known already: Spermatogenesis requires a precisely orchestrated cellular communication networks. EV is known to be ubiquitously released by eukaryotic cells. EV carries various cargo, including genomic DNA, mRNA, miRNA and proteins, that can be uptake by target cells and regulate their cellular processes, indicating that EV is an important and effective way of cell-cell communication. EVs secreted by the prostate and the epididymis have been characterized and shown to play important roles in sperm maturation and functions. However, the presence of EVs in the testis and their involvement in spermatogenesis remain elusive.
Study design, size, duration: We collected testis samples from mouse and isolated testicular EVs using a newly established tissue dissociation method.
Participants/materials, setting, methods: The physical properties of testicular EVs were assessed by dynamic light scattering and electron microscopy. Testicular EVs were validated by Western blot of established EV markers and Golgi marker. The small RNA cargo was profiled by RNA-sequencing and verified by real-time PCR. The uptake of testicular EVs was examined by the fluorescence-labelling of EVs.
Main results and the role of chance: Testicular EVs were isolated from the mouse testis using the newly established tissue dissociation method. Electronic microscopy results showed the hallmark cup-shape morphology of EVs with sizes ranged from 50 – 200 nm. The presence of hallmark EV markers CD63, CD81 and CD9 and the negligible amount of Golgi marker suggest clean isolation of testicular EVs with minimal membranous organelle contamination. Small RNA sequencing (RNA-seq) revealed RNA species commonly observed in EVs, including rRNA, tRFs, snoRNA, miRNAs and piRNAs. Importantly, we have identified three novel miRNAs that were not reported in the testis transcriptome. To study the type of testicular cells that uptake testicular EVs, we injected PKH-labelled testicular EVs into the interstitial space or seminiferous tubules. The results showed that EVs were uptake by Sertoli cells and all stages of germ cells.
Limitations, reasons for caution: The physiological function of testicular EVs awaits further investigation.
Wider implications of the findings: The testicular EVs may provide novel insight into our understanding of sperm production and inheritance.
Trial registration number: N/A

SESSION 34: ENDOMETRIOSIS - PATHOGENESIS AND DIAGNOSIS

07 July 2020 Parallel 4 10:00 - 11:30

O-131 Exome-wide screen for somatic mutations in endometriosis lesions

K. Ward[1], R. Chettier[2], H.M. Albertsen[2]

[1]Juneau Biosciences- LLC, Administration, Salt Lake City, U.S.A. ;
[2]Juneau Biosciences, Research and Development, Salt Lake City, U.S.A.

Study question: Which genes undergo somatic mutation during the development and progression of endometriosis lesions; do these genes differ from those that predispose women to develop endometriosis?
Summary answer: Endometriosis lesions develop somatic mutations in several genes. The mutations identified in lesions differ from germline variants that predispose women to develop endometriosis.
What is known already: Endometriosis is a clinically heterogenous condition affecting 10% of women. It is well established that germ-line mutations may predispose some women to develop endometriosis, however penetrance, expressivity, and pleiotropy of the "initiating" genes implicated to date are not understood. Clinical heterogeneity is even observed within a single patient as an affected woman may have some lesions that are progressive, invasive, and possibly metastatic or malignant while other lesions are not. Recent studies have shown that somatic mutations accumulate during the clonal evolution of individual endometriosis lesions.
Study design, size, duration: This study is a retrospective cohort association study. 2,932 DNA samples from unrelated women with surgically-confirmed endometriosis (GERMLINE) and 274 tissue blocks containing endometriosis lesions (LESION) underwent whole exome sequencing. Fisher's Exact Test was used to determine excess burden (alpha <0.001).
Participants/materials, setting, methods: DNA was extracted using standard methods. Exome sequencing was performed using an Ion Proton Instrument, AmpliSeq Exome Capture, and the Torrent Variant Caller. Missense and truncating variants having a minor allele frequency <0.005 in the gnomAD database were considered for analysis. We calculated somatic burden for each gene by first counting protein-altering variants identified in only one patient per group. We also calculated cumulative genetic burden for each gene by adding all coding variants identified.
Main results and the role of chance: A mean of 63 "singleton" variants per patient were detected in the GERMLINE samples and 65 singleton variants per patient in the LESION group. 11 genes showed excess somatic mutations in the LESION samples when compared to the GERMLINE results (MIEF1, MSX1, FAM149A, VEZT, FAM160B1, PCDHA6, RIBC1, IRAK4, HYAL2, AQP4, and DSE). Singleton variants in these genes were observed at a 6.3 to 22 fold excess in the LESION samples when compared with the expectations from the GERMLINE samples. None of these genes are among the top 1000 FLAGs ranking (frequently mutated genes). VEZT has been previously implicated as an endometriosis associated gene through GWAS studies.
Limitations, reasons for caution: The sample size is modest and replication of these results in additional cohorts is warranted. It is very unlikely formalin fixation or paraffin embedding caused the observed mutations, but untreated LESION samples are currently being tested in our laboratory.
Wider implications of the findings: Discovery of gene mutations underlying endometriosis progression may lead to new pathophysiology insights, improved diagnostics, and novel treatment approaches.
Trial registration number: Not applicable

O-132 The landscape of endometrial transcriptome in ovulatory obese PCOS women

V. Salamun[1,2], E. Vrtačnik Bokal[1], B. Peterlin[3], A. Maver[3], N. Kočevar[3], O. Maloku[4], T. Papler Burnik[1]

[1]University Medical Centre Ljubljana, Department of Human Reproduction-Division of Obstetrics and Gynecology- University Medical Centre Ljubljana-Ljubljana- Slovenia, Ljubljana, Slovenia ;
[2]Medical faculty of Ljubljana, University ljubljana, ljubljana, Slovenia ;
[3]University Medical Centre Ljubljana, Department of Genetics- University Medical Centre Ljubljana- Ljubljana- Slovenia, Ljubljana, Slovenia ;
[4]University Medical Centre Ljubljana, Department of Genetics University Medical Centre Ljubljana- Ljubljana- Slovenia, Ljubljana, Slovenia

Study question: To determine the coexisting influence of obesity and PCOS on the endometrial transcriptome in ovulatory obese PCOS patients during the window of implantation in spontaneous cycles.

Summary answer: Enrichment analyses revealed significant disruptions of inflammation, insulin signaling, fatty acid metabolism and lipotoxicity pathways in ovulatory obese PCOS endometrium compared to controls.

What is known already: Obese and PCOS women have a reduced rate of spontaneous conception even when their cycles are ovulatory indicating other factors like the uterine environment. The mechanism of this intricate interplay in which obesity modifies already different PCOS endometrium is not fully clarified. There are only a few analyses of the endometrial transcriptome in which the impact of obesity and/or PCOS on the endometrium was elucidated. The most relevant was the study of Belver et al. in which obese women showed a different endometrial gene expression compared to controls with pronounced changes of transcriptome in a combination of obesity and PCOS.

Study design, size, duration: Prospective transcriptomic analysis of endometrium using the RNA-seq method was done in university-affiliated infertility hospital between February 2017 and February 2018. Clinical information and endometrial samples were collected from 14 infertile patients that were divided in 2 groups: ovulatory obese PCOS (ovul-O-PCOS) and control group. The inclusion criteria for the ovul-O-PCOS group were obesity, PCOS, and infertility and for the control group were normal body mass and tubal or unexplained infertility.

Participants/materials, setting, methods: 14 patients were invoved in the study according to the study criteria. Ultrasound detection of follicular ovulation/anovulation with determination of progesterone levels on the day of endometrial biopsy. Endometrial biopsy collected between 21 and 23 of menstrual cycle. RNA isolation (RNeasy Kit, Qiagen, Germany), sequencing, library preparation and subsequent RNAseq data analyses were done.

Main results and the role of chance: According to functional and upstream analyses the most important biological processes in ovulatory obese PCOS compared to control group were related to inflammation (TNFR1 Signalling Pathway as the most important), insulin signaling and energy consumption (Insulin Receptor signaling and PI3/AKT pathway,) fatty acid metabolism (Stearate Biosynthesis I Pathway and Palmitate Biosynthesis I Pathway) and lipidotoxity.

Upstream analysis perfectly captured the pathophysiological mechanisms found through functional analysis of ovul-O-PCOS endometrium. Most of the upstream regulators were involved in some of the already mentioned mechanisms: inflammation (CASP1, EGR1, TGFb, ZAP 70), glucose metabolism and energy homeostasis regulation (insulin, insulin receptor, GSK3, MYC, IGF1), adipokines & lipid regulators (ADIPOQ, clofibrat as a lipid-lowering agent, PPARD, PPARGC1B). Additionally, the accentuated effect of estrogen (estrogen) and impaired progesterone effect (tretinoin and altretinoin- progesterone antagonists) was also found.

Limitations, reasons for caution: Since the comorbidity of obesity and PCOS was investigated, we found the duality of the pathology as the strong point of the study. The second strong point was strictly defined study population. The most important limitation could be the sample size.

Wider implications of the findings: Obesity adds the additional burden of lipotoxity of free fatty acids in endometrium to already known factors of inflammation and insulin resistance in the O-PCOS comorbid state. The only modifiable factor is weight loss that could represent a potential mechanism for normalisation of endometrium towards controls.

Trial registration number: KME 0120-491-2017

O-133 Three-dimensional ultrasonography versus diagnostic hysteroscopy in the differential diagnosis of intra-uterine benign disease. A single institution experience.

A.M.L. Gambaro[1], M. Monti[2], M.G. Piccioni[2], A. Musella[2], V. Colagiovanni[2], E. Marcoccia[2], M.C. Schiavi[2], C. Fazi[2], L. Muzii[2], L. Manganaro[3]

[1]Guy's and St Thomas' NHS Foundation Trust, Assisted Conception Unit, London, United Kingdom ;
[2]Sapienza University of Roma, Department of Obstetrical-Gynecological Sciences and Urological Sciences-, Roma, Italy ;
[3]Sapienza University of Roma, Department of Radiological Sciences, Roma, Italy

Study question: Comparison of diagnostic accuracy of three-dimensional transvaginal ultrasonography (3D-TVUS) versus hysteroscopy (HYS) in the assessment of uterine malformations and submucosal fibroids.

Summary answer: 3D-TVUS has a high detection rate for the studied pathologies, is less invasive and more cost-effective diagnostic tool.

What is known already: Both HYS and 3D-TVUS are currently used for diagnosis of uterine malformations and submucosal fibroids. Their accuracy and the indications are operator-dependent and largely variable, between 25% and 99% depending on the circumstances and the instruments used.

Study design, size, duration: Prospective observational study. From April 2010 to December 2018, 672 patients were enrolled as they met the inclusion criteria for the study.

Participants/materials, setting, methods: Patients found to have submucosal uterine fibroids or uterine congenital anomalies on a routine pelvic transvaginal ultrasound were prospectively studied. All patients underwent 3D-TVUS, HYS and pelvic MRI, each one performed by an expert operator. Women with endometrial polyps or suspected endometrial or uterine cancer were excluded. Median age was 32 years (range 23-66 years).Specificity, sensitivity, accuracy and k-index of 3D-TVUS and HYS were recorded and compared to MRI.

Main results and the role of chance: Submucosal fibroids were confirmed by MRI in 441 out of 672 (65.6%) women; uterine malformations were reported in 231 (34.4%) women. Both 3D-TVUS and HYS showed great sensitivity in uterine malformations and submucosal fibroids detection, however 3D-TVUS showed the highest specificity in detection of uterine malformations, while HYS showed the highest specificity in detecting submucosal fibroids. Moreover, 3D-TVUS had a slightly higher accuracy in the diagnosis of uterine malformations compared with HYS (96.8% vs 93.7% respectively), while k index was excellent for both diagnostic tools. The main limitation of HYS was in differential diagnosis of fundal submucosal fibroids and uterine septum/arcuate uterus.

Limitations, reasons for caution: All procedure were performed and reviewed by expert operators with state of the art diagnostic tools, so the results reported in the study might not reflect detection rates by average operators in everyday practice.

Wider implications of the findings: 3D-TVUS is a valid tool in primary detection of uterine malformations and submucosal fibroids. It could replace diagnostic HYS and/or laparoscopy in diagnosis of uterine malformations, both where intervention is not required or to guide the surgeon in preparation for the surgery.

Trial registration number: n/a

O-134 Integration of clinical factors and biomarkers for non-invasive diagnosis of endometriosis

A. Vanhie[1], D. O[2], C. Tomassetti[1], C. Meuleman[1], P. Mestdagh[3], T. D'Hooghe[2]

[1]University Hospital Leuven, Leuven University Fertility Center, Leuven, Belgium ;
[2]KU Leuven, Development and Regeneration, Leuven, Belgium ;
[3]UGent, Center for Medical Genetics, Gent, Belgium

Study question: Can integration of clinical data and ultrasound findings with biomarkers result in accurate combined clinical-biochemical diagnostic models for endometriosis?

Summary answer: In this proof-of-concept study we show that combining clinical factors and biomarkers results in a diagnostic model for that outperforms the individual factors or biomarkers.

What is known already: Diagnosis of endometriosis solely based on presence of symptoms has a low specificity and sensitivity. Transvaginal ultrasound can diagnose endometrioma's and deep endometriotic nodules, but does not rule out peritoneal endometriosis. Cancer antigen 125 (CA-125) levels have been shown to be elevated in some women with endometriosis. However, the sensitivity and specificity of CA-125 for endometriosis is low and serum CA-125 levels alone have no value as a diagnostic tool. Recently, circulating miRNAs have been described to be differentially expressed in patients with endometriosis, suggesting that they could be used for the non-invasive diagnosis of endometriosis.

Study design, size, duration: Retrospective case-control study in a cohort of 222 patients (151 women with endometriosis and 71 controls)

Participants/materials, setting, methods: Clinical and ultrasound data were extracted from the electronic patient record. Plasma was available in the biobank of the Leuven University Fertility Center. CA-125 was measured on a Roche Modular E170 instrument using a commercial assay (Roche Diagnostics,

Germany). RNA was extracted with the miRNeasy Plasma Kit and miRNA expression analysis was done by RT-qPCR using Qiagen miScript assays. Models were build using multivariate logistic regression and validated by a 10-fold cross validation.

Main results and the role of chance: We developed a diagnostic model which finally consisted of 2 clinical factors (dysmenorrhea and dyschezia), 4 biomarkers (hsa-miR-20a-5p, hsa-miR-21-5p, hsa-miR-28-5p and CA-125) and 1 interaction factor (hsa-miR-20a-5p*dyschezia). The diagnostic model had an AUC of 79% with a high sensitivity (82%) and moderate specificity (65%) at optimal cut-off (determined by the Youden-index). In the 10-fold cross validation diagnostic performance of the model dropped to an AUC of 66%.

Limitations, reasons for caution: The 10-fold cross-validation shows that an important drop in diagnostic performance could be expected when applying this model in an independent cohort.

Wider implications of the findings: Our data indicate that combined clinical-biochemical diagnostic models perform better than the individual factors. This implies that the classic design of endometriosis biomarkers studies should be reconsidered towards an approach where the bar for each individual biomarker is lowered while keeping the overall requirement of high sensitivity and specificity.

Trial registration number: not applicable

O-135 Local steroid metabolism in eutopic endometrium and corresponding endometriotic lesions: intra-patient variability

S. Xanthoulea[1], B. Delvoux[1], P. Koskimies[2], M.R. Häkkinen[3], J. Koskivuori[3], S. Auriola[3], A. Vanhie[4], C. Tomassetti[4], A. Romano[1]

[1]Maastricht University Medical Center, Gynaecology, Maastricht, The Netherlands ; [2]Forendo Pharma, Ltd., Turku, Finland ; [3]University of Eastern Finland, School of Pharmacy, Kuopio, Finland ; [4]KU Leuven, Obstetrics and gynaecology, Leuven, Belgium

Study question: Is the local steroid metabolism (including estrogens, progestogens, androgens and corticosteroids) different between the normal endometrium of patients and the endometriotic tissue from different anatomical locations?

Summary answer: Steroid levels differ between normal and endometriotic tissue. Irrespective of the location, endometriosis shows active synthesis of estrogens and sustained corticosteroid levels.

What is known already: Endometrial tissue produces locally steroids, relevant in endometriosis: estrogens control lesion establishment, progestogens oppose estrogen action, androgens are estrogen precursors and corticosteroids suppress inflammation. These events are related to endometriosis symptoms such as infertility and pain and offer novel therapeutic targets aimed at blocking local estrogen generation, such as 17beta-hydroxysteroid dehydrogenase 1 (HSD17B1).

To elucidate to what extent steroid metabolism is implicated in endometriosis, and what inter- and intra-patient variability exists, we profiled major steroids in blood and tissue (normal endometrium and endometriosis) of patients; we also determined the expression levels of major enzymes involved in local steroid metabolism.

Study design, size, duration: This is a retrospective study using biobanked frozen patient material. Eutopic endometrium, multiple endometriotic lesions from each patient, and peripheral blood of 14 women (seven in the secretory and seven in the proliferative phase) with histologically confirmed endometriosis were analysed. Endometriotic lesions originated from the uterosacral ligament/Pouch of Douglas, bladder, ovarian fossa, rectum/rectosigmoid. Patients had stage I (n=1), II (n=9), III or (n=3), or stage IV (n=1) endometriosis (ASRM classification).

Participants/materials, setting, methods: Plasma, eutopic endometrium (n=14) and endometriotic lesions (n=39) were obtained and stored following the EPHect/WERF guidelines (https://endometriosisfoundation.org/ephect/). Patients with endometriosis were not under hormonal medication for six months prior to the biopsy. RNA expression was determined by whole RNA-sequencing. Levels of major steroids were measured by Liquid Chromatography-Mass Spectrometry (LC-MS). HSD17B1 activity was measured in tissue lysates (cell-free extracts) by High Performance Liquid Chromatography (HPLC).

Main results and the role of chance: Estrogens (estrone, estradiol) were non-statistically significantly higher in eutopic and endometriotic tissues compared with blood (estradiol: 1.0 pmol/g eutopic; 3.2 pmol/g endometriotic; 0.4 pmol/mL blood – estrone: 0.3 pmol/g eutopic; 1.1 pmol/g endometriotic; 0.3 pmol/mL blood). Of note, estradiol:estrone ratios, approximately one in blood, were around three in tissue, indicating active local synthesis. 17-hydroxy-progestogens and androstenedione were over 4-fold higher in endometriotic lesions than eutopic tissue ($p<0.05$). The activity of HSD17B1 was comparable between eutopic and endometriotic tissues.

Regarding corticosteroids, active cortisol was 4-fold higher in endometriosis than in the eutopic tissue ($p<0.001$), whereas inactive cortisone was 2.5-fold lower in endometriosis ($p<0.001$). HSD11B1 (activation to cortisol) and HSD11B2 (deactivation to cortisone) mRNA levels were in line with the corticosteroid levels: HSD11B1 mRNA was higher in endometriosis, and the opposite was observed for HSD11B2 compared with the eutopic endometrium ($p<0.001$ for both enzymes). The levels of compounds acting as precursors for corticosteroid synthesis (i.e., 21-hydroxyprogesterone; 11-deoxycorticosterone) were higher in endometriosis compared with the eutopic tissue ($p<0.05$), and a number of enzymes involved in the generation of active compounds from these precursors were expressed in both eutopic endometrium and endometriotic tissue.

Limitations, reasons for caution: This is a retrospective study, that included patients with all stages of disease and with manifestation of different symptoms in a pooled analysis. Sub analyses in relation to type of endometriosis and kind of symptoms of the patient were hampered by the small patient population.

Wider implications of the findings: Steroid levels differed between tissue and blood. HSD17B1 activity was measured in most cases (irrespective to patient and tissue location), hence, inhibition of HSD17B1 is a valid strategy for lowering the local estrogen production in endometriosis. Sustained generation of anti-inflammatory cortisol may relate to the chronic inflammation associated with endometriosis.

Trial registration number: NOT APPLICABLE

O-136 Exploring the delays to diagnosis of endometriosis in the United Kingdom; a triphasic mixed-methods study

B. Karavadra[1], E. Morris[1]

[1]Norfolk & Norwich University Hospital, Obstetrics & Gynaecology, Norwich, United Kingdom

Study question: What are the reasons for the delay to diagnosis of endometriosis from a patient and healthcare worker perspective?

Summary answer: Delay was attributed to patient factors (symptom recognition, seeking help), healthcare system issues (waiting times, referral pathways) and clinician experiences (normalisation, general vs specialist gynaecologist).

What is known already: The average time to diagnosis of endometriosis in the United Kingdom is 7.5 years and It is widely known that a delayed diagnosis can have a significant impact on women quality of life and activities of daily living. In addition, repeated medical consultations prior to diagnosis can have a significant burden financially on the healthcare system.

Study design, size, duration: A triphasic study design was adopted and it involved an online questionnaire (1252 participants), semi-structured interviews with 16 participants with endometriosis and separate focus groups with 15 healthcare workers (General Practitioners, nurses and gynaecologists). A mixed methods approach was used whereby the findings were analysed by content analysis and grounded theory qualitative methodology. For the online questionnaire, women throughout the UK responded and for the qualitative aspects of the study, purposive sampling was used.

Participants/materials, setting, methods: Phase one involved developing an online questionnaire exploring women's experiences of being diagnosed with endometriosis and this was distributed via the Endometriosis UK charity website. In phase two, the findings from the phase one study were used to design a qualitative study exploring the finer details of delays in diagnosis and analysed by grounded theory. Phase three involved focus groups with healthcare workers to explore their opinions on the findings from the phase two study.

Main results and the role of chance: In phase one, 1252 women replied to the online questionnaire with an average delay to diagnosis of 5.5 years. Delay was attributed to patient factors (symptom recognition, seeking help), healthcare system issues (waiting times, referral pathways) and healthcare worker experiences (normalisation, general vs specialist gynaecologist). In phase two, 16 women took part in individual interviews. They provided significant detail into delays by highlighting the triadic combination of coping mechanisms, health seeking behaviours and the process of adjustment to symptoms. Phase three findings from 15 healthcare workers provided insight into the preconception's healthcare

workers had 'about the endometriosis patient' and the challenges of recognising abnormal symptoms.

Mixed-method's enabled a positivist and constructivist stance to be taken when exploring a complex problem like delay. The quantitative aspect enabled insight into the general factors attributed to delay, and the subsequent qualitative phase enabled in-depth exploration of these factors and the complex interaction between them.

Limitations, reasons for caution: The findings are based on participants in the United Kingdom (UK) and the respective healthcare system; therefore, the reasons for the delay to diagnosis may vary outside the UK.

Wider implications of the findings: This study provides new in-depth insight to the health-seeking behaviours, coping mechanisms and complex interaction of factors contributing to delayed diagnosis. It is hoped that the findings from this study will be used to encourage collaboration between professional bodies and patient groups to design a pre-diagnostic tool to facilitate diagnosis.

Trial registration number: Not applicable

O-137 Elevated levels of monocyte chemotactic protein-1 (MCP-1) in the follicular fluid reveals different populations among women with severe endometriosis.

P.E. Bouet[1], J.M. Chao de la Barca[2], H. El Hachem[3], S. Blanchard[4], P. Jeannin[4], P. Reynier[2], P. May-Panloup[5]

[1]Department of Reproductive Medicine, Angers University Hospital, Angers, France ; [2]Department of Biochemistry and Genetics, Angers University Hospital, Angers, France ; [3]Department of Reproductive Medicine, Clemenceau Medical Center, Beirut, Lebanon ; [4]Department of Immunology and Allergology, Angers University Hospital, Angers, France ; [5]Department of Reproductive Biology, Angers University Hospital, Angers, France

Study question: Is there a modification of the cytokine profile of the follicular fluid (FF) of women with endometriosis undergoing in vitro fertilization (IVF)?

Summary answer: In patients with endometriosis, we have identified a subtype with a high FF MCP-1 level, that is associated with an alteration of the oocyte microenvironment.

What is known already: Several factors implicated in the acute and chronic inflammatory reaction (hormones, cytokines, chemokines and markers of oxidative stress) are thought to be involved in the pathophysiology of endometriosis. Indeed, an alteration of the cytokine profile has been shown in the serum, the peritoneal fluid, the endometrial tissue, and in endometriomas of women with endometriosis. Different biological signatures have been assessed in order to better understand the pathophysiology behind the endometriosis-related infertility, using proteomics, metabolomics and the analysis of the cytokine profile. However, such studies have been scarce and have yielded disparate results.

Study design, size, duration: We performed a prospective observational study on the follicular fluid retrieved from 87 women undergoing IVF with or without intracytoplasmic sperm injection from January 2018 to February 2019 at the Angers University Hospital, France.

Participants/materials, setting, methods: The patients were divided into two groups: the endometriosis group and the control group. The endometriosis group comprised 43 patients with severe endometriosis. The control group included 44 patients undergoing IVF for other causes and without endometriosis. The cytokine profile of the FF was determined by multiplex fluorescent-bead-based technology allowing the measurement of 59 cytokines.

Main results and the role of chance: Univariate analysis showed a significant increase of nine cytokines in the FF in the endometriosis group compared to the control group, while Monocyte Chemoattractant Protein 1 (MCP-1) was the only variable retained in the multivariate analysis. We identified two subgroups of patients in the endometriosis group: MCP-1- group (n=23) which had FF MCP-1 levels comparable to the control group and MCP-1+ (n=20) which had significantly higher FF levels. Only patients in the MCP-1+ group had a significantly altered cytokine profile in the FF, and had a significantly higher serum estradiol level (p=0.002) and a significantly lower number of oocytes recovered (p=0.01) compared to the MCP-1- and the control group.

Limitations, reasons for caution: One potential limitation of our study is the lack of assessment of serum MCP-1 levels, which could have been compared to those in the follicular fluid.

Wider implications of the findings: Our study has shown an alteration of the oocyte microenvironment in women with endometriosis associated with high follicular fluid levels of MCP-1 allowing the identification of a subgroup of endometriosis patients with a potentially worse prognosis.

Trial registration number: Not applicable

SESSION 35: IMPACT OF ART ON HEALTH OUTCOMES OF CHILDREN

07 July 2020 Parallel 5 10:00 - 11:30

O-138 Differences in the landscape of mitochondrial DNA variants between ART and spontaneously conceived individuals links to maternal infertility and low birth weight

J. Mertens[1], F. Zambelli[2], F. Belva[3], A. Van Montfoort[4], E. Couvreau de Deckersberg[1], M. Bonduelle[3], K. Stouffs[3], S. Seneca[3], H. Van de Velde[5], C. Blockeel[5], K. Barbé[6], K. Sermon[1], C. Spits[1]

[1]Vrije Universiteit Brussel, Reproduction and Genetics, Brussels, Belgium ; [2]Clinica Eugin, Clinica Eugin, Barcelona, Spain ; [3]UZ Brussel, Center for Medical Genetics, Brussels, Belgium ; [4]Maastricht University Medical Center, Department of Obstetrics & Gynaecology-GROW School for Oncology and Developmental Biology, Maastricht, The Netherlands ; [5]UZ Brussel, Center for Reproductive Medicine, Brussels, Belgium ; [6]Vrije Universiteit Brussel, Interfaculty Center Data Processing & Statistics ICDS, Brussels, Belgium

Study question: Can mitochondrial DNA variants explain the differences in birth weight between ART and spontaneously conceived individuals?

Summary answer: We have found significant differences in the mitochondrial genome of children born after ART, which link to a background of maternal infertility and birth weight.

What is known already: Follow-up studies of children born after ART show an increased risk of lower birth weight and the potential development of an abnormal cardio-metabolic profile later in life. Efforts to find the molecular cause of these differences have focused on the epigenome, but have yet to yield conclusive results. In this study, we investigated variation in the mitochondrial genome, which is known to be linked to cardio-metabolic disorders in the general population and potentially to infertility. Our hypothesis was that mitochondrial DNA variants could explain the differences in birth weight between ART and spontaneously conceived individuals.

Study design, size, duration: We studied the full mitochondrial DNA (mtDNA) of 283 ART and 189 spontaneously conceived (SC) samples collected in multiple centers collaborating with large fertility clinics. The DNA was extracted from different tissues (ART: 116 blood, 66 placental and 101 buccal samples, SC: 65 blood, 51 placental and 73 buccal samples). The DNA was enriched for the mtDNA by long-range PCR and sequenced on an Illumina platform.

Participants/materials, setting, methods: The variant calling was performed using mtDNA server and MuTect, with a threshold of >1.5% load, versus the reference NC_012920.1. The results were correlated to maternal age, indication for ART, culture medium, gestational age, and birth weight corrected for gestational age and gender. Statistical analysis was done using SPSS. For the complex data of the heteroplasmic variants, an orthogonally rotated factor analysis was used to reduce the dimensionality of the studied dependent variables.

Main results and the role of chance: Haplogroup U4 was overrepresented in the ART group (ART: 5.3% vs. SC: 0.5%, p=0.004). ART individuals have more not previously described homoplasmic variants (ART: 31.4%, SC: 21.7%, p=0.021). ART Individuals whose mother was infertile more frequently carried homoplasmic tRNA variants than SC or individuals with infertile fathers (p=0.041). ART individuals carry higher heteroplasmic loads in the coding region (p=0.039) and component analysis, using rank randomized tests, indicated that they carry a different mtDNA variant composition from SC individuals (p=0.015),

which is driven by variants inducing non-synonymous changes and in the rRNA regions. These heteroplasmic variants were highest in individuals born from infertile mothers, followed by male factor infertility when compared to the SC group (significant trend, p=0.017). Maternal age nor gestational age were linked to an increased mutational burden. Finally, both ART and SC individuals ≤10th birth weight percentile more frequently carried homoplasmic tRNA variants (p=0.032). SC individuals with birth weight ≤10th and ≤25th percentile carried more frequently heteroplasmic coding variants (p=0.032 and p=0.008). In the ART group, only individuals from embryos that had been in Vitrolife G1 medium followed the same pattern as SC, with individuals ≤25th percentile carrying more heteroplasmic coding variants (p=0.0232).

Limitations, reasons for caution: Other factors not considered in this study could play a role in the birth weight, which we are currently correcting for. This study is observational and no functional tests were performed. Finally, after stratification for embryo culture medium, the sample sizes are small (N=49- 66).

Wider implications of the findings: These results suggest a link between maternal infertility and mtDNA variant composition, which is transmitted to the offspring. These variants correlate to birth weight, particularly in the SC individuals, suggesting a universal mechanism. Embryo culture medium appears to affect birth weight through another mechanism, masking the effect of mtDNA variation.

Study question: Is the risk of imprinting disorders increased in children conceived after assisted reproductive technology (ART)?

Summary answer: We found an odds ratio of 3.07 [95%CI 1.49-6.31] for Beckwith-Wiedemann syndrome in ART children, but no increased risk of three other imprinting disorders.

What is known already: Earlier studies, most of them small, have suggested an association between ART and imprinting disorders. Results, however, far from consistent.

Study design, size, duration: Binational register-based cohort study. All children conceived by ART in Denmark (n=45 393) born between 1994 and 2014 and in Finland (n=29 244) born between 1990 and 2014 were identified. The full background populations born during the same time periods in the two countries were included as controls. Odds ratios of imprinting disorders in ART children compared with naturally conceived (NC) children were calculated.

Participants/materials, setting, methods: From the national health registries in Denmark and Finland, we identified all children diagnosed with Prader-Willi syndrome (n=143); Silver-Russell17 syndrome (n=69); Beckwith-Wiedemann syndrome (n=105) and Angelman syndrome (n=72) born between 1990/1994 and 2014, respectively. he median follow-up time was 8 years and 9 months for ART children and 11 years and 9 months for NC children.

Main results and the role of chance: We identified a total of 389 children diagnosed with imprinting disorders, sixteen of these were conceived after ART. The overall odds ratio for the four imprinting disorders in ART children compared with NC children was 1.60 [95%CI 0.97-2.65]. Made up separately, eight ART children were diagnosed with Beckwith-Wiedemann syndrome, the odds ratio for this specific imprinting disorder was 3.07 [95%CI 1.49-6.31]. The risk of Prader-Willi syndrome, Silver-Russell syndrome and Angelman syndrome was not increased in children conceived after ART.

Limitations, reasons for caution: Imprinting disorders are rare events and our results based on few ART children with imprinting disorders. The etiology is complex and only partly clarified, and the clinical diagnoses challenged by a broad phenotypic spectrum.

Wider implications of the findings: In the existing studies results on the risk of imprinting disorders in children conceived after ART are ambiguous. This study adds that the risk of imprinting disorders in ART children is very small and perhaps restricted to Beckwith-Wiedemann syndrome

Trial registration number: not applicable

O-140 ICSI does not increase the odds of adverse perinatal outcomes in autologous/ donor oocyte cycles without male-factor subfertility: analysis of 121,448 singleton live births

P.R. Supramaniam[1], L.N. Lim[1], E. McVeigh[1], I. Granne[1], C. Becker[1], M. Mittal[2]

[1]Oxford University Hospitals NHS Foundation Trust, Gynaecology, Oxford, United Kingdom ;
[2]Imperial College Healthcare, Gynaecology, London, United Kingdom

Study question: Does ICSI increase the odds of adverse perinatal outcomes in autologous and donor oocyte cycles without male factor subfertility?

Summary answer: ICSI does not increase the odds of adverse perinatal outcomes in autologous and donor oocyte cycles in the absence of male factor subfertility.

What is known already: An increased incidence of obstetric complications is recorded in pregnancies conceived through assisted reproductive treatments (ART) compared to spontaneous conception. There is a paucity of information is available on the effect of method of fertilisation, particularly ICSI, on perinatal outcomes in the absence of male factor subfertility in either autologous or donor oocyte cycles.

Study design, size, duration: Retrospective cohort analysis of all fresh cycles conducted between 2002-2016, from the UK HFEA national database. 110,805 singleton live births(LB) have been recorded from all oocyte usage, of which, 105,618 were from autologous oocyte cycles and 5187 from donor oocyte cycles. Assuming that the adverse perinatal outcome rate for IVF is 10%, a power calculation demonstrated that 686 LBs would need to be analysed for 80% power and 5% significance to detect a 10% difference.

Participants/materials, setting, methods: The database was analysed for singleton live birth rate (SLBR), stratified by recipient age, donor age, number of previous IVF treatment cycles undertaken and type of cycle (fresh IVF versus fresh ICSI). Cycles complicated by male factor subfertility were excluded from the final analysis as this is known to influence the method of fertilisation. Statistical analysis was performed using Logistic Regression and Chi-square; p<0.05 was considered statistically significant.

Main results and the role of chance: The overall IVF to ICSI ratio for all treatment cycles, in the absence of male factor subfertility, favoured IVF (58:42) in 2002, with a yearly rise seen in ICSI cycles (46:54 in 2016).

IVF increased the risk of very preterm births (<32 weeks') (adjusted odds ratio [aOR] 1.25, 99.5% confidence interval [CI] 1.10-1.42, p<0.0001) and preterm births (32-36 weeks') (aOR 1.10, 99.5% CI 1.03-1.17, p<0.0001) compared to ICSI treatment cycles with autologous oocytes, using term delivery as the reference category. This significance was not sustained in donor oocyte cycles: very preterm births (aOR 1.17, 99.5% CI 0.70-1.96, p=0.393) and preterm births (aOR 0.90, 99.5% CI 0.69-1.17, p=0.250). The odds of a

post-dates delivery was increased in autologous oocyte cycles employing ICSI when compared to IVF (aOR 1.05, 99.5% CI 1.01-1.10, p=0.003), however, this was not maintained in donor oocytes (aOR 0.94, 99.5% CI 0.75-1.19, p=0.459). There was no significant difference demonstrated when the birthweight per method of fertilisation was analysed after adjusting for potential confounding factors in either oocyte category

Limitations, reasons for caution: The accuracy of the database is dependent on the information submitted to the HFEA. Until 2007, this data was manually captured adding the risk of data entry error. Furthermore, information on maternal confounding factors such as body mass index and smoking status was not available to be evaluated.

Wider implications of the findings: ICSI in the absence of male factor subfertility does no increase the odds of adverse perinatal outcome in autologous and donor oocyte cycles. This at present suggests that the adverse outcomes previously described with ICSI is related to the significant abnormalities associated with the male component rather than the technique.

Trial registration number: N/A

O-141 The risk of major congenital malformations in children conceived after ICSI: a Nordic cohort study

A.K. Henningsen[1], S. Opdahl[2], U.B. Wennerholm[3], A. Tiitinen[4], L.B. Romundstad[5], C. Bergh[3], M. Gissler[6,7], J. Forman[8], A. Pinborg[1]

[2]Norwegian University of Science and Technology, Department of Public Health and Nursing, Trondheim, Norway ;
[3]Institute of Clinical Sciences- Sahlgrenska Academy- University of Gothenburg-Sahlgrenska University Hospital, Department of Obstetrics and Gynecology, Gothenburg, Sweden ;
[4]University of Helsinki- Helsinki University Hospital-, Department of Obstetrics and Gynecology, Helsinki, Finland ;
[5]Spiren Fertility Clinic, Spiren Fertility Clinic, Trondheim, Norway ;
[6]THL Finnish Institute for Health and Welfare, Information Services Department, Helsinki, Finland ;
[7]Karolinska Institute- Division of Family Medicine, Department of Neurobiology-Care Sciences and Society, Stockholm, Sweden ;
[8]University of Copenhagen, Department of Biostatistics, Copenhagen, Denmark

Study question: Is the risk of major congenital malformations higher in children conceived after ICSI compared with children conceived after IVF?

Summary answer: We did not find any difference in the risk of being born with a major congenital malformation in children conceived after ICSI compared with IVF.

What is known already: It is well known that children born after ART have a higher risk of being born with a major congenital malformation compared with children born after natural conception (NC). It is still not clear whether the risk of congenital malformations is higher in children conceived after ICSI compared with IVF, as studies so far present diverging findings. It is also uncertain if cryopreservation of the embryos influences the risk of malformations in the offspring.

Study design, size, duration: Nordic cohort study based on national registry data from Denmark, Norway and Sweden. The analyses were based on singletons born after ART (n=98 026) and NC (n=4 804 844) between 1992 and 2015.

Participants/materials, setting, methods: The study included all singletons, both live-born and stillborn, conceived after ICSI (n=39 684); IVF (n=58 342) and NC (n=4 804 844). We differentiated between children conceived after transfer of fresh embryos versus frozen-thawed embryos. Malformations were coded in all countries using the International Classification of Diseases (ICD). The European Concerted Action on Congenital Anomalies and Twins (EUROCAT) was used to differentiate between major and minor malformations. Minor malformations were not included in the analyses.

Main results and the role of chance: I the multiple regression analyses, we adjusted for maternal age, parity, year of birth, child's sex, body mass index, smoking and country. We found no difference in the risk of being born with a major congenital malformation, when comparing children conceived after ICSI with children conceived after IVF, adjusted odds ratio (AOR) 1.06; [95% confidence interval (CI) 0.98-1.13]; p-value=0.09. Neither could we detect any difference in the risk of major malformations when comparing children born after transfer of a fresh ICSI embryo versus a frozen-thawed ICSI embryo, AOR 1.11; [95%CI, 0.98-1.26]; p-value=0.09. We also compared children conceived after transfer of frozen-thawed ICSI embryo with a frozen-thawed IVF embryo. The risk of major malformations was similar for the two groups, AOR 1.04; [0.90-1.21]; p-value=0.57. When we investigated the risk of malformations grouped by different organ systems, we did not find higher risk among ICSI children in any of the above comparisons. However, we confirmed that children born after ICSI have a significantly higher risk of being born with a major malformation compared with NC children, AOR 1.30; [95%CI 1.24-1.36]; p-value<0.0001.

Limitations, reasons for caution: Due to the poorer quality of registration of minor malformations in the national health registries, together with surveillance bias, we restricted our analyses to major malformations. We do not expect the detection of major congenital malformation to be biased by method of conception.

Wider implications of the findings: Since the first ICSI child was born in 1992, there has been concern whether the risk of congenital malformations is increased among ICSI children, where often poor-quality semen has been used for conception. Our findings based on 39 684 Nordic ICSI children, showing no differences compared to IVF, are reassuring.

O-142 The DNA methylation patterns within whole blood of adolescents born from IVF are not different from those adolescents conceived naturally within the Raine birth cohort.

B. Penova-Veselinovic[1], P. Melton[2], R.C. Huang[3], J. Yovich[4], P. Burton[5], R. Hart[6]

[1]University of Western Australia, Division of Obstetrics and Gynaecology, Perth, Australia ;

[5]Edith Cowan University, Concept Fertility Centre, Perth, Australia ;
[6]University of Western Australia & Fertility Specialists of WA, School of Women's and Infants Health, Perth- Western Australia, Australia

Study question: Do the epigenome-wide DNA methylation profiles of adolescents born from in-vitro fertilisation (IVF) differ from the epigenome of naturally conceived counterparts from a birth cohort?

Summary answer: There is no significant difference in the DNA methylation profiles of adolescents born from IVF when compared to their naturally conceived, age-matched counterparts.

What is known already: Epigenetic changes are heritable modifications that may alter gene expression without changing the DNA sequence. Growing evidence suggests that the adverse health outcomes reported in IVF-born offspring might have underlying epigenetic mechanisms. Both, features of infertile couples, as well as the IVF procedure itself have been shown to alter the epigenetic signature in offspring and placental tissue. As most studies investigated DNA methylation changes in cord blood/placenta tissue, and a recent study reported that these changes are mitigated by adulthood, it is essential to further investigate potential effects of IVF on the DNA methylation profiles in adolescents using whole blood.

Study design, size, duration: The Growing Up Healthy Study (GUHS) is a prospective study that recruited 303 adolescents to compare various long-term health outcomes and DNA methylation profiles with age-matched counterparts from a birth cohort (Generation 2 of the Raine Study). GUHS assessments were conducted in 2013-2017. The effect of IVF on DNA methylation levels of 238 adolescents mean age 16±1.67 (52.94% male) was compared to 1188 naturally conceived, age-matched controls, 17.25±0.58 (50.93% male) from the Raine Study.

Participants/materials, setting, methods: Genomic DNA from whole blood was used to generate the epigenome profiles of 238 GUHS adolescents and 14 technical replicates using the Infinium Methylation Epic Bead Chip that measures and quantifies approximately 850,000 DNA methylation probes. These generated profiles were compared to the DNA methylation profiles from the Raine Study that was quantified using Illumina 450K platform. DNA methylation profiles for both studies were normalized using the same quantile normalization procedure (BMIQ) for comparative purposes.

Main results and the role of chance: We defined adolescence by an age range between 13 and 19.9 years. The average age of the generated DNA

methylation profiles in the GUHS cohort was 16.06 years. The DNA-methylation profiles of the Raine Study participants have an average age of 17.25 years. After quality control and filtering, a total of 401,022 DNA methylation probes overlapped between the two studies. These DNA methylation probes were then each investigated and compared between the IVF born GUHS and naturally conceived Raine study adolescents. We tested for an association between these groups applying Firth's bias reduced logistic regression against the outcome of IVF vs naturally conceived. Potential confounders, namely the DNA methylation probe as well as technical variation due to different methylation platforms used between studies, were adjusted for within-study batch effects. After adjustment none of the compared DNA methylation probes reached a Bonferroni correction of 1.24E-0.7 (0.05/402,022) for statistical significance. Overall, a small minority, 3850 (0.96%) of the analyzed 401,022 DNA methylation probes showed nominal significance with a p-value <0.05, most likely to be false positives after controlling for cross-study comparisons. 1,810 Differentially Methylated Regions (DMR's) were identified between the cohorts; however none reached statistical significance after correcting for multiple testing.

Limitations, reasons for caution: With contradictory findings on small sample size studies to date, there is a need to better understand the complex outcomes and effects of IVF manipulations on the epigenome of offspring. To infer an association with higher statistical and biological significance, data from various groups should be pooled for a meta-analysis.

Wider implications of the findings: Our results support previous findings that the epigenome profiles of IVF born adolescents are stable, and not affected by the techniques used in IVF. The increased cardiometabolic risk factors observed in adolescents born from IVF treatment may result from other non-DNA methylation related epigenetic influences.

Trial registration number: NHMRC Project grant number 1042269

O-143 Female causes of infertility are associated with higher risk of preterm birth and low birth weight: analysis of 120 902 singleton live births following IVF

M.S. Kamath[1], B. Antonisamy[2], S.K. Sunkara[3]

[1]Christian Medical College and Hospital, Reproductive Medicine, Vellore, India ; [2]Christian Medical College and Hospital, Biostatistics, Vellore, India ; [3]King's College London-, Division of Women's Health- Faculty of Life Sciences and Medicine-, London, United Kingdom

Study question: Does cause of infertility affect perinatal outcomes of preterm birth (PTB) and low birth weight (LBW) following In vitro fertilisation (IVF) treatment?

Summary answer: The risk of PTB and LBW was significantly higher with female causes of infertility – ovulatory disorders, tubal disorders and endometriosis compared to unexplained infertility.

What is known already: Women with infertility have an increased risk of adverse perinatal outcomes. Risk of adverse perinatal outcomes is also higher following assisted reproductive treatments (ART) compared to spontaneous conceptions. Infertility can result from female and or male factors or unexplained when the cause cannot be delineated by standard investigations. Given that infertility and ART are contributory to the adverse perinatal outcomes, it is a matter of interest to delineate if the specific cause of infertility influences the perinatal outcomes following IVF treatment.

Study design, size, duration: Anonymous data were obtained from the Human Fertilization and Embryology Authority (HFEA). The HFEA has collected data prospectively on all ART cycles performed in the UK since 1991. Data from 1991 to 2016 comprising a total of 120 902 singleton live births following IVF ± ICSI for sole causes of infertility were analysed for PTB and LBW. Cycles having more than one cause of infertility and multiple births were excluded.

Participants/materials, setting, methods: Data on all women undergoing stimulated IVF ± ICSI treatment cycle were analysed to compare perinatal outcomes of PTB and LBW among singleton live births based on the cause of infertility (ovulatory disorders, tubal disorders, endometriosis, male factor, unexplained). Logistic regression analysis was performed adjusting for female age category, period of treatment, previous live births, IVF or ICSI, number of embryos transferred and fresh or frozen embryo transfer cycles.

Main results and the role of chance: The incidence of PTB following IVF based on infertility causes was 10.8% for ovulatory disorders; 10.5% for tubal disorders; 9.8% for endometriosis; 8.1% for male factor causes and 8.5% for unexplained infertility. Compared to unexplained infertility cause, the risk of PTB was significantly higher with ovulatory disorders (adjusted odds ratio-aOR 1.31, 95% CI 1.21, 1.41); tubal disorders (aOR 1.25, 95% CI 1.18, 1.34) and endometriosis (aOR 1.17, 95% CI 1.05, 1.29). There was no significant difference in the risk of PTB with male factor causes compared to unexplained infertility (aOR 1.25, 95% CI 1.18, 1.34).

The incidence of LBW based on infertility causes was 10.5% for ovulatory disorders; 9.4% for tubal disorders; 9.8% for endometriosis; 8.4% for male factor causes and 8.5% for unexplained infertility. Compared to unexplained infertility cause, the risk of LBW was significantly higher with ovulatory disorders (aOR 1.29, 95% CI 1.20, 1.40); tubal disorders (aOR 1.12, 95% CI 1.05, 1.20) and endometriosis (aOR 1.11, 95% CI 1.0, 1.24). The risk of LBW was significantly lower with male factor causes compared to unexplained infertility (aOR 0.94, 95% CI 0.89, 0.99).

Limitations, reasons for caution: Although the analysis was adjusted for several important confounders, there was no information on medical history of women during pregnancy to allow adjustment. Limitations with observational data would apply to this study including residual confounding.

Wider implications of the findings: This is the first study to address causes of infertility affecting perinatal outcomes of PTB and LBW. The information is important and needs to be understood further.

Trial registration number: Not applicable

O-144 The risk of cerebral palsy in ART children has more than halved over two decades – a Nordic collaborative study on 55,233 liveborn children

A.L. Spangmose[1], L. Hee[1], M. Gissler[2], A. Tiitinen[3], S. Opdahl[4], L.B. Romundstad[5], C. Bergh[6], U.B. Wennerholm[6], A.K. Henningsen[1], A. Pinborg[1]

[1]Fertility Clinic Rigshospitalet, Copenhagen University Hospital, Copenhagen, Denmark ; [2]Information Services Department- Finnish Institute for Health and Welfare THL, Department of Neurobiology- Care Sciences and Society- Karolinska Institute, Helsinki and Stockholm, Finland ; [3]Helsinki University Hospital and University of Helsinki, Department of Obstetrics and Gynecology, Helsinki, Finland ; [4]Norwegian University of Science and Technology, Department of Public Health and Nursing, Trondheim, Norway ; [5]Norwegian Institute of Public Health, Spiren Fertility Clinic- Center for Fertility and Health, Trondheim, Norway ; [6]Institute of Clinical Science- Sahlgrenska Academy, Department of Obstetrics and Gynecology, Gothenburg, Sweden

Study question: Has the risk of cerebral palsy (CP) changed over a 20-year period in children born after assisted reproductive technology (ART)?

Summary answer: Over two decades, the risk of CP in ART-children decreased with more than 50%, mainly due to single embryo transfer resulting in lowering twin rates.

What is known already: During the last two decades we have seen a considerable reduction in twin birth rates after ART treatment in Europe herein the Nordic countries. In the Nordic countries, the twin births rates in ART pregnancies have declined from almost 25% two decades ago to less than 5%, compared with 2–3% in the background population of spontaneously conceived (SC) pregnancies. Concomitantly the preterm birth (PTB) rate has diminished considerably. PTB increases the risk of CP, which is one of the most severe complications in ART-children with long term consequences for the children and their families.

Study design, size, duration: A Nordic registry-based cohort study using data from Denmark (birth years 1994–2010) and Finland (1990–2010) including two cohorts: 55,233 ART-children and 2,327,350 SC-children. Among the ART-children, 37,404 were singletons, 17,057 were twins and 772 were higher order multiples. We investigated the risk of CP in the following time periods: birth year 1990–1994, 1995–1999, 2000–2004 and 2005–2010. Children were followed up until 2014.

Participants/materials, setting, methods: Data originated from the CoNARTaS cohort (Committee of Nordic ART and Safety) containing

information from national ART- and patient registries. CP was defined as G80 ICD-10-diagnoses registered in the patient registry before the age of ten. Risk of CP was compared for ART vs. SC children, singletons and twins using logistic regression models. Adjustments were made for maternal age, parity, child's sex, country and birth year as well as plurality (if applicable).
Main results and the role of chance: Overall, 307 (0.6%) ART- and 5,911 (0.3%) SC-children were diagnosed with CP. During the study period the crude risk of CP in ART-children decreased consistently from 0.9% (1990–1994) to 0.4% (2005–2010), while the risk remained unchanged for SC-children (0.3%). For ART-singletons the risk of CP decreased from 0.7% (1990–1994) to 0.3% (2005–2010), but remained stable for ART-twins (0.7%), SC-singletons (0.2%) and SC-twins (0.8%). Throughout the study period the adjusted risk of CP was higher for ART- versus SC-children (adjusted odds ratio [aOR] 1.93 [95%CI 1.71;2.17]). The risk remained increased after further adjustment for plurality (aOR 1.18 [95%CI 1.04;1.34]). The risk of CP was higher for ART-singletons (aOR 1.32 [95% CI 1.10;1.57]) but similar for ART-twins compared with their SC counterpart. Analyses stratified on birth year showed a consistent decrease in risk of CP over time for ART- versus SC-children (1990–1994: aOR 2.88 [95%CI 1.81;4.32]; 2005–2010: aOR 1.34 [95%CI 1.12;1.61]). In 2005–2010 the risk of CP, after further adjustments for plurality, was no longer statistically significant (aOR 0.96 [95%CI 0.79;1.15]). Additionally, the risk of CP decreased substantially over time for ART-singletons compared with SC-singletons (1990–1994: aOR 2.53 [95%CI 1.20;4.63]; 2005–2010: aOR 1.21 [95%CI 0.88;1.62]).
Limitations, reasons for caution: Observational studies may have inadequate adjustment for potential confounding factors. Despite adjustment for some major confounders, residual confounding cannot be excluded.
Wider implications of the findings: Limiting the number of twins born after ART treatment lowers the risk of CP in the ART population. Multiple embryo transfer is still the standard care in many countries. Our findings emphasize that single embryo transfer should be encouraged worldwide.

O-146 Is COVID-19 symptomatic triage enough? The limited value of serological testing

C. González-Ravina[1], **V. Vergara**[2], **M. Cruz**[2], **N. Prados**[3], **A. Requena**[2]

[1]*IVI Sevilla, Andrology and Endocrinology laboratories, Sevilla, Spain*
[2]*IVI Madrid, Reproductive Medicine, Madrid, Spain*
[3]*IVI Sevilla, IVF Laboratory, Sevilla, Spain*

Study question: Do serological and molecular tests increase the detection of patients with SAR-CoV-2 after a negative triage?
Summary answer: Serological testing has limited value in detecting SARS-CoV-2 once triage has been negative if molecular testing is being performed before oocyte retrieval or embryo transfer
What is known already: Fertility community is uncertain about how to optimally provide care to infertile patients, without compromising safety, once the activity is re-established. The key principle established by the scientific societies for resuming activity is that anyone attending a clinic should be triaged negative. More precise methodology has been developed such as immunological tests that inform us of the state of the disease and molecular tests (RT-PCR) that measures viral load. These tests may help us to identify asymptomatic and pre-symptomatic carriers that could have not been detected only with triage and patients with past infections that may need no further tests.
Study design, size, duration: Between April 27th and May 19th, 2020, 1549 women were tested for SARS-CoV-2. Before these tests were performed, a symptomatic triage had been carried out in which patients were asked by telephone for the presence of symptoms of the virus or if they had been in contact with someone suspected or confirmed to have been infected with the disease. Only patients classified as negative triage attended the clinic for further testing.
Participants/materials, setting, methods: IgG and IgM antibody against SARS-CoV-2 in plasma samples were tested using enzyme linked immunosorbent assay (ELISA) kits (Epitope Diagnostics, USA). Women with asymptomatic triage and negative IgM started a treatment; on the 5th-8th day of stimulation for retrieval or 3-5 days before a frozen embryo transfer, a nasopharyngeal RT-PCR was performed in order to avoid an active infection during the treatment.
Main results and the role of chance: Study was performed in 17 private clinics belonging to IVIRMA group. Serological testing was carried out in 1549 patients before starting a treatment. Seroconversion rate for IgG was 3.8% (n=59) and for IgM was 0.7% (n=11). As previously discusses, only those patients in whom the recent presence of the infection had been ruled out (IgG+/IgM- or IgG-/IgM-) continued with the treatment. Before embryo transfer, both in fresh and frozen cycles, a molecular determination of the virus was carried out and we observed a 0.06% (n=1) rate of positive RT-PCR.

The possibilities of having a patient with negative IgG and IgM and a positive RT-PCR is due to the period between the pre-symptomatic or asymptomatic shedding and the first time at which the production of IgM starts, which can be up to 12 days. Even though a negative RT-PCR could be considered enough as immunity is not well established, there is no clear evidence that past infections could be re-infected, and IgG seem to be neutralizing. Serological testing of IgM prevents patients from starting endometrial priming or controlled ovarian stimulation decreasing the risk of cancelling the cycle while a positive IgG avoids repeating RT-PCR for each oocyte retrieval or embryo transfer
Limitations, reasons for caution: The low prevalence of infected patients after the triage makes these number very approximate. The utility of these tests will worsen as the virus incidence decreases.
Wider implications of the findings: In this current scenario, serological testing does not seem to be a cost-effective strategy to avoid asymptomatic carriers of the virus for starting a treatment, but it still detects a low number of asymptomatic patients. Lower occurrence of the virus may suggest the no need for a later screening.

O-147 Seroconversion of Immunoglobulins to SARS-CoV-2 of healthcare workers in nine European fertility units

S. Nelson M.B.B.Ch- Ph.D.[1], **S. Ehnert**[2], **T. Child**[3], **G. Trew**[4]

[4]*The Fertility Partnership, Boston Place, London, United Kingdom*

Study question: To assess SARS-CoV-2 seroconversion in healthcare workers in nine European IVF units on recommencement of clinical activity.
Summary answer: A large proportion of staff remain susceptible to SARS-CoV-2 infection with no evidence of seroconversion. Comprehensive risk mitigation strategies are essential for continued staff welfare.
What is known already: The diagnosis of COVID-19 is based on the detection of the SARS-COV2 virus using RT-PCR from nasopharyngeal samples at the time of active infection. Most patients infected with SARS-COV-2 develop antibodies (Ab) against SARS-COV2 proteins. Regulatory approved CE marked commercial ELISAs are now available to assess seroconversion, yet the prevalence of SARS-CoV-2 antibodies amongst healthcare workers in IVF units is unknown.
Study design, size, duration: Prospective cohort study of 175 staff members from 8 European IVF clinics and one diagnostic laboratory (5 Germany, 3 Austria), sampled over a two-week period with paired SARS-CoV-2 antigen testing and blood sampling for serology.
Participants/materials, setting, methods: Staff returning to work in the nine European clinics of The Fertility Partnership received paired oropharyngeal antigen testing for RT-PCR and blood sampling for serology. RT-PCR for SAR-CoV-2 was performed in accordance with WHO guidelines. Detection of SARS-CoV-2 antibodies was performed by the Abbott Diagnostics SARS-CoV-2 IgG

assay on an Abbott Architect i2000 according to the manufacturer's instructions. This qualitative assay detects IgG binding to an undisclosed epitope of the SARS-CoV-2 nucleocapsid protein.

Main results and the role of chance: Of the 175 staff members tested 0 (95%CI 0.0 to 2.1%) had evidence of SARS-CoV-2 as detected by RT-PCR. In contrast 6 healthcare workers 3.4% (95%CI 1.6 to 7.3%) had antibodies against SARS-CoV-2. There was no evidence of clustering within the clinics with four of the nine facilities having only one staff member affected (prevalence estimates ranging from 5.6% to 12.5%), and one clinic having three staff members affected (9.1% (95%CI 3.1% to 23.6%).

Limitations, reasons for caution: Understanding viral and host interactions during acute and convalescent phases are critical to interpret both the timing of initial seroconversion after exposure to SARS-CoV-2, and the subsequent duration of antibodies. At present studies regarding temporal seroconversion have been developed in conjunction with assay development, limiting the long-term conclusions of seroconversion.

Wider implications of the findings: A low proportion of healthcare workers in nine different sites had seroconverted and had evidence of SARS-CoV-2 antibodies. A large proportion of staff are still susceptible to infection and appropriate infection control procedures are essential to continue to mitigate risk and ensure staff welfare with the resumption of clinical services.

O-315 Streamlining follicular monitoring during controlled ovarian stimulation? A data-driven approach to efficient IVF care in the new era of social distancing

I. Robertson[1], F.P. Chmiel[2], Y. Cheong[1]

[1]University of Southampton, Human Development and Health, Southampton, United Kingdom

[2]University of Southampton, IT Innovation- Electronics and Computer Science, Southampton, United Kingdom

Study question: What is the optimal follicle tracking ultrasound strategy for controlled ovarian stimulation (COS) in order to minimise face-to-face interactions but retain predictive power for both trigger timing and over response?

Summary answer: Data from follicle tracking scans on day 8, 9 or 10 can be used to make accurate predictions of trigger timing and risk of over-response.

What is known already: British Fertility Society guidance for restarting ART following Covid-19 pandemic related shutdowns recommends aiming to reduce the number of visits for monitoring during ovarian stimulation. If reduction is needed, prioritising attendance for scans on the most predictive cycle days is prudent. Current evidence on optimal monitoring during ovarian stimulation is sparse, and protocols vary significantly, with some centres priding themselves on monitoring intensity. Small studies of simplifying IVF therapy by minimising monitoring have reported no adverse effects. There are opportunities to learn from the adaptations necessary during these extraordinary times to improve efficiency of IVF care in the longer term.

Study design, size, duration: A retrospective database analysis of 9294 ultrasound scans performed during monitoring of 2322 IVF cycles undertaken by 1875 women in a single centre. The primary objective was to identify when in the IVF cycle data obtained from ultrasound is most predictive of both oocyte maturation trigger timing and an over-response to stimulation. Ethical approval for this study was obtained from the University of Southampton ERGO II and NHS REC (IRAS Project ID: 275218).

Participants/materials, setting, methods: Anonymised retrospective database analysis of IVF/ICSI cycles at a tertiary referral IVF centre in the United Kingdom. Machine learning models built combining demographic and follicular tracking data to predict oocyte maturation trigger timing and over-response. The primary outcome was the cycle days from which scan data yields optimal model prediction performance statistics. Random Forest Regressors were implemented as our predictive models, trained using cross-validation at treatment cycle level and evaluated on the out-of-fold samples.

Main results and the role of chance: The earliest day for which our model has high accuracy to predict both trigger day and risk of over-response (>18 follicles >=11mm or >=18 eggs) is cycle day 8. The model using day 8 data is strongly predictive of the day of trigger administration MSE (mean squared error) 1.70 +/-0.11. At cycle day 8, our model can predict over-response with high precision and recall (AUROC of 0.91 +/- 0.01). The model for predicting trigger day uses patient age, number of follicles at baseline scan and follicle count by size for the current scan. The model to predict over-response uses age and number of follicles of a given size.

In contrast, models using data from a baseline scan are not highly predictive of the trigger administration day (the mean MSE of models using data only from baseline scans is 3.83 +/- 0.24). Over-response can be predicted at baseline using AFC and age with moderate accuracy (mean AUROC 0.77 +/- 0.01).

These results suggest that, if there is a significant need to reduce patient contacts per cycle in order to facilitate safe access to care, priority for patients attending for scans after day 7 of the treatment cycle should be considered.

Limitations, reasons for caution: This is a single-centre retrospective study. RCTs with healthy live birth primary outcome should guide changes to IVF care. However, for safety in extraordinary times, clinics may have to adjust protocols immediately, with no time to await optimal evidence. These results may provide help for those making these challenging decisions.

Wider implications of the findings: These results are timely and prospective evaluation of streamlined follicular tracking for COS monitoring may be warranted. Previous small studies have shown that minimal monitoring protocols did not adversely impact outcomes. If IVF can safely be made less onerous, without compromising success, this could help reduce burden related treatment drop-out.

O-316 Maternal-fetal vertical SAR-CoV-2 (COVID-19) viral transmission during pregnancies is possible and currently cannot be dismissed

Study question: Is there vertical transmission (from woman to baby antenatally or intrapartum) after SARS-CoV-2 (COVID-19) infected pregnancy?

Summary answer: SARS-CoV-2 (COVID-19) infected pregnancies leaves open the possibility of vertical viral transmission from mother to baby.

What is known already: The majority of viruses do not cross the placental barrier; but when they do, can cause serious fetal illness including birth defects, miscarriage, abnormalities of growth and development, neurological injuries, fetal demise, preterm delivery and neonatal complications. Such examples are Zika, CMV, rubella, HIV/AIDS viral infections in pregnancy. The expression of SARS-CoV-2 receptors angiotensin-converting enzyme 2 (ACE2) plays essential roles in human infection and transmission and is found in maternal-fetal interface and human fetal heart, liver and lung. SARS-CoV-2 vertical transmission from mother to baby constitutes a major defining question in this pandemic to help clinical practices and patients.

Study design, size, duration: A systematic review searching terms related to SARS-CoV-2 (COVID-19), pregnancy, neonatal complications, viral and vertical transmission was suggested. The final computerized database search was performed on 30/04/2020. No language restriction was placed on published articles. The duration was from December 2019- 15th May 2020 for extracting the literature and screening the articles for potential interest. As data source was international there was considerable heterogeneity in patient exposures, quality control and possibly variants of SARS-CoV-2 virus.

Participants/materials, setting, methods: A systematic review was performed in PUBMED, EMBASE, CENTRAL, WEB of SCIENCE, Web of

Knowledge, the WHO, RCOG, ESHRE, ASRM, NEJM, BMJ, Lancet, Welcome and Cochrane Central Register of Studies, UKOSS, Office of National Statistics (ONS-UK) , Department of Health (UK), Google Scholar and any references of relevant articles. Data relevant to SARS-CoV-2 diagnostic interpretation was also collected. Mostly small case series with a high degree of heterogeneity was assembled on an excel spread sheet.

Main results and the role of chance: From 58 papers, 480 COVID-19 positive pregnant women were identified and 688 babies born covered in 80 publications. Most publications (47/80, 58.7%), reported small number (<5) of babies. From 71 papers, 10 babies were COVID-19 positive. 1st RT-PCR diagnostic tests were done in 356 babies, 2nd RT-PCR was done in 90 cases, IgM tests done in 28 babies, and IgG tests done in 28 babies. From 71 studies and 356 babies, 13 tested positive in 1st RT-PCR. After 2nd RT-PCR, 7 became negative, whereas 3 babies testing negative on 1st RT-PCR became positive. On 2nd RT-PCR, 3 babies became positive (who were initially reported as negative in 1st RT-PCR), 3 continued to remain positive (positive in 1st RT-PCR) but 3 who were positive in 1st RT-PCR were not tested again. On the 1st RT-PCR, 44 studies reported time of testing while 27 studies did not. Earliest RT-PCR positive test was 2 hours while in 2 studies, 10 women tested had positive amniotic fluid, and 3/11 placental swabs tested positive for SARS-CoV-2 RNA but babies remained negative. Changes to placental pathology reported.

In 4 unrelated report, 100% of patients initially tested negative, turning positive after 2nd and 3rd re-tests for SARS-CoV-2 RNA.

Limitations, reasons for caution: Caution should be exercised in interpreting test results; sampling methods, timing, patient infectivity level, SARS-COV-2 viability tests, sensitivity and specificity. Controls are generally lacking in reports. Small, globally heterogeneous cases reported. Voluntary case reports submission to research databases are heterogeneous, potentially breaching patient anonymity and some clinics may withhold data.

Wider implications of the findings: When factoring in the incubation period and efficacy of the diagnostic test results, it suggests the viral infection pre-existed the tests. Thereby it is likely that vertical transmission had occurred but validation and controlled experiments are needed to allow a definitive assessment to counsel pregnant women on SARS-COV-2 pandemic risks.

Abstract text

Over the life course, the mammalian genome undergoes profound setting and resetting of epigenetic information. Germ-cell specification, gametogenesis, and early embryo development are characterised by phases of widespread erasure and rewriting of DNA methylation. This extensive reprogramming largely prevents transmission of epigenetic information across generations; however, reprogramming events must also ensure correct genomic imprinting, an essential epigenetic mechanism that does depend on faithful, long-term persistence of gamete-derived methylation in the next generation. This underscores the importance of understanding how methylation patterns are established in the germline and the extent to which they may be influenced by adverse physiological or environmental factors, or procedures applied in assisted reproduction.

We recently pioneered genome-wide analysis of DNA methylation in single cells, as well as methods for joint profiling of DNA methylation, gene expression and chromatin accessibility. We are deploying these capabilities to explore effects of factors such as maternal age and maternal diet on the epigenetic quality of the oocyte, and to investigate whether any anomalies detected persist in the embryo. In addition, with detailed knowledge of the mechanisms underlying DNA methylation in the oocyte, we are keen understand how such epigenetic anomalies arise.

Study question: Do different modalities used for frozen-thawed embryo transfer (FET) treatment cycles in normoovulatory patients undergoing IVF/ICSI are linked with different pregnancy rates?

Summary answer: Live birth was superior in HR cycles without GnRH analogs and miscarriage was higher when progesterone was administered through gel vs. tablets.

What is known already: A variety of strategies and regimens for FET have been used and proposed. Reports have been plenty, with no existing consensus regarding the best protocol to choose or to prepare the endometrium, through a luteal plase "creation" or replacement. Crucial parameters for the right choice consist of control and flexibility in the timing of transfer, cost, and proper endometrial development, along with rates of pregnancy, miscarriage and live birth. Currently, uncertainty exists concerning the type, adjunct or dose of regimen to offer, while many IVF Units use variable and mixed protocols.

Study design, size, duration: This is a four-center two-arm retrospective cohort study conducted at both University and Private Assisted Reproductive Units in Greece, using data from 456 cycles with vitrification from 369 women during the last 5 years.
Participants/materials, setting, methods: The following modalities were analyzed: 1. Natural cycle (NC), using hCG as ovulatory trigger, without luteal support (Group 1), 2. NC, using hCG, with luteal support (Group 2) 3. Hormone Replacement cycle (HRC) plus GnRHa suppression (Group 3) 4. HRC without GnRHa suppression (Group 4). The primary outcome measures were live birth and miscarriage rates.
Main results and the role of chance: From all four centers, data for 456 cycles through vitrification from 369 women was provided. Live birth was higher in Groups 2 and 3 as compared to Group 4 (by 81%), and when the stable estrogen dose was administered compared to the increasing, by 8.82 times (1.25, 62.03). Regarding miscarriage, 19 events were recorded; progesterone administration through gel was significantly associated with a higher risk, compared to tabs [4.77 (1.80, 12.67)]. Regarding secondary outcomes, biochemical and clinical pregnancy rates were lower in Group 3 compared to Group 4 [0.70 (0.6, 0.82) and 0.70 (0.61, 0.80), respectively] and when the stable estrogen dose was administered compared to the increasing [0.83 (0.72, 0.96) and 0.87 (0.77, 0.97), respectively]. The rest of the comparisons yielded non-significant results. In the multivariable analysis, live birth appeared to be significantly affected only by the endometrial preparation modality: Group 3 experienced higher rates compared to Group 4 (6.51 (2.66, 15.93)].
Limitations, reasons for caution: Limitations of the study include its retrospective nature that is linked with known and unknown biases and the small cohort size.
Wider implications of the findings: HRC without GnRHa and probably NC with hCG and luteal support appears to be superior to HRC with GnRHa, concerning live birth. Miscarriage was increased in women receiving progesterone gel compared to tabs. Age was a significant predictor of negative biochemical and clinical pregnancy rates.
Trial registration number: NCT03965949

O-153 Follicular flushing leads to higher oocyte yield in monofollicular natural cycle IVF – a randomized controlled trial

A. Kohl Schwartz[1], I. Calzaferri[1], M. Roumet[2], A. Limacher[2], A. Fink[1], A. Wueest[1], S. Weidlinger[1], V. Mitter[1], B. Leeners[3], M. Von Wolff[1]

[1]Bern University Hospital, Division of Gynecological Endocrinology and Reproductive Medicine, Bern, Switzerland ;
[2]Clinical Trial Unit Bern, University of Bern, Bern, Switzerland ;
[3]University Hospital Zurich, Department of Reproductive Endocrinology, Zurich, Switzerland

Study question: Does follicular flushing increase the number of mature oocytes in monofollicular natural cycle in-vitro fertilization?
Summary answer: Follicular flushing increases the number of mature oocytes, increases the fertilisation rate and reveals a trend towards a higher transfer rate.
What is known already: In polyfollicular IVF and in oligofollicular poor responders, flushing neither increases the oocyte yield nor the pregnancy rate. In monofollicular IVF the effect of flushing had so far been addressed by two studies. One prospective study with minimal stimulation IVF demonstrated an increased oocyte yield. One retrospective study with Natural Cycle (NC)-IVF showed an increased oocyte yield and an increase of the transfer rate. A prospective randomized study specifically analysing monofollicular IVF was still missing.
Study design, size, duration: Prospective randomized controlled trial including 164 women who were randomized for either aspiration without or with flushing from 2016-2019.
Participants/materials, setting, methods: Infertile women 18-42 years of age with an indication for IVF treatment at a university-based infertility unit. Women undergoing monofollicular NC-IVF in vitro fertilization were randomized to either follicular aspiration only or follicular aspiration directly followed by five follicular flushes at a 1:1 ratio. The intervention was done without anaesthesia, using a gauge 19 single lumen needle. Flushing volume was calculated (sphere formula) based on the size of the follicle.
Main results and the role of chance: A total of 164 women were included; 81 were allocated to "aspiration only," and 83 to additional "flushing." Primary analysis was based on the intention to treat: oocyte yield, defined as collected mature oocyte rate, was higher (n=64/83, 77.1%) in the flushing group compared to the aspiration only group (n=48/81, 49.3%, risk difference (RD): 18.2% (95% CI 3.8 - 31.6%), p-value=0.02). In the flushing group, most oocytes were retrieved in the first 3 flushes (63/83, 75.8%). Fertilization rate was higher in the flushing group (n=53/83, 63.9% versus n=38/81, 46.9%; RD: 16.8% (96% CI 1.5 - 31.4%), p= 0.045). Transfer rate was also higher in the flushing group (n=52/83, 62.7% versus n=38/81, 46.9%; RD: 15.71 (95% CI 0.3 - 30.3%), but the difference was not significant (p= 0.06). The clinical pregnancy rate per transfer was not significantly different between the two groups. The median duration of the intervention was significantly shorter with "aspiration only" (0.43 min; IQR 0.3, 0.5) versus "flushing" (2.38 min; IQR 2.0, 2.7; p<0.001). There was no significant difference in the mean VAS pain score between the follicular flushing (3.4 ±1.8) and the aspiration group (3.1 ±1.89).
Limitations, reasons for caution: Sample size was not powered to analyse pregnancy and live birth rates.
Wider implications of the findings: Our study proved that flushing of single follicles in Natural Cycle IVF increases the oocyte yield. In contrast to polyfollicular and oligofollicular IVF flushing seems to be beneficial in the monofollicular setting if the technique used in our study (single-lumen needle, 5 flushings with flushing volume adaptation) is applied.
Trial registration number: NCT 02641808.

O-154 Do we trust in evidence based medicine? A multicentre retrospective analysis of 2677 first IVF/ICSI cycles before and after the OPTIMIST trial.

E. Papaleo[1], A. Revelli[2], M. Costa[3], M. Bertoli[4], S. Zaffagnini[5], F. Tomei[6], F. Cantatore[1], M. Reschini[7], A. Rebecchi[1], F. Parissone[5], M. Manno[6], M. Sironi[4], T. Tessari[4], D. Colia[3], E. Somigliana[7]

[1]S. Raffaele Hospital, Centro Scienze della Natalità, Milano, Italy ;
[2]University of Turin, IVF unit, Turin, Italy ;
[3]International Evangelic Hospital, IVF Unit, Genoa, Italy ;
[4]Azienda Ospedaliera "C. Poma", IVF Unit, Mantua, Italy ;
[5]Azienda Ospedaliera Universitaria Integrata, IVF Unit, Verona, Italy ;
[6]Ospedale Santa Maria degli Angeli, IVF Unit, Pordenone, Italy ;
[7]Fondazione IRCCS Ca' Granda- Ospedale Maggiore Policlinico, IVF Unit, Milan, Italy

Study question: To evaluate whether the practice of individualizing r-FSH starting dose has been substituted and outdated after the largest RCT in ART, the OPTIMIST trial.
Summary answer: OPTMIST trial influenced physicians to standardize r-FSH starting dose and to reduce the mean starting dose in predicted POR women undergoing COS.
What is known already: Individualizing r-FSH starting dose has been subject of many studies over the past 20 years. Although the "one size fits all" approach has been discouraged for decades by most authors, van Tilborg *et al*. (2017) on behalf of the OPTIMIST study group demonstrated in a large prospective RCT that dosage individualization, in general, does not appear to improve overall live birth rates. This implies that, while reduction of dosage may create better safety in predicted high responders, the use of high dosages of r-FSH, typical of predicted low responders, lacks any cost-benefit advantage and may be abandoned.
Study design, size, duration: We performed a retrospective analysis of seven italian fertility centers including all first IVF/ICSI cycles from January 1st 2017 to December 31st 2018, before and after the OPTMIST publication on November 2017. Patients were distributed according to their ovarian reserve markers in: predicted POR (AFC ≤ 7 and/or AMH <1.1), predicted normo-responders (AFC 8-15 and/or AMH 1.1-3.5) and expected hyper-responders (AFC > 16 and/or AMH > 3.5).
Participants/materials, setting, methods: 2677 patients between 18 and 42 years old undergoing their first IVF-ICSI cycle were included. The study group A (before OPTIMIST) included 1325 patients who underwent their first cycle from January 2017 to December 2017. The study group B (after OPTIMIST) included 1352 patients who underwent their first cycle from January 2018 to December 2018. In both study groups data regarding patients characteristics (age, BMI, AMH, AFC,), stimulation protocols and stimulation outcomes were collected.

Main results and the role of chance: In the study group "before" 401/1325 (30, 2%) patients were expected POR, 566 (42, 7%) expected normo-responders, 358/1325 (27, 0%) predicted hyper-responders. In the study group "after" patients' distribution was 366/1352 (27.0%), 601/1352 (44.4%), 385/1352 (28.4%) for each group **(**p=NS**)**. Comparing 2017 and 2018 there was an increased prescription of standard 150UI proposed by OPTIMIST trial, from 20.8% to 24.1% (p=0.046). Interestingly, we also observed a significant reduction of overall use of starting dose >300UI from 10.3% in 2017 to 5.6% in 2018 (p <0.01). In predicted POR undergoing their first COS, the mean FSH starting dose reduced from 317UI to 302 UI (p< 0.03). This approach did not determine any differences in terms of oocytes retrieved in the before and the after group respectively (4.21 ± 3.1 vs 4.22 ±3.4, p=0.258), metaphase II oocytes when ICSI was used (3.04± 2.4 vs 3.2 ± 2.7, p=0.43) or total number of oocytes fertilized (IVF/ICSI) (3.0 ±2.6 vs 2.8 ± 2.59, p=0.42). Cumulative pregnancy rate was also comparable between the two years (20.3% vs 20.9% in 2017 and in 2018 respectively, p=0.84).

Limitations, reasons for caution: Retrospective nature of the study. Overall cumulative pregnancy rate is still partly pending at the time of data collection, because a proportion of non-pregnant patients (mainly hyper- and normo-responders and mainly treated in 2018) might return in the future for frozen embryo transfer attempts.

Wider implications of the findings: Our clinical results confirm that EBM provided by the OPTIMIST trial has somehow influenced our ART daily practice, bringing to a reduction of starting doses without limiting outcomes. On the other hand, adherence to the OPTIMIST indications is still generally poor.

Trial registration number: not applicable

O-155 Experience in random-start ovarian stimulation in cancer patients

Y. Martirosyan[1], T. Nazarenko, Alekseevna[2], A. Birukova, Mikhailovna[1], L. Dzhanashvili , Georgievna[1]

[1]National Medical Research Center for Obstetrics- Gynecology and Perinatology named after V.I. Kulakov- Ministry of Health of Russia, Research and educational center for assisted reproductive technologies named after F. Paulsen-senior, Moscow, Russia C ;

[2]National Medical Research Center for Obstetrics- Gynecology and Perinatology named after V.I. Kulakov- Ministry of Health of Russia, the Research and educational center for assisted reproductive technologies named after F. Paulsen-senior, Moscow, Russ

Study question: What is the effectiveness of ovarian function stimulation in the luteal phase of the cycle compared with the follicular phase in patients underwent fertility preservation?

Summary answer: Ovarian stimulation in the luteal phase allows us to optimize strategies of ovarian stimulation in cancer patients without compromising the oocyte yield.

What is known already: The choice of ovarian stimulation protocol for cancer patients is based on a balance between two main factors: the limited time available for fertility preservation (FP) before the start of gonadotoxic therapy, and the need to obtain a sufficient number of suitable oocytes and embryos for cryopreservation. Despite data about comparable efficacy of the ovarian stimulation with GnRH-ant in the follicular phase of the cycle and stimulation in the luteal phase, many questions remain open.

Study design, size, duration: We performed a prospective observational study at the National Medical Research Center for Obstetrics, Gynecology and Perinatology named after V.I. Kulakov from February 2019 to December 2019. A total of 160 women who had FP consultation prior to neoadjuvant chemotherapy were identified. 47 patients were enrolled for the study according to inclusion criteria.

Participants/materials, setting, methods: Depending on the phase of the menstrual cycle when ovarian stimulation was started, two groups of patients were identified: I - ovarian stimulation started in the early follicular (n=34) and II - luteal phase group (n=13).

We measured the number of retrieved oocytes and mature oocytes, stimulation duration, initial and total gonadotropin dose, the parameters of steroidogenesis. Differences were tested using a two-sided Student's t-test or a Pearson's Chi2 test, as appropriate.

Main results and the role of chance: All patients included in the study were comparable in age and AMH level (33.38 ± 3.73; 33.3 ± 5.47 years, p=0.967580 ; AMH - 3.0 ± 2.14 ng /ml 2,72±0,41 ng / ml, p=0.693440). Antral follicle count (AFC) were significantly lower in the II group 9,2±1,2; 5,8±1,14, p=0.046535). There were no differences in the mean number of oocytes retrieved in the follicular phase group, and luteal phase group (10,33 ±2,57 versus 11,62±1,64; p=0.676949). Similarly, no significant differences were observed in the number of M II occytes (6,9±1,14 versus 8,92± 0,94; p=0.179224), stimulation duration (12,6±0,6; 13,5±1,1, p=0.476761), initial (243,06 ± 12,96 IU versus 233,33 ± 20,73 IU, p=0.694155) and total gonadotropin dose (2635,44 ±187,75 IU versus 2145,83 ±277,72 IU, p=0.158947). Estradiol (E2) and progesterone (P) levels on the day when the ovulation stimulation was started were different among the two groups (211,62±40,19 pmol/L versus 693,47±151,04 pmol/L, p<0.05;1,13±0,1 nmol/L versus 22,44±9,97 nmol/L, p<0.05). Perhaps due to the regression of the corpus luteum, we observe comparable levels of E2 and P in both groups on the 6th day of ovarian stimulation and on the day of the trigger administration. Premature LH surge did`t observe in the absence of GnRH-ant administration in the II group.

Limitations, reasons for caution: The current work is a pilot study. Larger prospective trials are planning.

Wider implications of the findings: Our data allow us to talk about the comparable effectiveness of ovarian stimulation of the follicular and luteal phases of the cycle. Modern knowledge on folliculogenesis lets us to optimize strategies of ovarian stimulation not only from the point of flexibility.

Trial registration number: None

O-156 Pituitary supression is not necessary for blocking LH surge during luteal-phase stimulation

M. Cruz Palomino[1], E. Henzenn[1], A. Requena[1]

[1]IVI Madrid, Reproductive Medicine, Madrid, Spain

Study question: Can we avoid the administration of pituitary suppressors during a luteal phase stimulation without affecting the ovarian response?

Summary answer: In absence of pituitary supressors during luteal-phase stimulation, it is posible to block a physiological LH surge without impacting normal ovarian response

What is known already: New stimulation approaches allow for a total disarticulation between the time of the menstrual cycle, ovarian stimulation start and embryo transfer. Double stimulation (DuoStim) was initially designed to optimize clinical outcomes in poor ovarian response, but it could be also useful in fertility preservation for non-medical reasons, especially for oocyte/embryo accumulation. Pituitary suppressors block the LH surge; however, in a protocol as specific as DuoStim, it could be assumed that these suppressors are not necessary in the luteal phase because the endogenous progesterone released during follicular phase is sufficient to block the LH surge during the luteal phase

Study design, size, duration: Prospective and observational analysis performed in IVI Madrid between September and December 2019. Participants were randomly assigned to each of the study groups. Participants underwent the same stimulation protocol in the follicular phase and for luteal phase stimulation, they were allocated in a control group with pituitary suppressors (n=10) or in a study group, where this medication was not administered (n=10). Statistical analysis was performed by ANOVA and Chi-squared where applicable.

Participants/materials, setting, methods: Follicular-phase stimulation was the same for both study groups; daily tablet of 10 mg of acetate of medroxyprogesterone (AMP) from first day of stimulation, 225 IU/day ecombinant FSH and triggering with 0.1 mg GnRH agonist. For the control group, luteal-stimulation is identical to the previous one; and in the study group, the only difference is that AMP was not administered daily from the start of the stimulation. LH, estradiol and progesterone were monitored during luteal-phase.

Main results and the role of chance: As expected, and in the case of a homogeneous population such as oocyte donors, no differences were observed between the two study groups in follicular-phase stimulation, either with respect to endocrine profile or ovarian response. For control and study group respectively, the results were as follows: basal LH (6.11±1.6 IU vs 6.6±2.4 IU, p=0.680); LH on the triggering day (3.1±1.8 IU vs 2.3±0.7 IU, p=0.548); progesterone on the triggering day (1.4±0.3 ng/ml vs. 1.1±0.1 ng/ml, p=0.180); retrieved oocytes (16.7±3.0 vs. 20.1±5.4, p=0.389);and metaphase II oocytes (14.2±3.5 vs. 16.7±4.5, p=0.496).

These results are maintained for the luteal-phase stimulation, meaning that the endogenous profile in the stimulated folicular-phase is capable of inhibiting LH surge, not affecting the results derived from this second stimulation. For control and study group respectively, the results were as follows: basal LH (1.6±1.3 IU vs 1.7±0.6 IU, p=0.335); LH on the triggering day (0.5±0.4 IU vs 1.5±0.6 IU, p=0.300); progesterone on the triggering day (0.6±0.1 ng/ml vs. 0.4±0.1 ng/ml, p=0.398); retrieved oocytes (14.5±1.6 vs. 12.8±2.1, p=0.575);and metaphase II oocytes (11.7±1.0 vs. 10.4±2.3, p=0.609).

Finally, it should be noted that no rescue protocol with administration of GnRH antagonist was applied in the study group, because of ovulation risk

Limitations, reasons for caution: These results could be considered as an interim analysis, as they are framed within a pilot study prior to conducting a larger study so, although the current data are encouraging, we are not able to draw solid evidences due to our small simple size

Wider implications of the findings: In a certain group of patients such as oocyte donors, double stimulation implies advantages such as the possibility of achieving more oocytes in less time, optimizing the economic profitability of the egg donation program without compromising clinical results becuase of the absence of pituitary supresor during luteal-phase.

Trial registration number: Not applicable

Abstract text

Abstract title: International Committee for Monitoring Assisted Reproductive Technologies (ICMART) Preliminary World Report on ART, 2016

Study question: In 2016 what was global utilization, effectiveness and safety of ART?

Summary answer: Globally, ART utilization and data collection continue to increase but with wide variations in utilization, effectiveness and safety.

What is known already: ICMART began ART global data collection in 1991. Utilization, effectiveness and safety have continuously improved with more cycles, higher pregnancy rates and lower multiple birth rates, the latter as a result of transfer of fewer embryos. Frozen embryo transfer (FET) and donor egg cycles continue to increase. However, wide variations in practice and outcomes exist globally. Over 8 million ART babies have been born. ICMART has helped develop registries internationally, notably with the African Network and Registry for Assisted Reproductive Technology (ANARA). A new electronic data collection platform is being developed; nevertheless, data collection and quality remain challenging. China has recently published its first comprehensive report on assisted reproductive technology service availability, efficacy and safety in mainland China: 2016.

Study design, size, duration: Countries and regions annually collect ART data, some prospectively and others retrospectively. ICMART retrospectively requested these data from all known global sources for 2016 and reviewed them for missing or incorrect data. The dataset was corrected and then analyzed utilizing standardized definitions from The ICMART/WHO Revised Glossary on ART Terminology, 2009 which was current at the time but is now replaced by The International Glossary on Infertility and Fertility Care, 2017, and previously developed methods. Preliminary results are presented. China results are summarized and compared with other global data.

Participants/materials, setting, methods: The European IVF Monitoring Consortium (EIM), Latin American Network of Assisted Reproduction (REDLARA), Australian/ New Zealand Registry and ANARA submitted regional data, and other countries contributed national data, through standardized formats to ICMART. A few individual clinics with no registry access also contributed. Data were reviewed, corrected, validated to the extent possible, analyzed and summarized by ICMART using descriptive statistics. China CDC and National Health Commission published their data in Human Reproduction.

Main results and the role of chance: Data collection and analysis are ongoing, so presented results are preliminary. The number of ART cycles continues to increase, but utilization is still highly variable among countries and regions. Regional and country differences persist in the age of the population treated, number of embryos transferred, rate of multiple births, use of ICSI, cryopreservation cycles and other factors.

The role of chance is minimal. Actual global ART results are limited to reporting countries and clinics representing approximately 2/3 of global cycles. However, this is a very large sample size from which imputation of total global results is performed. Addition of data from China improves significantly global reporting of ART data. China results are not different than overall global data.

Limitations, reasons for caution: Some countries have limited data and many countries have limited data validation. ICMART can perform only minimal verification of submitted data. Widespread adherence to consensus definitions provided in the Glossary takes time and requires translation into multiple languages. China data has some similar and different limitations.

Wider implications of the findings: ICMART World Reports standardize data, track trends, enable comparisons, stimulate questions and improve ART quality. Better understanding of ART increases societal acceptance and support for equitable access and ART research. Addition of China data is an important milestone in global ART data reporting.

[7]University of New South Wales, National Perinatal Epidemiology and Statistics Unit- Centre for Big Data Research in Health- School of Women's and Children's Health, Sydney, Australia
[8]Equal3 Fertility, Equal3 Fertility, Cupertino, U.S.A.

Study question: How is the transition to SET being realized in a global perspective? What are key issues for policymaking regarding the number of embryos transferred in various countries in the world?

Summary answer: The global SET rate significantly rose during the last 10 years, resulting in safer ART outcomes with lower multiple pregnancy rates and better infant indicators. However, different policies on SET resulted in some countries and regions continuing to have very high multiple rates. It is important to consider the use of multiple strategies that have successfully been introduced

in some countries to encourage the transition to SET and have resulted in safer ART.

What is known already: Decreasing the number of embryos transferred at ART strongly correlates with better outcomes of infants, namely, lower multiple pregnancy rates, lower preterm rates and fewer low birthweight infants. Acceptance of SET has been variable in regions and countries due to multiple factors.

Study design, size, duration: Retrospective analysis of the accumulated ICMART world ART registry data between 2002 and 2014 which had 601,243 and 1,647,777 initiated cycles reported, respectively, to determine the trend of average number of embryos transferred, the SET rates, and their outcome parameters by countries. Individual country data are also used for selected counties.

Participants/materials, setting, methods: ICMART world ART registry data annually reported by contributors from regional or national registries from 53-77 countries between 2002 and 2014.

Main results and the role of chance: The global average number of fresh embryos transferred and the SET rate were 2.47 and 12.4% in 2002 and improved to 1.73 and 40% in 2014. In FET cycles the results were even better at 1.43 and 61.6% in 2014. In response to the decreased number of embryos transferred, global multiple pregnancy rates in fresh non-donor IVF and ICSI cycles dropped from 28.2% (triplet 2.5%) in 2002 to 16.7% (triplet 0.5%) in 2014. However, countries can be grouped into 3 categories, those: 1) continuously maintaining highest SET rate; 2) achieving higher SET rate during the period; 3) continuing to have low SET rates throughout the period. The highest countries have SET rates of approximately 80% while other countries have only 10-20% with multiple pregnancy rates of approximately 30%.

Limitations, reasons for caution: The data accumulated by ICMART from different countries are of variable quality and comprehensiveness. Additionally, it is not possible for ICMART to validate the data.

Wider implications of the findings: These trends are important to follow. Clinical practices regarding number of embryos transferred are affected by cultural values, societal financial support of ART, changes in technology such as PGT-A, and other factors.

INVITED SESSION

SESSION 41: ALMER EXCHANGE SESSION - IVF LABORATORY AUTOMATION

07 July 2020 Parallel 3 14:00 - 15:00

O-159 Cons

C. Racowsky[1]

[1]*Brigham & Woman's Hospital, Department of Obstetrics & Gynecology ASB 1 + 3*

O-160 Pros

G.D. Smith[1]

[1]*6428 Medical Science I University of Michigan, Departments of OB/GYN- Physiology- and Urology, Ann Arbor- MI, U.S.A.*

Abstract text

Andrology and embryology laboratory practices have evolved over the last 4-5 decades, ultimately leading to increased technologies, increased personnel work hours per cycle, and increased success in treating infertility and preserving fertility. The manual labor component of andrology/embryology laboratory is intensive with many technologies requiring high degree of training and subject to technologist variability, drift, and retraining. Integration of new principles of bioengineering, microfluidics, and automation have been beneficial in other areas of everyday life, science, and medicine. In this presentation we will provide examples of scientific and social automation and discuss potential benefits. The integration of microfluidics for mechanical benefit and microenvironmental/physiological benefit will be proposed. Discussions will focus on proof-of-principle applications of microfluidics and automation to andrology, embryology, and cryobiology as they relate to laboratory tasks and the potential benefits they provide, both practically and biologically. Finally, we will discuss the goals and needs for integration of microfluidics for cell manipulation, insemination, culture, sampling, assays, and cryopreservation. This integration will facilitate automation within the clinical andrology/embryology laboratory and will have enabling influences on other evolving technologies such as machine learning and artificial intelligence for data collection and decision making in the IVF lab. These are not trivial goals and will require significant design, testing, and multidisciplinary interactions to be successful in the next generation of andrology/embryology practical laboratory patient care.

INVITED SESSION

SESSION 42: STRESS AND INFERTILITY - THE CHICKEN OR THE EGG

07 July 2020 Parallel 4 14:00 - 15:00

O-161 Just relax and it will happen?: the case for stress causing lack of pregnancy

J. Boivin[1]

[1]*Cardiff University, School of Psychology (Cardiff Fertility Studies Research Group), United Kingdom*

O-162 Just relax and it will happen?: The case against stress as a cause of infertility

A. Lawson[1]

[1]*Northwestern University, Obstetrics & Gynecology and Psychiatry, Chicago, U.S.A.*

Abstract text

"Just relax. It will happen." It's a phrase commonly heard by women struggling to get pregnant. Although the statement is likely intended to let women know that others are optimistic about their chances of having a baby, at its core it blames women for being too stressed to conceive. For generations, many have believed that psychological stress caused physiological changes that interfered with a woman's chances of conceiving. Although anecdotal stories of women relaxing and getting pregnant have been widely shared, rigorous research examining the role of stress in the etiology of infertility is limited. What little research exists does not support a direct link between the relationship between stress and infertility.

If, as hypothesized, psychological stress/distress can interfere with fertility then it could be argued that activities that produce a relaxation response could improve pregnancy chances. Indeed multiple studies have examined the positive effects of relaxation or relaxing activities and the cessation of stress inducing activities (e.g, fertility treatment) on both fertility and the reduction of emotional distress. However, these studies are also often not appropriately designed to rigorously answer the question about whether or not a relationship between relaxing and pregnancy chances exists. Because controversy exists regarding the relationship (or lack thereof) between stress and infertility, inconsistency in counseling of patients regarding the need for stress reduction is rampant. This presentation will address the biological and psychological issues in stress and infertility and will provide direction to providers for how to address these issues with patients.

SELECTED ORAL COMMUNICATIONS

SESSION 43: ICSI IN 2020

07 July 2020 Parallel 1 15:15 - 16:30

O-163 Advancement in the future automation of ICSI: Use of deep convolutional neural networks (CNN) to identify precise location to inject sperm in mature human oocytes

J. Dickinson[1], A. Meyer[1], N. Kelly[1], P. Thirumalaraju[2], M. Kanakasabapathy[2], D. Kartik[2], C. Bormann1, H. Shafiee[3]

[1]Massachuesetts General Hospital, Obstetrics and Gynecology, Boston, U.S.A. ;
[2]Brigham and Women's Hospital, Division of Engineering in Medicine- Department of Medicine, Boston, U.S.A. ;
[3]Brigham and Women's Hospital, Department of Medicine- Harvard Medical School, Boston, U.S.A.

Study question: Can a deep-learning artificial intelligence algorithm be used to accurately identify the appropriate location to perform ICSI on metaphase II (MII) human oocytes?
Summary answer: The AI trained network can be used to accurately identify the correct location on the oocyte to inject sperm for ICSI.
What is known already: ICSI is a procedure that includes, alignment of MII oocytes, selection and immobilization of sperm, and injection of sperm at a precise location that does not interfere with the mitotic spindle. The spindle is located adjacent to the extruded polar body (PB) and cannot be visualized using brightfield microscopy. Therefore, it is standard practice to align oocytes based on the location of the PB and to inject sperm 90° from this visible structure. The goal of this study was to train an artificial intelligence (AI) algorithm to identify the position of the PB and the corresponding location for sperm injection.
Study design, size, duration: Using a retrospective dataset of denuded MII oocytes, a deep CNN model was trained and tested to classify between 12 classes at 4-6 hours post oocyte retrieval. The twelve classifications resembled the pattern of digits on a clock, spaced 30° apart to provide an accurate location the extruded PB.
Participants/materials, setting, methods: We developed a deep convolutional neural network that was trained with 13992 annotated images of MII oocytes. We classified the location of the PB and corresponding location for sperm injection. The validation set containing 1920 oocyte images served to ensure the program training was complete. The developed network was evaluated using another independent set of 3900 MII oocyte images with known PB and sperm injection location classifications.
Main results and the role of chance: The deep learning CNN was able to correctly identify the location of the PB and corresponding location for sperm injection with 98.9% accuracy with a 95% confidence interval (CI) ranging between 98.5% to 99.2% (n=3900). Furthermore, a receiver operator characteristic (ROC) revealed micro and macro area under the curves (AUC) of 1, which confirmed that the AI can accurately identify the position of the PB and the corresponding location for sperm injection.
Limitations, reasons for caution: Only MII oocytes were used in this trial. Images were obtained using a single imaging platform (EmbryoScope) at a single timepoint. All cumulous cells were removed from the oocytes prior to training. It is unclear whether residual cumulous cells would affect the accuracy of the algorithm.
Wider implications of the findings: Advanced ICSI automation requires precision that cannot be achieved using tracking algorithms. Automation requires complex decisions that can be achieved using deep-learning technologies. Prior studies showed ability for CNNs to identify morphologically normal sperm. This study compliments this work by accurately identifying the correct position to inject sperm into oocytes.
Trial registration number: not applicable

O-164 The application of AOA-artificial oocyte activation in patients with previous unsuccessful attempt increases the ongoing pregnancy per treatment but not per transfer; a multivariable study

A. Galán Rivas[1], L. Alegre[1], M. Meseguer[1], T. Viloria[1], A. Pellicer[2], A. Tejera[1]

[1]Instituto Universitario IVI Valencia, IVF Lab, VALENCIA, Spain ;
[2]IVIRMA Roma, Reproductive Medicine, Roma, Italy

Study question: To check the effectiveness of AOA in patients with previous very low or failed fertilization rates in terms of fertilization, implantation and ongoing pregnancy outcomes.
Summary answer: After applying AOA the ongoing pregnancy rates of the patients per initiated treatment were enhanced, as well as a significant reduction in the cancellation rate.
What is known already: Different authors have demonstrated better results after using AOA in couples with low or non-fertilization in previous treatments: (Heindryckx et al., 2005, Heindryckx et al., 2008, Montag et al., 2012). Recently, we have seen extensively described similar benefits by the use of AOA for couples with previous standard ICSI failure (Fawzy et al., 2018). The implementation of this technique in the current clinical routine has been possible after reporting no detrimental impact on neither human gametes (Ebner et al., 2015) nor on the offspring (Vanden Meerschaut et al., 2014).
Study design, size, duration: Retrospective cohort study, from four consecutive years. We studied 509 oocytes from 66 patients who were treated with standard ICSI, and were compared to 616 oocytes from the same cohort of patients but using AOA.
Participants/materials, setting, methods: 66 patients were included in the study generating 163 cycles; standard group was composed of 509 oocytes generating 75 cycles (18 fresh cycles, 4 frozen cycles, 1 mixed and 52 cancelled cycles). AOA group included 616 oocytes resulting from the same patients, but creating 88 cycles (31 fresh cycles, 37 frozen cycles). AOA technique involves oocyte injection by spermatozoa and incubation for 10 minutes with calcium ionophore. Outcome analysis included a multivariable logistic regression model.
Main results and the role of chance: Although no differences were observed in relation with the day of transfer (Day 3 vs Day 5) and maternal age at the time of the cycle, we performed a multivariable logistic regression including those variables as potential bias factors. The study was performed to assess the impact of AOA on ongoing pregnancy per cycle as well as per transfer. We observed that the application of AOA in our patients increased the chances of a viable pregnancy by more than 4 times (OR=4.57, p=0.008) per cycle but not per transfer (OR=0.964, Not significant). When embryos were available for transfer AOA did not increased the chances of a viable pregnancy.
Limitations, reasons for caution: The retrospective analysis of this study may be a reason to take into consideration. Another limitation was not to study the PLCζ levels of the sperm, then we presumed that this dysfunction was presented in the spermatozoa and, in consequence, was the responsible for the fertilization failure.
Wider implications of the findings: Our findings suggest the use of AOA for a particular population where the fertilization was failed in previous attempts. After AOA application, the fertilization rate was enhanced, increasing the chances of success per treatment. The use of AOA is comforting after checking non-existence of detrimental impact on the offspring.
Trial registration number: none

O-165 Toward an ICSI chip: automated microfluidic oocyte denudation module

A. Mokhtare[1], P. Xie[2], A. Abbaspourrad[1], Z. Rosenwaks[2], G. Palermo[2]

[1]Cornell University, Department of Food Science and Technology, Ithaca, U.S.A. ;
[2]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: To determine whether novel microfluidic technologies can improve the efficiency and quality of an oocyte denudation process for intracytoplasmic sperm injection (ICSI).
Summary answer: The inevitable exposure of oocytes to high mechanical stresses, different oxygen concentrations, and temperature variations can be alleviated using an automated microfluidic oocyte denudation module.
What is known already: A microfluidic device has recently been introduced in the clinical field and has proven successful in selecting competent spermatozoa. Conventional cumulus removal (CR) techniques use high mechanical stress (pipette flushing) with enzymatic treatment or high fluidic stresses (vortexing) to treat cumulus-oocyte-complexes (COC) prior to ICSI. These operations not only impose unfavorable stresses on oocytes, but also require a highly skilled embryologist. Microfluidic technologies offer novel opportunities to streamline ART to facilitate gamete preparation, reduce mechanical and cytotoxic stress, and minimize inter-operator variability. Such automated and continuous systems

may replace manual CR operation while ensuring optimal environmental conditions.

Study design, size, duration: We developed a semi-automated oocyte denudation microfluidic chip (ODMC) controlled through microcontrollers with a graphical user interface (GUI). The chip consists of a 2-layer microchannel, with channel width similar to the diameter of mouse COC (200 µm). The bottom layer contains bas-relief structures to gently agitate the pressure-driven laminar flow inside microchannels without imposing excessive stress on the oocytes. Denudation rate and embryo developmental competence were compared between oocyte cleaning by ODMC and manual pipetting.

Participants/materials, setting, methods: COCs were retrieved from 3 superovulated B6D2F1 mouse oviducts and individually dissected. ODMCs were fabricated from polydimethylsiloxane (PDMS) by planar photolithography and installed with inlet and outlet reservoirs that facilitate injection and expulsion of hyaluronidase (80 IU/ml) throughout ODMCs. COCs were gently oscillated inside the channels on top of the bas-relief structures and denuded by laminar chaotic mixing. The GUI allows users to assess denuding oocytes in real-time and unload cleaned oocytes at their discretion.

Main results and the role of chance: Murine COCs were processed by ODMC with optimized geometry and operating parameters including oscillating frequency, flow rate, channel width, and number of bas-relief structures. The oscillating frequency and flow rate were able to tumble COCs to expose the entire surface to bas-relief structures to evenly strip-off cumulus cells (CCs). Using a high-speed camera recording real-time denudation, we observed that angular displacement of fluid and transverse flows surrounding COCs are the main denudation mechanisms. Computational fluid dynamics (CFD) simulations quantified microfluidic profiles in the ODMC to that of manual pipetting (MP). CFD results showed that the maximum shear stress imposed on COCs was 40% less in the ODMC compared to MP at the same flow rate. Denudation efficiency, defined as the percentage of complete CC deprivation at the outlet reservoir, was comparable between the ODMC and MP (95% vs. 91%) without oocyte loss. To ensure that our ODMC does not compromise the developmental potential of the gametes, piezo-actuated ICSI was performed on 50 oocytes processed by each method. ODMC and MP groups yielded comparable post-ICSI survival (84.0% vs. 82.0%), fertilization (92.9% vs. 90.2%), and blastocyst formation rates (90.5% vs. 87.8%), confirming that ODMC does not have adverse effects on preimplantation development.

Limitations, reasons for caution: PDMS is known for easy prototyping, high optical transparency, and biocompatibility. However, adverse effects including small molecule adsorption and gas permeability can be disadvantageous in delicate embryology procedures. Large-scale mouse embryo assay should be performed to assess teratogenicity of PDMS. Clinical-grade polystyrene may be utilized due to a lower toxicity.

Wider implications of the findings: This device offers a glimpse into the potential of a fully automated embryology laboratory and is being optimized for ICSI. Constructing different modules in addition to COC denudation is required for maturity recognition, injection, and storage of the conceptuses to follow embryo evaluation when applied in conjunction with artificial intelligence.

Trial registration number: not applicable

O-166 Marginal differences in preimplantation development between conventional IVF and ICSI in patients with non-male factor infertility: a sibling oocyte study.

N. De Munck[1], A. Bayram[1], A. Arnanz[1], A. Abdala[1], I. El-Khatib[1], A. El-Damen[1], L. Melado[2], B. Lawrenz[2], H.M. Fatemi[2]

[1]IVI RMA Middle East Fertility Clinic LLC, IVF lab, Abu Dhabi, United Arab Emirates ; [2]IVI RMA Middle East Fertility Clinic LLC, Gynaecology, Abu Dhabi, United Arab Emirates

Study question: Are there differences in the morphokinetic behavior between conventional IVF and ICSI in cycles with pre-implantation genetic testing for aneuploidies?

Summary answer: Preimplantation development is marginally, yet significantly different between embryos generated by conventional IVF and ICSI.

What is known already: Conventional IVF results in a delayed (4 hours) pronuclear formation and first mitotic divisions when compared to ICSI on sibling oocytes. This difference disappears around the time of morula formation in donor oocyte cycles. On the other hand, it has also been shown in autologous oocytes that IVF blastocysts start to expand 3 to 4 hours earlier than ICSI-generated blastocysts. When standardizing for the time of pronuclear fading, the differences in early cleavage disappear between IVF and ICSI, while blastulation and blastocyst expansion occurs earlier for IVF embryos.

Study design, size, duration: Prospective cohort study between November 2018 and April 2019, including 568 oocytes (30 patients) with non-male factor infertility for which half of the sibling oocytes were inseminated with conventional IVF (n=283) and the other half with ICSI (n=285). Embryos were cultured in an Embryoscope time-lapse incubator and trophectoderm biopsy was performed on good-quality blastocysts. The following timings were annotated: tPNf, t2-9, tSC, tM, tSB, tB, tEB, cc2(t3-t2), cc3(t5-t3), s2(t4-t3), s3(t8-t5) and Blast(tSB-t2).

Participants/materials, setting, methods: Univariate ($p<0.20$) and multivariate ($p<0.05$) analysis was performed in order to find morphokinetic differences between conventional IVF and ICSI. A secondary analysis was performed which corrects for the difference in time of fertilization, by standardizing all time lapse parameters for the time of pronuclear fading. Subgroup analysis for all day 5+6 biopsied blastocysts was performed. Results are presented as average ± SD, Odds Ratio [95% CI].

Main results and the role of chance: A total of 283 and 285 cumulus oocyte complexes were assigned to conventional IVF and ICSI of which 183 (64.7%) and 190 (66.7%) were normally fertilized, respectively. Conventional IVF generated 120 blastocysts that were biopsied, of which 59 (49.2%) were euploid, while 116 blastocysts were biopsied after ICSI of which 56 (48.3%) were euploid. Gender distribution (male/female) for blastocysts with informative outcome was 60/49 and 50/55, respectively.

When comparing the development of all normally fertilized zygotes between IVF and ICSI in the univariate model, a significant difference was found for tPNf ($p=0.005$), t2 ($p<0.001$), t3 ($p=0.001$), t4 ($p=0.003$), t5 ($p=0.001$), t6 ($p=0.096$), t7 ($p=0.177$) and Blast ($p=0.004$) of which only t2 remained significant in the multivariate model (OR: 1.282 [1.020-1.612], $p=0.033$); IVF: 29.3 ± 10.4 versus ICSI: 25.9 ± 5.1. After standardizing for tPNf, only corrected tSB ($p=0.009$) and Blast ($p=0.004$) showed significant differences between IVF and ICSI. However, only Blast appeared significant in the multivariate model: OR: 0.803 [0.648-0.994], $p=0.044$; IVF: 70.8 ± 8.2 versus ICSI: 72.5 ± 9.7. Taking into consideration the standardized kinetics of biopsied blastocysts, only a difference was observed for t2: OR: 1.519 [1.045-2.206], $p=0.028$; IVF: 3.4 ± 2.6 versus ICSI: 3.1 ± 3.3.

Limitations, reasons for caution: Only couples with non-male factor infertility and a normal response to ovarian stimulation were included, and therefore, the results cannot be extrapolated to other patient populations.

Wider implications of the findings: Following the recent debate on the over-use of ICSI, this study shows that conventional IVF results in the same number of blastocysts for biopsy with similar developmental kinetics, thereby reinforcing the use of conventional IVF in this patient population.

Trial registration number: NCT03708991

O-167 Intracytoplasmic sperm injection versus conventional in vitro fertilisation in couples with non-male factor infertility: a randomised controlled trial

Q.V. DANG[1], L. Vuong[2], Q. Nguyen[1], T. Ho[3], A. Ha[1], B. Truong[3], Q. Pham[4], R. Wang[5], R. Norman[6], B. Mol[5]

[1]My Duc Hospital, IVF Department, Ho Chi Minh City, Vietnam ; [2]University of Medicine and Pharmacy at Ho Chi Minh City, Department of Obstetrics and Gynecology, Ho Chi Minh City, Vietnam ; [3]An Sinh Hospital, IVF Department, Ho Chi Minh City, Vietnam ; [4]My Duc Hospital, HOPE Research Center, Ho Chi Minh City, Vietnam ; [5]Monash University, Department of Obstetrics and Gynecology, Melbourne, Australia ; [6]The University of Adelaide, Robinson Research Institute and Adelaide Medical School, Adelaide, Australia

Study question: Does intracytoplasmic sperm injection (ICSI) result in a higher ongoing pregnancy rate compared to conventional in vitro fertilisation (IVF) in couples with non-male factor infertility?

Summary answer: In couples with non-male factor infertility, ICSI did not result in a higher ongoing pregnancy rate compared to conventional IVF

What is known already: There is an increasing trend worldwide in the use of ICSI for couples with non-male factor infertility. Randomised controlled trials

(RCTs) have not demonstrated better outcomes of ICSI compared to conventional IVF, but their statistical power was limited and most studies used fertilisation as primary outcome. Moreover, non-randomised studies suggest no benefit and maybe even harm from ICSI compared to conventional IVF in this population.
Study design, size, duration: This open-label, multi-center RCT was conducted at two IVF centers in Vietnam. The protocol has been published (Dang et al., 2019). A sample size of 1064 couples was calculated to demonstrate a 10% difference between ICSI and conventional IVF (power 0.90, two-sided alpha 5%, loss to follow-up 10%). Randomisation was done using a computer-generated randomisation list, with a variable block size of 2, 4 or 8.
Participants/materials, setting, methods: Couples were eligible if the male partner had normal sperm count and motility (WHO, 2010) and had undergone ≤2 previous IVF/ICSI attempts. Women undergoing in vitro maturation cycles, using frozen semen or having a poor fertilisation (≤25%) in previous cycle were not eligible. The primary outcome was ongoing pregnancy resulting in live birth after the first embryo transfer. Intention-to-treat analyses were used.
Main results and the role of chance: Between March 2018 and August 2019, 1064 couples were randomly assigned to ICSI (n=532) or conventional IVF (n=532). Baseline characteristics were comparable between the two groups (mean female age 32 years, total sperm counts 190 million, sperm motility 43%). The follow-up for live birth is ongoing and will be available by June 2020. Ongoing pregnancy rates after the first embryo transfer were 36.3% in the ICSI group versus 32.7% in the conventional IVF group (RR 1.11; 95% CI 0.94-1.31; p=0.25). Fertilisation rate per oocyte retrieval and total fertilisation failure rate also did not differ siginficantly between the two groups (55.6% versus 52.7% and 5.5% versus 6.4%, respectively). The mean number of embryos and number of frozen embryos were not significantly different between the two groups, 5.9 ± 4.0 versus 5.7 ± 4.5 and 3.9 ± 2.9 versus 3.8 ± 3.1, respectively. Mean number of embryo transferred were 1.91 ± 0.29 and 1.90 ± 0.30. Implantation rates were 28.5% in the ICSI group versus 28.9% in the conventional IVF group. The rates of clinical pregnancy and miscarriage were 43.0% versus 39.6% (RR 1.08; 95% CI 0.94-1.25; p=0.29) and 4.7% versus 5.1% (RR 0.92; 95% CI 0.54-1.57; p=0.89), respectively.
Limitations, reasons for caution: Double blinding was not possible due to the nature of the interventions. This study excluded couples with a poor fertilisation (≤25%) in previous cycle, which limits its generalizability. The results are based on preliminary analysis, as follow-up of live birth is still ongoing.
Wider implications of the findings: In couples with non-male factor infertility, ICSI did not show significant benefit over conventional IVF. This questions the value of routinely use of ICSI in non-male fertility in routine assisted reproduction.
Trial registration number: NCT03428919

SELECTED ORAL COMMUNICATIONS

SESSION 44: WHAT ARE THE OPTIMAL REGIMES FOR FROZEN EMBRYO TRANSFER?

07 July 2020 Parallel 2 15:15 - 16:30

O-168 Natural cycle frozen-thawed embryo transfer (FET): A comparison of outcomes following blastocyst transfer on day six versus day seven after urinary luteinising hormone (LH) surge.

M. Noble[1], J. Craig[1], A. Bevan[1], T. Child[1,2]

[1]Oxford Fertility, Institute of Reproductive Sciences, Oxford, United Kingdom ; [2]University of Oxford, Department of Women's and Reproductive Health, Oxford, United Kingdom

Study question: In natural cycle FET (NC-FET) is there a difference in clinical outcome between frozen-thawed blastocyst transfer on the sixth compared to the seventh day after urinary luteinising hormone (LH) surge?
Summary answer: We observed double the odds of ongoing pregnancy (≥24 weeks) when frozen-thawed blastocyst transfer occurred on day six rather than day seven after urinary LH-surge
What is known already: Despite the recent rise in the annual number of FET cycles, a large survey of IVF clinics highlighted little consensus between IVF clinics regarding the day of blastocyst transfer in NC-FET. Only two small retrospective studies have compared different days of blastocyst transfer in NC-FET. The first compared blastocyst transfer on day five versus day six after serum LH surge; demonstrating higher live birth rate in the day five group. However, the most recent study demonstrated a similar ongoing pregnancy rate when blastocysts were transferred on day six compared to day seven after a serum LH level of ≥20 IU/L.
Study design, size, duration: We retrospectively analysed all NC-FETs between January 2017 and March 2019, before and after a protocol change (May 2018) from blastocyst transfer occurring on day seven after urinary LH surge (LH+7) to day 6 (LH+6). The primary outcome was **ongoing pregnancy rate ≥24 weeks (OPR)**. We included 558 NC-FET cycles (180 LH+6; 378 LH+7). As an independent control, outcomes from medicated FET were also compared between time periods (651 before, 483 after).
Participants/materials, setting, methods: We included all cycles involving NC-FET of vitrified-thawed, unbiopsied blastocyst(s) derived from autologous oocytes between January 2017 and March 2019 at Oxford Fertility. Outcomes were compared using Chi-squared and multivariate binary logistic regression. The primary outcome was ongoing pregnancy beyond 24 weeks. Over the time period other aspects of clinical practice remained unchanged and, as an independent control, outcomes from medicated FER cycles were also compared between time periods.
Main results and the role of chance: A total of 774 natural cycle FET cycles were started during the study period and after the inclusion criteria were applied a total of 558 cycles were analysed (180 LH+6; 378 LH+7). Baseline characteristics were similar, including age at FET and oocyte recovery, number of oocytes collected in the fresh cycle, fertilisation method (IVF or ICSI), endometrial thickness, day of blastocyst cryopreservation (day five or six), number of embryos transferred and proportion of top-quality embryos.

Ongoing pregnancy rate (OPR) beyond 24 weeks was significantly higher when blastocyst transfer occurred on LH+6 compared to LH+7 (45.0% v 29.1%, p< 0.0001). Adjusting for potential confounders the adjusted odds ratio was 2.13 (95% CI: 1.44-3.14, p<0.0001). Clinical pregnancy rate (52.2% v 32.8%; aOR 2.28, 95% CI 1.56 – 3.31, p<0.0001) and biochemical pregnancy rate (61.7% v 42.1%; aOR 2.26, 95% CI 1.56 – 3.30, p<0.0001) were also significantly (p<0.0001) higher in the LH+6 group. Miscarriage rate was similar between groups (26.1% v 30.2%, aOR 0.75 95% CI 0.42- 1.32, p=0.317).

The OPR for medicated FET was stable between time periods (38.9% after v 43.0% before; aOR 0.90, 95%CI: 0.70-1.16, p=0.41).
Limitations, reasons for caution: Our study is not randomised and compares groups before and after change in practice, rather than patients undergoing treatment contemporaneously. The fact that OPR for our independent control, medicated FET cycles, remained stable between the same time periods is reassuring. However, randomised prospective studies are needed to confirm our findings.
Wider implications of the findings: We observed double the odds of OPR (≥24 weeks) in cycles in which blastocyst transfer occurred at urinary LH+6 compared to LH+7, which is highly significant. Moreover, the high OPR highlights NC-FET with urinary LH testing as an effective, convenient and elegant method of FET in ovulatory women.
Trial registration number: Not applicable

O-169 Pregnancy outcome and cost-effectiveness comparisons of artificial cycle-prepared frozen embryo transfer with or without GnRH agonist pretreatment for polycystic ovary syndrome: a randomized controlled trial

L. Luo[1], Q. Wang[1]

[1]1st affiliated hospital of Sun Yat-Sen University, Center of Reproductive Medicine, Guangzhou, China

Study question: Can gonadotropin releasing hormone agonist (GnRH-a) pretreatment improve pregnancy outcome of artificial cycle-prepared frozen embryo transfer (AC-FET) for women with polycystic ovary syndrome (PCOS)?
Summary answer: For women with PCOS, GnRH-a pretreatment prior to AC-FET does not improve live birth rate but increases direct costs compared to AC-FET without GnRH-a pretreatment.

What is known already: For women with normal ovulation, randomized controlled trials (RTCs) and meta-analyses have reported similar live birth rates after AC-FET with or without GnRH-a pretreatment. However, two recent retrospective studies reported that AC-FET with GnRH-a pretreatment improved pregnancy outcomes for women with PCOS.
Study design, size, duration: A total of 342 women with PCOS (24–40 years of age) scheduled for AC-FET from January 2017 to November 2018 were enrolled in this RCT. Of these patients, 170 received AC-FET without GnRH-a pretreatment (AC group) and 172 with GnRH-a pretreatment (G-AC group). A total of 328 FET cycles were analyzed. Primary outcome was live birth rate and secondary outcomes were clinical pregnancy and early pregnancy loss rates. A cost-efficiency analysis was also performed.
Participants/materials, setting, methods: This study was conducted at the reproductive center of a university-affiliated hospital. Frozen embryos for transfer were obtained from the first ART cycle, and no patient received more than two cycles. All patients included received blastocyst transfer.
Main results and the role of chance: Neither live birth rate per FET cycle nor live birth rate per embryo transferred differed significantly between AC and G-AC groups [92/163 (55.8%) vs. 85/165 (51.5%) and 92/234 (39.3%) vs. 85/245 (34.7%), respectively; both P>0.05]. Clinical pregnancy and early pregnancy loss rates were also comparable between groups. The median direct cost was significantly lower in the AC group compared to the G-AC group (4526.6 RMB vs. 7984.0 RMB, P<0.001). The median direct cost per live birth was also significantly lower in the AC group (8117.6 RMB vs. 15415.1.0 RMB, P<0.001).
Limitations, reasons for caution: Indirect costs during the FET cycle and costs during the whole pregnancy period were not analyzed. Pregnancy-related complications and neonatal outcomes were also not analyzed.
Wider implications of the findings: For women with PCOS, endometrial preparation for FET was equally effective with and without GnRH-a pretreatment, but the direct cost was much higher with GnRH-a pretreatment.
Trial registration number: 81701403

O-170 Safety and IVF outcomes of Day 6 vitrified blastocyst transfers : comparison with Day 5 vitrified blastocyst transfers with propensity score matching

D.S. Park[1], S.W. Lyu[1], H.M. Park[1], J.H. Jeong[1], W.S. Lee[1]

[1]Fertility Center of CHA Gangnam Medical Center, Department of Obstetrics and Gynecology, Seoul, Korea- South

Study question: Does day 6 (D5) vitrified blastocyst transfer (VBT) have similar live birth rate (LBR) with day 5 (D6) VBT?
Summary answer: D6 group has significant lower LBR than D5 group in propensity score matching study.
What is known already: In fresh embryo transfer cycles, D6 blastocyst has significantly lower pregnancy rate compared with D5 blastocyst. However, it is unclear whether this result is maintained in VBT cycles, because of conflicting studies.
Study design, size, duration: This is retrospective cohort study with propensity score matching. We evaluated 1157 cycles of VBT performed between January 2014 and December 2015, at the Fertility Center of CHA Gangnam Medical Center.
Participants/materials, setting, methods: All VBT cycles were allocated to two groups according to the day of blastulation: There were 933 VBT cycles of D5 group and 224 VBT cycles of D6 group. The propensity scores were calculated using binary logistic regression analyses based on the patient and cycle baseline variables. The matched ratio for D5 vs D6 was 3:1, respectively. All patients were underwent natural endometrial preparation.
Main results and the role of chance: After matching, there were no significant differences of baseline characteristics between D5 and D6 groups. D6 group had significantly lower implantation rate (IR), clinical pregnancy rate (CPR) and LBR (IR 44.2% vs. 53.1%, p=0.023; CPR 48.4% vs. 60.4, p=0.009, LBR 33.5% vs. 51.8%, p<0.001). There were no significant differences in the ectopic pregnancy rate (1.3% vs. 2.8%, p=0.458) and multiple pregnancy rate (29.3% vs. 30.2%, p=0.816). Miscarriage rate was higher in Day 6 group (29.3% vs. 10.7%, p<0.001). Neonatal outcomes of D5 and D6 groups were not significantly different.
Limitations, reasons for caution: Although we performed analysis using propensity score matching to control for potential confounders between the study groups, retrospective design itself has limitations.
Wider implications of the findings: If there are no differences with morphological grade between day 5 and day 6 blastocysts, it should be considered to transfer day 5 vitrified blastocysts first in order to shorten time to live birth.
Trial registration number: not applicable

O-171 Comparison of day-5 serum progesterone levels using different routes of administration for artificial endometrial preparation: Intrapatient variation.

M. Cerrillo Martínez[1], G. Nardini[1], M. Cruz[2], M. Mayoral[1], M. Toribio[3], E. Labarta[4], J.A. García Velasco[5]

[1]IVI Madrid, Reproductive Medicine, Madrid, Spain ;
[2]IVI Madrid, embriology, Madrid, Spain ;
[3]IVI Madrid, Nurse department, Madrid, Spain ;
[4]IVI Valencia, Reproductive Medicine, Madrid, Spain ;
[5]IVI Madrid- URJC, Reproductive Medicine, Madrid, Spain

Study question: Is there any variability on the day-5 serum progesterone levels during artificial endometrial preparation using different routes of administration for Luteal phase (LP)?
Summary answer: Day-5 serum progesterone levels seem to be maintained above 9.2 ng/mL irrespective of the route of administration.
What is known already: Progesterone for artificial endometrial preparation can be administered orally, vaginally, subcutaneously or intramuscularly. Although the use of different P4 preparations differ among countries and physicians, vaginal route seems to be the most preferred one, but new options for luteal support are available nowadays. Previous studies suggest that a minimum threshold of day-5 serum progesterone levels needs to be reached during hormonal replacement therapy in order to improve ongoing pregnancy rates. However, there is controversy on the efficacy of distinct types of progesterone preparations and routes of administration. More studies are needed to fully understand the physiology of progesterone in ART
Study design, size, duration: Prospective cross-over pilot study performed between January and June 2019 in IVI-RMA Global clinic, Madrid, Spain. We aimed to evaluate if there is significant intrapatient variation on the day-5 serum progesterone levels with the use of different routes of administration during hormonal replacement therapy. IRB approval 1809-MAD-063-MC
Participants/materials, setting, methods: Three different protocols were administered to 5 participants underwent 3 consequtive cycles of HRT. LP support consisted on 1°) vaginal progesterone 400 mg/12 hours ; 2°) subcutaneous progesterone 25 mg/12 hours ; and 3°) intramuscular progesterone 50 mg / 24 h . After estrogen priming for 10 days, P4 was given for 5 days, with daily serum P were performed. Linear regression model accounted for progesterone levels (response variable) and route of administration (explanatory variable).
Main results and the role of chance: The mean day-5 serum progesterone levels depending on the route of administration were as follows a) 14.6 ± 5.5 ng/mL; b) 47.9 ± 22.3 ng/mL; and c) 60.3 ± 65.5 ng/mL. The linear regression model showed that changing vaginal progesterone to either subcutaneous or intramuscular route had a statistically significant effect on serum progesterone levels, with an average increase of 25 ng/mL (5.4-45.1 ng/mL; p=0.01) using the subcutaneous route and 32 ng/mL (13-52.7 ng/mL; p=0.001) with the intramuscular route. The mixed effects model proved that the subcutaneous preparation maintained the mean progesterone level at 29.5 ng/mL (SE: 7.6, fixed effect), while the intramuscular preparation showed a mean value of 18.1 ng/mL (SE: 9.75, fixed effect). Age and body mass index did not produce a significant effect on the results of the mixed model analysis. Despite the route of administration, all progesterone preparations achieved a mean day-5 serum level above the threshold of 9.2 ng/mL, which is considered the optimal cutoff according to a previous prospective cohort. Of note, one patient did not reach the recommended day-5 concentration with vaginal progesterone.
Limitations, reasons for caution: This is a cross-over pilot study with preliminary data and few patients. Further studies are needed to better understand circulating progesterone levels during hormonal replacement therapy and its impact on reproductive outcomes. Nevertheless, considering the scarcity of data, our results provide important insights and draw attention to intrapatient variability.
Wider implications of the findings: Apparently, the three types of progesterone preparations lead to sufficient circulating hormone levels in the day of

the embryo transfer. However, in the era of personalized reproductive medicine, endometrial preparation and luteal phase support deserve further investigation and patient-specific behaviors must be taken into account.
Trial registration number: NONE

O-172 Frozen-thawed embryo transfer in natural cycles leads to higher clinical pregnancy rates compared to artificial endometrial preparation cycles

N. Aslih[1], Y. Atzmon[1], M. Michaeli[1], A. Bilgory[1], E. Shalom-Paz[1]
[1]*Hillel Yaffe Medical Center, IVF unit, Hadera, Israel*

Study question: Which endometrial preparation protocol in Frozen Embryo Transfer (FET) Cycles offers the optimal results?
Summary answer: Frozen-thawed embryo transfer in natural cycles leads to higher clinical pregnancy rates compared to artificial endometrial preparation cycles.
What is known already: Number of FET Cycles has risen dramatically through the years due to several factors including: efficient cryopreservation strategies (vitrification), elective single embryo transfer strategies which lead to a higher number frozen embryos and transfers per Ovum Pick Up (OPU) and increasing use of Pre Gestational Diagnosis and Screening (PGD/PGS) techniques. The optimal protocol for endometrial preparation has yet to be determined. Artificial preparation of the endometrium is a well-established protocol offering a more flexible time table and patient monitoring. On the other hand, raising experience with natural cycles for FET suggests non-inferior results.
Study design, size, duration: A retrospective study. 703 FET cycles performed in the years 2016-2018 were analyzed. Cycles were divided into two groups: Group A – artificial endometrial preparations (n=390), Group B – natural cycle (NC FET) (n=313).
Participants/materials, setting, methods: Group A – FET with artificial endometrial preparation by exogenous estrogen (Estrofem®, Novo Nordisk) and Progesterone preparations (Endometrin®, Ferring or Duphastone®, Abbott or Crinone®, Merk Serono).Group B – FET based on ovulation cycles included: natural ovulation cycles, modified natural cycles using hCG (Ovitrelle Merck-Serono) for the final triggering of spontaneous and Letrozole induces ovulation.Data collection was performed including demographics, causes infertility, history of fertility treatments, current fresh cycle details and FET cycle outcomes.
Main results and the role of chance: both groups were comparable in terms of patient characteristics, demographics, infertility causes, treatment protocols and number of embryos transferred. Although the mean ESHRE score of the transferred embryos was significantly lower in group B, we found **a** significantly higher clinical pregnancy rate in Group B (NC FET) compared to Group A (Artificial endometrial Preparation), 43.1% Vs. 30.9%, P value = 0.021.
Limitations, reasons for caution: A retrospective study, included different protocols of ovulation cycle for FET.
Wider implications of the findings: large Randomized Controlled Trials are needed to establish the superiority of natural cycle protocol over the artificial endometrial preparation protocols for FET.
Trial registration number: Not Applicable

SESSION 45: SPERMATOGENESIS SUBTLE REGULATORY EFFECTORS

07 July 2020 Parallel 3 15:15 - 16:30

O-173 Environmental pollution affects the protamine-histone content in human sperm and changes their properties making able to promote DNA oxidative damage: the contribution of molecular investigations.

M. PISCOPO[1], G. Lettieri[1], F. Febbraio[2], G. D'Agostino[1], E. Mele[1], C. Cardito[1], T. Notari[3], L. Montano[4]
[1]*University of Naples, Biology, Naples, Italy ;*
[2]*Institute of Biochemistry and Cellular Biology, National Research Council CNR, Naples, Italy ;*
[3]*Reproductive Medicine Unit of Check Up Polydiagnostic Center, GEA - Gynecology Embryology Andrology, Salerno, Italy ;*
[4]*Andrology Unit of the "S. Francesco d'Assisi" Hospital, Local Health Authority ASL Salerno, Salerno, Italy*

Study question: Does the content and properties of DNA binding proteins in human sperm change in response to environmental pollution?
Summary answer: We provide evidences that environmental pollution alters human sperm protein framework, their binding to DNA and makes these proteins able to promote DNA oxidative damage.
What is known already: The nucleohistone–nucleoprotamine transition is fundamental in order to ensure condensation of the sperm nucleus into a compact hydrodynamic shape and a protection of the DNA delivered by the spermatozoa. The exposure to many environmental contaminants produce sperm DNA damage. We have already reported a significant increase of sperm telomere length, a higher DNA fragmentation index, and a lower antioxidant activity in males recruited in high environmental impact areas. The major cause of male infertility seems to be sperm DNA damage but the molecular mechanisms which lead to DNA break are not yet fully understood.
Study design, size, duration: In order to investigate the impact of environmental pollution on molecular alterations of human sperm, we collected, sperm samples from 240 healthy males living in high and low environmental impact areas of Campania (Italy). We extracted and characterized the sperm protein content, analyzed their DNA-binding affinity and investigated on the possibility that these proteins participate to oxidative DNA damage. The study was performed from October 2017 to December 2019, within the EcoFoodFertility initiative.
Participants/materials, setting, methods: Sperm samples were obtained with informed consent from 240 healthy males, not presenting other factors affecting semen quality, living in areas at high (n=160) and low (n=80) environmental impact. The sperm proteins were extracted and their electrophoretic pattern characterized. Sperm proteins DNA binding ability was determined by electrophoretic mobility shift assays and fluorescence measurements. The involvement of sperm proteins in DNA oxidative damage was evaluated by their ability to convert supercoiled to relaxed plasmid DNA.
Main results and the role of chance: We found, as expected, a canonical protamines/histones ratio in the 95.06% of people living in low-impact area. Differently, this result was observed only in the 16.61% of samples from males living in high environmental impact areas. In these latter about the 62% showed the presence of only histone, and the remaining 21.78% a not canonical protamines/histones ratio. Moreover, also the samples showing a canonical protamines/histone ratio, presented a different DNA binding mode with respect to those from people living in low-impact area. However, our most relevant result was the finding that, in presence of some pollutants, sperm proteins change their protective ability, participating to DNA oxidative damage. This result was particularly marked for those samples presenting a not canonical protamine/histone ratio. The presence of excess of copper and chromium (two heavy metals involved in Fenton-like reaction) found in the semen of people living in high impact areas, could explain the occurrence of DNA oxidative damage. In fact, we have already reported, in other organism, that the binding of these metals to sperm proteins promote DNA break. The differences observed in our work, that are not due to chance, suggest that environmental pollution has impact, at molecular level, on semen quality.
Limitations, reasons for caution: The altered protamine/histone ratio and the DNA oxidative damage promoted by sperm proteins does not necessarily imply infertility in men living in high environmental impact areas. Limitations are due to the impossibility of carrying out *in vitro* fertilization tests.
Wider implications of the findings: Our molecular approaches could represent additional tools for semen quality evaluation and represent a starting point for develop therapeutic protocols to counteract with these types of sperm alterations. Moreover, our findings give new insights into mechanisms of DNA damage, which is implicated also in several human diseases.
Trial registration number: not applicable

O-174 The super-enhancer-driven long non-coding RNAs as key cell identity genes define the essential core regulatory circuitry in non-obstructive azoospermia through activation of immune signaling pathway.

"Abstract withdrawn by the authors"

O-175 Beta2-adrenergic receptors are mainly expressed in the terminal piece of the human sperm flagellum

J.L. Girela[1], M. Francou[1], A. De Juan[1], J. De Juan[2]

[1]University of Alicante, Biotechnology, San Vicente Del Raspeig, Spain ;
[2]University of Alicante, Instituto Universitario de Estudios de Genero, San Vicente Del Raspeig, Spain

Study question: How is the expresión and distribution of beta2-adrenergic receptors (ADRB2) in human sperm?
Summary answer: Using ultra high resolution microscopy techniques we indentified that the expression of ADRB2 is mainly restricted to the terminal piece of the human sperm flagellum.
What is known already: Recent studies have shown that spermatozoa have very complex machinery for cell signalling. As part of that machinery, numerous neuroreceptors are expressed in the sperm membrane. Human sperm is regionalised, with several physiological processes restricted to determined areas, being therefore expected that specific molecules involved in those processes should also be restricted to that area. Although indirect methods had determined the presence of ADRB2 in human sperm, there is no direct evidence nor the description of the localisation of that receptor. ADRB2 is the direct target of medications used to treat health problems like Hypertension (beta blockers) or asthma (bronchodilators).
Study design, size, duration: Sperm from young healthy donors (n =7) were included in the study. All the samples were normozoospermic according to WHO 2010 criteria. As a positive control, we used the neuroblastoma cell line SH-SY5Y known to express ADRB2. We design the study by developing new techniques that allow us to use high- resolution microscopes (i.e. Laser Scanning Confocal Microscopy LSCM and Field Emission Scanning Electron Microscopy or FE-SEM) to identify the localisation and distribution of ADRB2
Participants/materials, setting, methods: To identify the presence of messenger and protein we used RT-PCR and Western Blot techniques respectively. Immunolabelling techniques were performed by using the same anti-ADRB2 primary antibody followed by the fluorochrome-conjugated secondary antibody for LSCM or gold conjugated for FE-SEM. Negative controls were performed by omitting the primary antibody. In FE-SEM images we quantify the number of gold nanoparticles in the sperm cells and in the background to determine the specificity of the technique.
Main results and the role of chance: We confirm the presence of both messenger and ADRB2 protein in human sperm cells in all the samples, demonstrating the expression of the receptor. LSCM images showed a predominant distribution of the ADRB2 receptor on the Sperm flagellum, with and brighter signal at the terminal piece. In the FE-SEM images, the mean number of gold particles found in the end piece of the sperm flagellum was significantly higher than the one found in the mid and principal piece ($p<0.001$).
Limitations, reasons for caution: The present study only shows the presence of the receptors on the sperm plasma membrane. The activity of those receptors should be investigated by developing bioassays based on the use of agonist and/or antagonist. A more reliable genetic overexpression or knockout approach was not possible in human sperm.
Wider implications of the findings: The presence of ADRB2 in the flagellum of human sperm cells is in concordance with the suggested function of that receptor, the regulation of sperm motility and hyperactivation. It may also suggest a possible side effect of betablockers or bronchodilators with the male fertility potential that needs to be investigated.
Trial registration number: Not applicable

O-176 A novel approach for male contraception: modulation of phosphoprotein phosphatase 1 complexes using bioportides

J. Silva[1], M.J. Freitas[1], J. Santiago[1], S. Jones[2], S. Guimarães[3], S. Vijayaraghavan[4], G. Colombo[5], J. Howl[2], M. Fardilha[1]

[1]iBiMED - Instituto de Biomedicina, Universidade de Aveiro, Aveiro, Portugal ;
[2]Research Institute in Healthcare Science, University of Wolverhampton, Wolverhampton, United Kingdom ;
[3]i3S - Instituto de Investigação e Inovação em Saúde, Universidade do Porto, Porto, Portugal ;
[4]Kent State University, Kent State University, Kent, U.S.A. ;
[5]University of Pavia, Department of Chemistry, Pavia, Italy

Study question: Are bioportides capable of disrupting Phosphoprotein Phosphatase 1 (PPP1) complexes as a strategy to modulate sperm motility?
Summary answer: A cell penetrating peptide (CPP) was able to deliver a peptide as a sychnologically-organized bioportide into spermatozoa with a significant impact on motility.
What is known already: Phosphoprotein phosphatase 1 catalytic subunit gamma 2 (PPP1CC2) is a PPP1 isoform restricted to testicular germ cells and spermatozoa and its inhibition is essential for sperm motility acquisition. PPP1 specificity and activity is regulated by the interaction with PPP1-interacting proteins. The mechanism of sperm motility acquisition is a perfect target for a new male contraceptive since it affects only the post-testicular sperm maturation.
Study design, size, duration: We designed a peptide based on the region including the PPP1 binding motif of a sperm-specific interactor (A-kinase anchor protein 4, AKAP4) covalently coupled to inert CPP (penetratin) as a sychnologically-organized bioportide construct. A mutated homologue was also designed as a control. We evaluated the intracellular accumulation of the bioportide in normozoospermic human sperm and its impact on sperm viability and motility at different time-points.
Participants/materials, setting, methods: Molecular dynamics simulations were used to design the bioportide, that was synthetized by microwave-assisted solid phase. The complex disruption was assessed by blot overlay. Fluorescent cell imaging analysis was used to study the intracellular accumulation of the bioportide in human sperm. Sperm viability was evaluated with the trypan blue test and sperm motility was monitored by computer-assisted sperm analysis.
Main results and the role of chance: In vitro studies revealed that the bioportide was able to disrupt the PPP1CC2/AKAP4 complex. Exposure of human sperm to the bioportide led to a significant decrease in both fast (mean decrease of 83.9 ± 15.8 % compared with negative control; 79.0 ± 24.8 % compared with mutated control; $p<0.01$) and slow progressive motility (mean decrease of 74,1 ± 24,1 % compared with negative control; 72,0 ± 28,5% compared with mutated control; $p<0.01$) and a significant increase in the percentage of immotile sperm (mean increase of 220.4 ± 29.6 % compared with negative control; and 148.2 ± 68.2 % compared with mutated control; $p<0.01$), with no impact on sperm viability. No significant alterations were observed in non-progressive motility. No time-dependent effect was observed.
Limitations, reasons for caution: Studies in animal models are needed to validate these results and investigate pre-clinical safety and feasibility.
Wider implications of the findings: This study exploited two ground-breaking areas of the pharmaceutical field by combining CPP technology with protein-protein interaction modulators to generate a bioportide capable of blocking sperm motility by disrupting a sperm-specific PPP1 complex. This approach has the potential to allow the development of a "male pill" to arrest sperm motility.

O-177 In vitro co-exposure to Benzo(a)pyrene (B(a)P) and aged cerium dioxide nanoparticles (CeO2NPs) enhances DNA damage in human and rat gametes

J. Perrin[1], M. Cotena[2], V. Tassistro[2], C. Sunyach[2], J. Rose[3], M. Auffan[3]

[1]Ap-hm, CECOS Centre clinicobiologique d'AMP CHU La Conception, Marseille Cedex 5, France ;
[2]aix marseille university, Institut Méditerranéen de Biodiversité et d'Ecologie, Marseille, France ;
[3]CNRS, Centre Européen de Recherche et d'Enseignement en Géosciences de l'Environnement, Aix en Provence, France

Study question: Do the addition of Benzo(a)pyrene (B(a)P) enhance the DNA damage induced by *in vitro* exposure to aged cerium nanoparticles (CeO_2NPs) in human and rat gametes?

Summary answer: *In vitro* gametes co-exposure to aged CeO_2NPs + B(a)P induced significant higher DNA damage than exposure to CeO_2NPs alone in human and rat gametes.

What is known already: Polycyclic aromatic hydrocarbons (PAHs) are ubiquitous pollutants affecting millions of humans through environmental, dietary and occupational sources. B(a)P is a PAH, known for its carcinogenic and reprotoxic potential. Higher DNA damage was observed in Cumulus - Oocyte Complexes of B(a)P-exposed mice than in those of vehicle controls after oral administration. CeO_2NPs are widely used as diesel additive to increase fuel economy; during combustion, they are associated to PAH and then released in air. Pristine CeO_2NPs affect *in vitro* fertilization in mice and induce significant DNA damage in human sperm. The potential hazard due to the co-exposure CeO_2NPs-B(a)P is still unknown.

Study design, size, duration: Pristine CeO_2NPs were extracted from Envirox™ diesel additive and combusted at 850°C, (average combustion temperature in a diesel engine), to obtain aged CeO_2NPs, which were physico-chemically characterized. B(a)P was purchased from Sigma-Aldrich. Rat gametes were sampled in epididymis and oviducts after cervical dislocation of sexually mature males and 26-days-old females (after ovarian stimulation). Human frozen sperm from fertile donors were purchased from Germetheque biobank (France).

Participants/materials, setting, methods: Human and rat gametes were exposed *in vitro* to very low concentrations of CeO_2NPs (1 $\mu g.l^{-1}$), to B(a)P alone (1.13µM) and to 1 $\mu g.l^{-1}$ CeO_2NPs + 1.13µM B(a)P during 1 hour in Ferticult© Medium + 1% DMSO + 1% S9mix at 37°C, 5% CO_2. DNA damage was analysed by alkaline comet assay (ACA) and quantified by Olive Tail Moment (OTM) in oocytes and follicle cells and by % Tail DNA in sperm.

Main results and the role of chance: In human sperm, co-exposure to CeO_2NPs + B(a)P induced significantly higher DNA damage (mean % Tail DNA±SEM = 35.35 ± 0.75) compared to CeO_2NPs alone (29.57 ± 0.68) ($p < 0.0001$) and B(a)P alone (18.07 ± 0.79), ($p < 0.0001$).

In rat sperm, co-exposure induced significantly higher DNA damage (mean %Tail DNA±SEM = 32.4 ± 0.43) compared to CeO_2NPs alone (22.73 ± 0.43) ($p < 0.0001$) and B(a)P alone (13.91 ± 0.44), ($p < 0.0001$).

In rat follicle cells, co-exposure induced significantly higher DNA damage (mean±SEM OTM = 8.48 ±0.35) compared to CeO_2NPs alone (4.31 ± 0.30) ($p < 0.0001$) and B(a)P alone (1.83 ± 0.34), ($p < 0.0001$).

In rat oocytes, co-exposure (7.5±0.7) induced a significant increase of DNA damage compared to B(a)P alone (4.28±0.7) ($p = 0.0046$), but not if compared to CeO_2NPs alone (8.43±0.8) ($p >0.05$).

The significant increase in genotoxicity induced by co-exposure to CeO_2NPs and B(a)P suggest the implication of the so-called "Trojan Horse" mechanism by which nanoparticles can act as a carrier of another chemical compound by promoting the interaction with cells. This hypothesis is supported by the results obtained in oocytes, which show a potentialized effect of B(a)P due to the co-exposure with CeO_2NPs.

Limitations, reasons for caution: These results cannot be extrapolated to *in vivo* toxicity of CeO_2NPs + B(a)P after inhalation, but demonstrate that interactions between the mixture CeO_2NPs + B(a)P can significantly and synergistically enhance the DNA damage in human and rat sperm and in rat follicle cells and oocytes.

Wider implications of the findings: These results show for the first time that interactions between aged CeO_2NPs and B(a)P synergistically potentiated toxicological effects on human and rat gametes. This information should help further our understanding of the combined toxicity of PAH and nanoparticles, as PAH are the most ubiquitous organic compound pollutants in ambient air.

O-178 Non-invasive metabolic imaging with fluorescence lifetime imaging microscopy (FLIM) detects differences in ploidy of human blastocysts

J. Shah[1,2], M. Venturas[3,4], T. Sanchez[5], A. Penzias[1,2], D. Needleman[3], D. Sakkas[2]

[1]*Beth Israel Deaconess Medical Center, Obstetrics and Gynecology, Boston, U.S.A. ;* [2]*Boston IVF, Reproductive Endocrinology and Infertility, Boston, U.S.A. ;* [3]*Harvard University, Molecular and Cellular Biology and School of Engineering and Applied Sciences, Cambridge, U.S.A. ;* [4]*Universitat Autònoma de Barcelona, Department de Biologia Cellular- Fisiologia i Immunologia, Cerdanyola, Spain ;* [5]*None, None, Boston, U.S.A.*

Study question: Can non-invasive metabolic imaging via fluorescence lifetime imaging microscopy (FLIM) detect differences between euploid and aneuploid discarded human blastocysts?

Summary answer: Non-invasive metabolic imaging via FLIM can detect significant differences between embryos deemed aneuploid, euploid and of unknown ploidy status.

What is known already: FLIM of endogenous nicotinamide adenine dinucleotide dehydrogenase (NADH) and flavin adenine dinucleotide (FAD) autofluorescence reveals the metabolic state of mouse embryos. In mouse and other animal models, the metabolic state of embryos correlates with embryo viability. Ploidy status is one of the primary determinants of embryo viability. Metabolic state correlates with ploidy status in a number of non-embryonic systems, including yeast and cancer cells.

Study design, size, duration: This was a prospective observational study that included 158 discarded human vitrified blastocysts of which 110 had known ploidy status (12 euploid; 98 aneuploid) by preimplantation genetic testing and the remaining 48 embryos were of unknown ploidy status. All blastocysts were day 5 or 6 with Gardner morphology grade A or B except 4 that were grade C. Multilevel models were used for analysis with $p<0.05$ showing significance.

Participants/materials, setting, methods: Metabolic imaging via FLIM of NADH and FAD was used in a University affiliated private IVF laboratory to study discarded human blastocysts. Eight metabolic parameters were obtained from each blastocyst (4 for NADH and 4 for FAD): short (t1) and long (t2) fluorescence lifetime, fluorescence intensity (I), and fraction of the molecule engaged with enzyme (F). The redox ratio (Intensity of NADH)/(Intensity of FAD) was also calculated for each embryo.

Main results and the role of chance: Each blastocyst was warmed, incubated for 2 hours and imaged to analyze its metabolic signature. The mean ages in years for the unknown ploidy, euploid, and aneuploid groups were 32.0 ± 4.9, 37.0 ± 4.6, and 36.9 ± 3.7, respectively. In comparing blastocysts from the aneuploid, euploid, and unknown groups, the FLIM parameters of NADH-I ($p<0.0001$), NADH-t2 ($p<0.02$), FAD-I ($p<0.0001$), FAD-t1 ($p<0.001$), and redox ratio ($p<0.0001$) showed significant metabolic differences. When comparing ploidy status to embryo day, a number of significant metabolic differences were seen in the FAD parameters. FAD-F, FAD-t1 and FAD-t2 all showed significant differences ($p<0.01$) when comparing euploid day 5 versus day 6, aneuploid day 5 versus day 6, and unknown day 5 versus day 6. Furthermore, euploid day 5 versus day 6 showed significant differences in redox ratio ($p<0.0001$) while unknown ploidy day 5 versus day 6 showed significant differences in redox ratio and FAD-I ($p<0.02$).

Limitations, reasons for caution: The study was performed using discarded frozen human blastocysts, which may differ metabolically from non-discarded human embryos. Only a small number of blastocysts deemed euploid (12) were assessed. Additional data is required to validate the results.

Wider implications of the findings: FLIM has revealed significant metabolic differences between discarded human blastocysts associated with ploidy status. It is unclear if these associations are correlative or causative (and, if so, if ploidy impacts metabolism or if metabolism impacts ploidy). Further studies are needed to determine if FLIM can assist in clinical embryo selection.

O-179 Clinical outcomes after transfer of 110 euploid and 11 mosaic blastocysts identified using non-invasive preimplantation genetic testing for aneuploidy

J. Zhang[1], M. Olcha[1], M. Elzaky[1], M. Jaremko[1], A. Chavez[2]

[1]*New Hope Fertility Center, Reproductive Endocrinology, New York- NY, U.S.A. ;* [2]*New Hope Fertility Center, Reproductive Endocrinology, Mexico City, Mexico*

Study question: What is the biochemical pregnancy rate after single embryo transfer (SET) of euploid and mosaic embryos identified via non-invasive pre-implantation genetic testing for aneuploidy (PGT-A)
Summary answer: Transfer of 110 euploid and 11 mosaic embryos resulted in a 63.6% and 36.3% positive beta-human chorionic gonadotropin level (ß-hCG), respectively
What is known already: PGT-A has been widely used around the world to identify ploidy status of embryos. The knowledge obtained can help assist clinicians and patients with prioritization of embryos for transfer. The transfer of single euploid embryos has be shown to improve per cycle pregnancy rate, reduce miscarriage rate, and prevent transfer of embryos harboring certain genetic anomalies such as Down Syndrome. The primary modality for obtaining DNA from blastocysts has been trophectoderm biopsy, which requires removal of embryonic cells. Recently, the advent of non-invasive methods have been developed which allow embryonic DNA to be amplified by analysis of culture media only.
Study design, size, duration: Retrospective data analysis of biochemical pregnancy rates after 110 euploid and 11 mosaic embryos were transferred between August 1st 2019 to December 30th 2019.
Participants/materials, setting, methods: Ploidy information on 24 chromosomes was derived by testing spent media collected on Day 5, 6, or 7. Media was processed on site using Non-Invasive Chromosomal Screening (NICS) platform (Yikon Genomics), utilizing multiple annealing and looping-based amplification cycles (MALBAC) for whole-genome amplification followed by next-generation sequencing. Initial ß-hCG levels were analyzed 7-10 days after SET. ß-hCG levels were measured with an automated immunoassay analyzer (TOSOH). Chi squared analysis was used to compare biochemical pregnancy rates.
Main results and the role of chance: A total of 70 out of 110 (63.6%) euploid SETs and 4 out of 11 (36.3%) mosaic SETs resulted in a positive ß-hCG. As expected, the pregnancy rate after euploid embryo transfer was significantly higher than mosaic embryo transfer (p=0.03).
Limitations, reasons for caution: A small study size is the major limitation. Additionally, caution should be taken when generalizing results as there are many other clinical and embryologic practice parameters that could affect pregnancy rates in general.
Wider implications of the findings: This data helps demonstrate that a non-invasive PGT-A platform can be utilized successfully in a private setting without compromising clinical outcomes. Furthermore, the use of a non-invasive methods to identify embryo ploidy may reduce risk to the embryo, however this has yet to be determined
Trial registration number: not applicable

O-180 Single tube long fragment read (stLFR) with massively parallel sequencing achieved patient-only haplotyping for preimplantation genetic testing of monogenic disorders

S. Chen[1], X. Cheng[2], D. Chen[2], H. Yan[2], J. Xia[2], P. Liu[2], X. Yin[2], F. Chen[2], C. Xu[1]

[1]The International Peace Maternity and Child Health Hospital- School of Medicine- Shanghai Jiao Tong University, Reproductive Genetics Department, Shanghai, China ;
[2]MGI- BGI-Shenzhen, R&D center, Shenzhen, China

Study question: Can massively parallel sequencing (MPS) offer an approach for preimplantation genetic testing of monogenic disorders (PGT-M) haplotyping with only a patient?
Summary answer: Single tube long fragment read (stLFR) with MPS achieved patient-only haplotyping for PGT-M.
What is known already: Several MPS-based PGT methods have been developed including low-depth MPS such as OnePGT, MARSALA and haploseek as well as high-depth MPS. Parents-child trios or parents with additional family members are required for PGT-M haplotyping with low-depth MPS. Moreover, a reference embryo can be used for phasing, that parents-only haplotyping without proband can be achieved by relative high-depth MPS. PGT-M haplotyping for parents-only has been reported to be performed by stLFR previously. However, PGT-M haplotyping for patient-only in some cases that the spouse is uncertain or unavailable have not been reported.
Study design, size, duration: We recruited 2 families that had undergone *in vitro*fertilization (IVF) and traditional PGT-M treatment. Each participant was on an informed-choice basis and signed a written consent. Both families were with parental-proband trios and the offspring monogenic disorder was inherited from only one spouse (both the wives). We obtained 12 and 5 embryos for the 2 families, respectively. Parental-proband trio haplotyping and PCR-Sanger sequencing would validate the result of patient-only haplotyping.
Participants/materials, setting, methods: Embryos were trophectoderm biopsied in Day5 blastocyst stage, and used for Qiagen REPLI-g Kit whole genome amplification (WGA). High molecular weight genomic DNA was extracted from the spouse patient peripheral blood, and used for MGIEasy stLFR Library Prep Kit (Item No.1000005622) according to instructions. Regular WGS libraries from WGA DNA and family members bulk DNA, together with spouse patient stLFR libraries were used for DNBSEQ-G400 sequencing with 15X depth each sample and haplotype analysis.
Main results and the role of chance: According to the co-barcoding information in the spouse patient(both the wives) stLFR sequencing data, we phased the pathogenic mutationCOL4A5 c.1834G>C and COL1A1 c.769G>A in the 2 families, and confirmed the pathogenic maternal haplotype linkage with the mutation allele by patient-only haplotyping. Combining the pathogenic haplotype information and embryonic informative SNP alleles, we determined the genetic status of monogenic disorders for each embryo. In COL4A5 family, 7 embryos were affected with pathogenic maternal haplotype and 5 embryos were normal. In COL1A1 family, 2 embryos were affected and 3 embryos were normal. The patient-only haplotyping results were validated by parental-proband trio haplotyping and were 100% concordant. PCR-Sanger sequencing of mutationCOL4A5 c.1834G>C and COL1A1 c.769G>A in the 2 families, respectively, showed 100% concordance with the patient-only haplotyping. PGT for aneuploidy (PGT-A) was performed by MPS. In COL4A5 family, 2 aneuploidy embryos and 10 euploidy embryos were tested. In COL1A1 family, 3 aneuploidy embryos and 2 euploidy embryos were determined. The MPS PGT-A results were validated by SNP-array and showed 100% concordant. Three embryos inCOL4A5 family and one embryo in COL1A1 family were both euploidy and with normal maternal haplotype that were available for implantation.
Limitations, reasons for caution: The patient-only PGT-M haplotyping by stLFR MPS is applicable in the families that only one spouse carry the pathogenic mutation. Otherwise, parents-only PGT-M haplotyping by stLFR MPS can be performed.
Wider implications of the findings: The patient-only PGT-M haplotyping by stLFR MPS provides an effective PGT solution for patients with IVF artificial insemination by donor (AID) or patients with unavailable spouse. Both patient-only and parents-only haplotyping provide complement to the current PGT methodology and can be clinically applied according to the actual situations.
Trial registration number: Not applicable

O-181 First report about preimplantation genetic testing for the Xq24 microdeletion related to X-linked mental retardation, Nascimento type in a woman with recurrent pregnancy loss

I. Lebedev[1], E. Soloveva[1], D. Zhigalina[1], L. Minaycheva[1], O. Kanbekova[1,2], A. Nemtsova[2], K. Tolmacheva[1], E. Fonova[1], N. Skryabin[1], A. Kashevarova[1], M. Lopatkina[1], I. Stepanov[2], L. Nazarenko[1], A. Svetlakov[1]

[1]Research Institute of Medical Genetics, Tomsk National Research Medical Center, Tomsk, Russia C.I.S. ;
[2]Tomsk Regional Perinatal Center named after I.D. Evtushenko, ART Department, Tomsk, Russia C.I.S.

Study question: Can the presence of inherited chromosomal microdeletions associated with microdeletion syndromes be effectively detected in human preimplantation embryos by current PGT approaches?
Summary answer: Combining STR-haplotyping (PGT-M) and array-CGH (PGT-A) provides high-resolution detection of inherited chromosomal microdeletions less than 300 kb in size in human preimplantation embryos.
What is known already: Copy number variations (CNVs), including chromosomal microdeletions and microduplications less than 5 Mb in size, have significant impacts on human pathology as they are strongly associated with intellectual disability, developmental delay and congenital malformations. The average resolution of current PGT-A and PGT-SR technologies, including NGS and array-CGH, is approximately 5-10 Mb, ruling out the possibility of preimplantation genetic testing for the most severe microdeletion and microduplication syndromes. Moreover,

segmental aneuploidies lack any genotype-phenotype correlations at the blastocyst stage. However, some CNVs have low penetrance and can be inherited from healthy parents, providing a chance to be detected in preimplantation embryos.
Study design, size, duration: Here, we report about preimplantation genetic testing of a 270-kb Xq24 microdeletion associated with X-linked syndromic mental retardation, Nascimento type (OMIM 300860) by combining STR-haplotyping and array-CGH in a couple with recurrent pregnancy loss. A previously investigated woman and her mother are carriers of the Xq24 microdeletion, as detected by array-CGH and confirmed by quantitative real-time PCR, but did not demonstrate the classical syndromic phenotype due to extremely skewed X-chromosome inactivation (sXCI).
Participants/materials, setting, methods: A 30-year-old woman had 8 pregnancies; one was terminated by a medical abortion; six were spontaneous abortions, including two males with a Xq24 microdeletion and one female without a microdeletion but random XCI. The woman also gave birth to a healthy girl without microdeletion and random XCI. PGT was performed using WGA (REPLI-g MDA, Qiagen), nested-PCR for STR markers within deleted, 0.8 Mb upstream and 1.0 downstream regions and array-CGH (GenetiSure Pre-Screen Microarray, Agilent Technologies).
Main results and the role of chance: To develop a system for preimplantation STR-haplotyping PGT setup was performed as for monogenic disorders. Family DNA samples were used to haplotype normal and mutant X-chromosomes. Seventeen polymorphic STR markers were selected and tested in the PGT-M setup, and 12 were approved as informative. The system was validated in single cells. Nine oocytes were fertilized by ICSI, and 8 zygotes were obtained in the IVF programme with standard ovarian stimulation. Trophectoderm biopsy was performed for 4 blastocysts on Days 5-6 followed by WGA by MDA, which was successful for 3 samples. STR-haplotyping combined with testing for *AMEL* and *SRY* genes revealed a hemizygous Xq24 microdeletion in male embryo, heterozygous carrier female embryo and normal female embryo. Array-CGH revealed monosomy 4 in female carrier embryo sample. Standard array-CGH data processing did not find microdeletion but detailed analysis allowed us to obtain concordant results with regard to the Xq24 microdeletion despite small size rearrangement. The same microdeletion arr[hg19] Xq24(118518668_118836030) like in the patient was also detected in hemizygous male and heterozygous female carrier embryos. Normal female embryo was recommended for transfer.
Limitations, reasons for caution: Only inherited chromosomal microdeletions can be detected by combining PGT-M and PGT-A. *De novo* microdeletions and microduplications are still missed using PGT approaches. STR-haplotyping requires a preliminary step for selecting heterozygous markers. Risks of heterozygous for X-chromosome microdeletions female embryos transfer are unknown and should be further estimated.
Wider implications of the findings: Our data indicate the successful detection of clinically significant chromosomal microdeletion by combining PGT-M and PGT-A. Implementation of PGT-A reduces the risk of aneuploid embryo transfer. The presented approach provides new strategies for PGT in women with recurrent pregnancy loss and sXCI. This study was supported by RFBR (18-015-00437a).
Trial registration number: not applicable

O-182 Cell-based non-invasive prenatal testing (cbNIPT): an alternative to chorionic villus sampling to confirm diagnosis of unaffected fetuses following preimplantation genetic testing for monogenic disorders (PGT-M)

[10]Department of Gynecology and Obstetrics, Aalborg University Hospital, Aalborg, Denmark ;
[11]Department of Gynecology and Obstetrics, Kolding Regional Hospital, Kolding, Denmark

Study question: To investigate cell-based non-invasive prenatal testing (cbNIPT) following preimplantation genetic testing for monogenic disorders (PGT-M) as an alternative to invaisve chorionic villus sampling (CVS).
Summary answer: CbNIPT had a high specificity of fetal cell isolation (95 %). Successful diagnosis in agreement with PGT-M and CVS was achieved in all seven cases.
What is known already: Although the risk of misdiagnosis associated with preimplantation genetic testing (PGT) is low (< 1 %), the consequences are severe. Hence, prenatal analysis is recommended folllowing PGT, but only approximately 50 % of patients opt for the procedure. The current golden standard for prenatal analysis is chorionic villous sampling, which is assocated with discomfort and a small risk of miscarriage (< 1 %). It is possible that a more comfortable and non-invasive alternative would increase the proportion of patients receiving prenatal analysis were recommended, thereby increasing the chance of detecting the rare case of misdiagnosis.
Study design, size, duration: Desciptive case-series. Seven patients achieving pregnancy following PGT-M had a blood sample taken on the day of CVS, from which potential fetal cells were isloated using a subset of fetal specific cell surface markers within 48 hours. Fetal cells were analyzed by STR marker analysis and direct mutation detection and compared to the original PGT-M analysis of the transferred embryo and the CVS result. Patients were enrolled between November 2018 and August 2019.
Participants/materials, setting, methods: The following was evaluated for the isolated potential fetal cells:- Number of potential fetal cells isolated in total, the range and median per case - Fraction of cells receiving a diagnosis including range and median per case - Fraction of successfully diagnosed cells of fetal origin including range and median per case - Fraction of fetal cells receiving a diagnosis including range and median per case - Agreement between fetal cells, original PGT-M analysis and CVS analysis.
Main results and the role of chance:

	N (%)	Range	Median per case
Fetal cells isolated	29		5
Fraction of cells receiving a diagnosis	21/29 (72 %)	1-6	2
Fraction of successfully diagnosed cells being of fetal origin	20/21 (95 %)	1-6	2
Fraction of fetal cells receiving a diagnosis	20/20	1-6	2
Agreement between fetal cells, original PGT-M analysis and CVS analysis per case basis.	7/7	-	-

Limitations, reasons for caution: Measures are warranted in order to increase the diagnostic success rate per cell sample, and larger series are needed to validate robustness before cbNIPT can replace CVS in the clinical practice.
Wider implications of the findings: Since cbNIPT can be performed in early pregnancy, as early as gestational week four, results can be obtained in time for CVS to be performed in case of a failed analysis. Hence, cbNIPT can be offered as a primary non-invasive option of prenatal testing.

SESSION 47: DOES EMOTIONAL BALANCE BEFORE BEING PARENTS AND AFTER EXIST?

07 July 2020 Parallel 5 15:15 - 16:35

O-183 In-depth analysis of what influences whether patients' commit to achieve parenthood (parenthood-engagement) and undergo fertility treatment (treatment-engagement) before and after a treatment cycle.

S. Gameiro[1], S. Mesquita da Silva[2], U. Gordon[3], G. Baccino[4], J. Boivin[5]

[1]School of Psychology, United Kingdom, Cardiff, United Kingdom ;
[2]University of Oporto, Faculty of Sports, Oporto, Portugal ;
[3]Bristol Fertility Clinic, Bristol Fertility Clinic, Bristol, United Kingdom ;
[4]fivmadrid, fivmadrid, Madrid, Spain ;
[5]Cardiff University, School of Psychology, Cardiff, United Kingdom

Study question: Which factors are associated with patients' commitment/effort to achieve parenthood (parenthood-engagement) and undergo fertility treatment (treatment-engagement) before and after a treatment cycle?
Summary answer: Before the cycle parenthood-engagement and treatment-engagement are associated with stronger chidlwish, after the cycle parenthood-engagement is associated with stronger childwish and treatment-engagement with achieving pregnancy.
What is known already: Infertile patients have to actively engage with their parenthood goal (parenthood-engagement) if they want to achieve it, which often means engaging with fertility treatment (treatment-engagement). Engagement is the level of commitment/effort one puts towards achieving a goal, as opposed to stop pursuing it (disengagement) and pursuing other goals (reengagement). Psychological theories predict that engaging is adaptive (i.e., results in better mental-health) while goals are achievable, but when they become totally blocked it is adaptive to disengage and reengage. Infertility research has provided weak support to these predictions, maybe because of methodological limitations (e.g., poor blockage operationalization, neglect of other predictors).
Study design, size, duration: Prospective study with two moments: before a treatment cycle (T1), 6 weeks after its outcome (T2). Determinants of engagement were participants' strength of childwish, objective (prognosis, cycle outcome) and subjective (perceptions of) blockage, and patient's general ability to disengage and reengage when facing blocked goals. Engagement was expected to mediate associations between determinants and mental-health (anxiety, depression) and was conceptualized in terms of effort/commitment to achieve parenthood (parenthood-engagement) and to continuing with fertility treatment (treatment-engagement).
Participants/materials, setting, methods: The NHS-UK provided ethical approval. Patients starting an IVF, ICSI, IUI cycle using own or donated gametes were consecutively recruited and completed T1 and T2 questionnaires. Childish and subjective blockage were assessed with single-item questions. Objective blockage was prognosis data (T1) and cycle outcome (T2), collected from medical records. General ability to disengage and reengage were measured with the Goal Disengagement and Reengagement Scale, parenthood-engagement with the OPS-scale, treatment-engagement with the FertiQol-persistence, mental-health with HADS.
Main results and the role of chance: The final sample comprised 117 participants (33% response rate, 47% attrition rate). Average age was 35.81 (SD=4.14) years, 77 (66%) were women, 19 (16%) had children and 49 (42%) achieved pregnancy on their treatment cycle.

Mixed ANOVAs WS:Time(T1, T2) x BS:Outcome(not pregnant, pregnant) were run to investigate changes from T1 to T2 on determinants, engagement and mental-health. Subjective blockage decreased for pregnant participants ($\eta2$=.223,p<.01) but remained stable for non-pregnant ($\eta2$=.036,p >.05). Disengagement ability increased for all participants ($\eta2$=.045,p<.05). Parenthood-engagement decreased ($\eta2$=.104,p<.001) for all participants. Treatment-engagement decreased for non-pregnant participants ($\eta2$=.386,p<.001) but remained stable for pregnant ($\eta2$=.010,p>.05).

Results from mediation analysis (MEDIATE macro; Preacher & Hayes, 2004) showed that, at T1, higher childwish (ß=.40,SE=.09) and lower ability to disengage (ß=-.28,SE=.10) were associated with higher parenthood-engagement. At T2, higher T1 parenhood-engagement (ß=.59,SE=.08) and childwish (ß=.14,SE=.07) and lower subjective blockage (ß=-.14,SE=.07) and ability to disengage (ß=-.18,SE=.07) were associated with higher parenthood-engagement. There were significant associations between parenthood-engagement and mental-health.

At T1, childwish (ß=.35,SE=.08) was associated with higher treatment-engagement and this with lower anxiety (ß=-.33,SE=.12) and depression (ß=-.51,SE=.11). At T2, T1 treatment-engagement (ß=.46,SE=.10), being pregnant (ß=.58,SE=.16) and lower ability to reengage (ß=-.21,SE=.08) were associated with higher treatment-engagement, and this with lower depression (ß=-.25,SE=.09).
Limitations, reasons for caution: Response and attrition rates were similar to other questionnaire studies but worse-prognosis patients were more likely to attrite from the study. Engagement measures were self-reported but their predictive power of undergoing another cycle (n=76 patients without pregnancy/childbirth) was as expected: parenthood-engagement did not predict uptake, OR=.925,95%CI[.811,1.053], but treatment-engagement did, OR=1.261,95%CI[1.060,1.500].
Wider implications of the findings: The forces associated with parenthood and treatment engagement change from before to after a treatment cycle. Before, patients' engagement with parenthood and treatment reflect their strong desire for children. After, they reflect a conflict between patients' desire for children and their immediate emotional reaction to the cycle outcome.
Trial registration number: not-applicable

O-184 Meditation and mindfulness reduce stress in women with recurrent pregnancy loss: A randomized controlled trial

K. Kirchheiner Jensen[1], M.C. Krog[2], A.M. Kolte[2], S. Hedegaard[2], M. Chonovitsch[1], A.L. Lunøe[2], E.C. Koert[2], L. Schmidt[3], H. Svarre Nielsen[1]

[1]Amager Hvidovre University Hospital, Department of Obstetrics and Gynecology, Hvidovre, Denmark ;
[2]Rigshospitalet Copenhagen University Hospital, Recurrent Pregnancy Loss Unit-Fertility Clinic 4071, Copenhagen, Denmark ;
[3]University of Copenhagen, Department of Public Health, Copenhagen, Denmark

Study question: Does a 7-week meditation and mindfulness program reduce perceived stress among women with recurrent pregnancy loss (RPL) ?
Summary answer: A 7-week meditation and mindfulness program significantly reduced perceived stress in women with RPL compared to a standard supportive care program for women with RPL.
What is known already: Previous studies have shown that both perceived stress and moderate-severe depression is significantly more prevalent among women with RPL compared to other women trying to conceive. Despite the severe mental impact on women experiencing RPL, evidence-based care for the psychological consequences is currently limited. Meditation and mindfulness interventions have shown to be beneficial in reducing stress and negative feelings as well as improving well-being for patients with a wide range of medical conditions. However, to our knowledge, it has never been investigated if meditation and mindfulness can reduce stress among women with RPL.
Study design, size, duration: A two-armed randomized controlled trial (RCT) designed to evaluate a meditation and mindfulness intervention for women with RPL versus standard supportive care for women with RPL. Participants were included from November 2018 to April 2019. Of 163 invited, 76 were enrolled and randomly assigned to either supportive care (control group 38 participants) or to a 7-week meditation and mindfulness program lead by a professional instructor in addition to supportive care (intervention group 38 participants).
Participants/materials, setting, methods: Patients in a tertiary RPL unit were invited to participate. The intervention group had three meditation and mindfulness workshops with two to three-week intervals. Additionally, the intervention group meditated daily, supported by an online audio guide. The control group was instructed not to meditate during the 7-week study period. Participants' mental health was evaluated twice by the perceived stress scale,

the major depression inventory, COMPI fertility problem stress scales and COMPI marital benefit measure.
Main results and the role of chance: There were no differences between the groups at baseline. The main outcome, perceived stress, decreased significantly both in the intervention group (mean difference 5, standard deviation 4, p-value 0.001) and in the control group (mean difference 2, standard deviation 4, p-value 0.006). However, the perceived stress score in the intervention group decreased significantly more compared with the control group, p-value 0.027. The infertility-specific stress in the personal domain (COMPI Fertility Problem Stress Scales) decreased significantly in the intervention group (p-value 0.04), otherwise all other secondary outcomes showed no significant differences between the two groups. Seven women left the intervention group after the first session, indicating that it was too stressful to participate, whereas two women left the control group.
Limitations, reasons for caution: It is unknown if participants in the control group meditated, despite being instructed not to. Likewise, we are unaware if the participants in the intervention group meditated as instructed. Meditation and mindfulness can be an overload for women experiencing RPL since seven participants left the intervention group.
Wider implications of the findings: This is the first RCT study investigating the effect of meditation and mindfulness on the mental health of women experiencing RPL. Meditation and mindfulness reduced perceived stress significantly more than our routine supportive care. Guided self-administered meditations could be a useful tool in the care for women experiencing RPL.
Trial registration number: NCT03905395

O-185 The realism of men and women's expected IVF live birth rates

K. Peeraer[1], J. Devroe[1], T. D'Hooghe[2], J. Boivin[3], J. Vriens[4], E. Dancet[1]

[1]Leuven University Hospital, Departement of Development and Regeneration, Leuven, Belgium ;
[2]KU Leuven, Departement of Development and Regeneration, Leuven, Belgium ;
[3]Cardiff University, School of Psychology, Cardiff, United Kingdom ;
[4]Laboratory of Endometrium- Endometriosis & Reproductive Medicine, Department of Development and Regeneration, Leuven, Belgium

Study question: Which live birth rates (LBR) do IVF-patients expect and are they in line with their IVF-prognosis and affected by their gender and general optimism?
Summary answer: During IVF women and especially men expect unrealistically high IVF-LBRs and the difference between men and women is not explained by general level of optimism.
What is known already: The general public is known to overestimate in vitro fertilisation (IVF) success rates. Qualitative interviews showed that well informed women cryopreserving their oocytes were unrealistically optimistic about their chances on a live birth as they thought they and/or their gynaecologist would perform better than average (de Groot et al., 2016). To the best of our knowledge, the LBRs expected by patients during their IVF-cycle have yet to be studied and compared to patient's personalized IVF-prognosis. In addition, whether these expected LBRs are affected by factors like gender and level of optimism is unknown.
Study design, size, duration: We prospectively surveyed the expected LBRs and degree of general optimism of 69 couples having an oocyte aspiration in our clinic between March and December 2019. Men and women were asked to each fill out their own questionnaire. Additionally, couples' personalized IVF-prognosis was calculated using the van Loendersloot prognostic model (van Loendersloot et al., 2013, Sarais et al.,2016) after validation and calibration on our clinics data (c-statistic of 0.74).
Participants/materials, setting, methods: Eligible couples completed at least one 2nd-6th IVF-cycle with own gametes after a previous IVF-cycle with the same partner in our clinic. The level of general optimism was assessed with the reliable 'LOT-R' questionnaire (Scheier et al., 1994). The degree of mis-estimation was calculated with the following formula: (expected IVF-LBR - prognosis)/prognosis. A positive sign shows overestimation, a negative sign shows underestimation and the absolute value quantifies the extend of mis-estimation.
Main results and the role of chance: The 67 participating couples (participation rate=97.10%) had a mean IVF-prognosis (i.e. calculated LBR per completed IVF-cycle, including fresh and frozen embryo transfers) of 31.8% (range=4.8%-59.4%; SD=16.9). Eighty-five percent of women over-estimated their IVF-LBR (mean overestimation 33.66%; SD=20.02) and 47.8% even expected their IVF-LBR to be more than double their calculated IVF-prognosis (mean overestimation 46.47%; SD=16.10). Eighty-eight percent of men over-estimated their IVF-LBR (mean overestimation 38.81, SD=21.84) and 53.7% even expected their IVF-LBR to be more than double their calculated IVF-prognosis (mean overestimation 51.10%; SD=17.75). Men expected significantly higher IVF-LBRs compared to their female partners (64.4% vs. 58.6%; Paired t-test; p=0.028) and their degree of mis-estimation was also significantly higher (2.3 vs 1.8; Paired t-test; p=0.013). Male and female partners did not differ in level of optimism (Paired t-test; p=0.074) and the correlation between the level optimism and expected IVF-LBR was rather weak (Pearson correlation coefficient in women: 0.428; p=0.000 and in men: 0.254; p=0.038). The correlation between the IVF-prognosis and the level of optimism was also weak (women: Pearson correlation coefficient of 0.022; Men: Pearson correlation coefficient of -0.163).
Limitations, reasons for caution: Recruitment is ongoing to end up with a larger scale prospective cohort study with follow-up until the studied IVF-cycle is completed, by achieving a live birth or a negative pregnancy test after the transfer of the last (fresh and frozen) embryo.
Wider implications of the findings: This study documents (the extend of) the interesting overestimation of IVF-LBRs by couples going through IVF. Whether couple's overestimation leads to distress and ultimately IVF-discontinuation, as suggested by qualitative interviews (Peddie et al., 2005), and is associated with actual LBRs will be followed up.
Trial registration number: not applicable

O-186 Sperm donor conception and disclosure to children aged from <1 to 17 years old: a follow-up study of parents attitudes and children reactions to disclosure.

V. Drouineaud[1], M. Benchaib[2], E. Chapel-Lardic[1], N. Mendes[3], J.P. Wolf[1], C. Chalas[1], L. Ferreux[1], D. Rivet-Danon[1], C. Jean[1], C. Patrat[1], O. Blagosklonov[4], A. Condat[3]

[1]Assistance Publique – Hôpitaux de Paris AP- HP Centre- Université de Paris-, Service de Biologie de la Reproduction - CECOS, Paris, France ;

[3]Assistance Publique-Hôpitaux de Paris AP-HP- Groupe Hospitalier de La Pitié-Salpétrière-, Service de Psychiatrie de l'enfant et de l'adolescent-, Paris, France ;
[4]CHU Minjoz, CECOS Franche-Comté - Service de Biologie et Medecine de la Reproduction - Cryobiologie-, Besançon, France

Study question: When do heterosexual parents disclose their use of sperm donation to their child according to the age?
Summary answer: 45.1% of children aged from <1 to 17 years old were informed the day of inclusion. 51.35% were informed between 0-2 and 40.54% between 3-5.
What is known already: In France, gamete donation is free, voluntary and anonymous since 1994. The Bioethics Law does not give any indication concerning the attitude with regard to the disclosure to the child conceived with donor gamete. In the past, couples conceiving through gamete donation were adviced to maintain secrecy. For many years, centers for the study and preservation of eggs and sperm (CECOS) invite couples before ART to disclose to their future child about their origin ton ensure trust. A previous 10-year retrospective follow-up French study reported that 38% of the couples disclosed to the child.
Study design, size, duration: A retrospective follow-up study was performed. Parents with 82 children conceived with donor sperm and aged from 1 to 17 years old were included.
Participants/materials, setting, methods: Parents of 82 children were asked questions of quantitative and qualitative nature about decisions towards their child and other people about their use of donated sperm, how they disclosed and children reactions to disclosure. Five groups were analysed according to the children age: 0-2; 3-5; 6-10; 11-14 and 15-17 years old. The study was set in two centers for the study and preservation of eggs and sperm (CECOS): APHP, Cochin, Paris and Besançon.
Main results and the role of chance: 45.1% of children aged from <1 to 17 years old were informed the day of inclusion: 21.05% of the children aged

0-2 , 45.00% of those aged 3-5, 52.38% of those aged 6-10, 52.94% of those aged 11-14 and 80.00% of those aged 15-17.

51.35% of the children were informed between 0 and 2 years old, 40.54% between 3-5, 8.11% between 6-10, 0% between 11-17. In 54.05% of the cases, both parents disclosed to the child while 2.70% did it separately. Most of the parents who informed their child had informed their family and/or friends about gamete donation before ART (94.59%) and 5.41% after the birth. Although 73.17% couples intended to inform their children about gamete donation before conception, 58.33% disclosed to offspring after birth and 41.67% kept the origin secret. All parents disclosed to their child in a voluntary way. 35.13% used a book and 40.54% told a story and used a book simultaneously. After disclosure, the reactions of the child were different according to the age: indifference (50%) and curiosity (45%) were the most observed in children aged 0-2 while 50% of the kids aged 3-5 showed indifference and/or accepted disclosure. Children aged 6-10 were often curious (66%).

Limitations, reasons for caution: Only parents were interviewed in this study and it should be of great interest to query children conceived through sperm donation. Despite the high response rate, rare parents refused to participate in the study, suggesting that they might not be inclined to disclose the donor origin to their child.

Wider implications of the findings: Attitudes moved towards greater openness about the use of donated gametes, probably due to the evolution of mentalities and awareness of the couples by CECOS centers. Psychological counselling of couples is of particular importance before treatment but also after the child has been born.

Trial registration number: NA

O-187 'Doing' kinship: Experiences of non-genetic parenthood of Dutch heterosexual couples using donor sperm treatment

M. Siermann[1], M. Visser[1], A. Schrijvers[1], M. Mochtar[1], T. Gerrits[2]

[1]Academic Medical Centre Amsterdam, Centre for Reproductive Medicine, Amsterdam, The Netherlands ;
[2]University of Amsterdam, Faculty of Social and Behavioural Sciences, Amsterdam, The Netherlands

Study question: How do Dutch heterosexual couples diagnosed with male infertility who achieved parenthood through donor sperm treatment experience non-genetic parenthood?

Summary answer: For participants genetics were both relevant and irrelevant: genetics were irrelevant for parenthood, but highly relevant for creating similarities between father and child.

What is known already: Male infertility can lead to emotional distress, stigma, and questioning one's sense of masculinity. Non-genetic parenthood can lead to perceived difficulties in parenthood and inequality between parents. Furthermore, donor conception may challenge norms on the role of genetics for kinship. There is limited knowledge on how heterosexual couples experience male infertility, non-genetic parenthood and kinship.

Study design, size, duration: We performed a qualitative in-depth interview study between September 2018 and January 2019 with both partners of thirteen Dutch heterosexual couples who conceived after donor sperm treatment. Participants were recruited through the participant list of a previous mixed-methods study of the University of Amsterdam and the Academic Medical Centre Amsterdam on guidance to donors, parents and children.

Participants/materials, setting, methods: We held semi-structured individual interviews with thirteen genetically related mothers and thirteen non-genetically related fathers (M_{age} fathers = 43.4 years, range 36-64 years; M_{age} mothers = 39.2 years, range 33-46 years). Their 26 children (average: 2 children per couple) were between 1 and 13 years old (M_{age} = 5.4 years). Interview questions were based on literature and clinical experiences of experts in the field of donor conception. Interviews were transcribed and analyzed using thematic analysis.

Main results and the role of chance: All parents in the study were 'doing' kinship: they negotiated the importance of nature versus nurture. Most parents (men and women) saw genetics as irrelevant for experiencing parenthood, for bonding with their children, and for the preferred role of the donor in their future lives. Yet, most of them saw genetics of the donor as relevant for generating similarities between father and child. Having the same donor for all children was seen as essential for nearly all of the parents. Based on the donor's genetic bond with their child, some parents (mainly fathers) had fears around the donor's role in the children's lives and the consequences for the position of the non-genetic father. A few parents (mainly mothers) saw genetics as relevant in terms of possible inherited illnesses from the donor.

Limitations, reasons for caution: There is a possible self-selection bias, with mostly people who are open about donor conception and non-genetic parenthood in their own lives being represented in the study.

Wider implications of the findings: This study gives initial insights into how heterosexual couples in the Netherlands diagnosed with male infertility experience non-genetic parenthood. The findings show the importance of undertaking more qualitative and quantitative studies into experiences of non-genetic parenthood, both to improve guidance for donor conception and to increase knowledge on the topic.

[5]Sugiyama Clinic Marunouchi, Obstetrics & Gynecology, Tokyo, Japan ;
[6]Tatedebari Sato Hospital, Obstetrics & Gynecology, Gunma, Japan ;
[7]Takasaki Art Clinic, Obstetrics & Gynecology, Gunma, Japan

Study question: The aim of the present study was to identify the risk factors associated with severe psychological stress in women undergoing infertility treatments.

Summary answer: Severe psychological stressors in women undergoing infertility treatments include long infertility duration, no childbirth history, low family income, resignation from job, and infertility-related harassment.

What is known already: Infertility is one of the most stressful experiences for couples who desire to have a child. In Japan, women are increasingly getting married at a later age after their prime reproductive age, thereby leading to declining birthrates and increasing proportions of infertile women. The ratio of the employed women has also risen up to 44.5%, which includes more than 70% of the reproductive-aged women. Therefore, the number of working women undergoing infertility treatments has increased. These women face psychological stress not only during their infertility treatments, but also in their jobs.

Study design, size, duration: This was a cross-sectional multi-center study that was performed from August 2018 to December 2018. We conducted a survey by administering anonymous self-report questionnaires to 1727 subjects in four IVF clinics. This study was approved by the local ethics committee.

Participants/materials, setting, methods: The questionnaire consisted of questions on infertility treatments, work/life conditions, and included the Kessler Six-question Psychological Distress Scale (K6) score for the objective analysis of the psychological distress. Of the 1727 subjects, 1672 subjects were recruited for the analysis; among the excluded 55 subjects, including 36 under treatment for mental disorders and 19 with no data of the K6 scores. We also focused on 1335 subjects who were working when they started the infertility treatments.

Main results and the role of chance: The mean age of the 1672 subjects was 37.6 ± 4.8 years, and the mean K6 score (range: 0–24) was 4.8 ± 4.4; 103 women (6.2%) had K6 scores ≥ 13 (K6 high), and they were diagnosed with severe psychological disorders. Multivariate logistic regression analysis showed that "K6 high" is strongly associated with long infertility duration of 2 years or more (odds ratio [OR] 1.874, 95% confidence interval [CI] 1.080–3.253), no experience of childbirth (OR 2.037, 95% CI 1.046–3.969), and low family income with 6.0 million yen (49,000 euro) or less (OR 1.887, 95% CI 1.041–3.418). Among the 1335 subjects who were working when they started the infertility treatments, 266 women (19.9%) had to resign from their jobs for the

infertility treatment. Multiple regression analysis showed that "high K6" is strongly associated with low family income (OR 2.830, 95% CI 1.517–5.278), the experience of resignation from their jobs (OR 2.081, 95% CI 1.045–4.144), infertility-related harassment at the workplace (OR 2.074, 95% CI 1.080–3.983), and difficulty in working during the infertility treatments (OR 2.938, 95% CI 1.150–7.504).
Limitations, reasons for caution: The pregnancy outcomes and the time-dependent changes in these women could not be analyzed because we had only conducted the survey in the form of anonymous self-report questionnaires in this cross-sectional study.
Wider implications of the findings: Severe psychological stress is associated with increased risks of infertility and pregnancy loss. Meanwhile, a beneficial effect of mental care on pregnancy loss has been reported. Therefore, a compassionate mental care system should be established and women should be supported for balancing their infertility treatment schedules with their jobs.

O-189 Does higher level of serum folate before ovarian stimulation worsen outcomes of assisted reproductive technologies in normogonadotropic women?

M. Polzikov[1], D. Blinov[2], T. Ushakova[1], Z. Barakhoeva[3], M. Ovchinnikova[4], L. Vovk[5], Y. Fetisova[5], O. Sergeyev[6]

[3]"AltraVita" Human Reproduction Clinic, n/a, Moscow, Russia C.I.S. ;
[4]Group of companies "Mother and Child", Hospital Lapino, Moscow, Russia C.I.S. ;
[5]Group of companies "Mother and Child", Perinatal Medical Centre PMC, Moscow, Russia C.I.S. ;
[6]Belozersky Institute of Physico-Chemical Biology- Lomonosov Moscow State University, Group of Epigenetic Epidemiology, Moscow, Russia C.I.S.

Study question: To investigate the association of serum folate levels before in vitro fertilization with outcomes of ART in a single ovarian stimulation (OS) GnRH-antagonist protocol.
Summary answer: Using multivariable models we suggested that higher serum folate concentrations in normogonadotropic patients was associated with worse early and clinical ART outcomes.
What is known already: Women of reproductive age are recommended to consume about 400 mg folic acid per day from fortified foods, supplements, or both 2–3 month before conception and during pregnancy. Folic acid supplements with different dosage are commonly used by infertile women which can lead to elevated folate concentration. Study by Murto et al. (2014) has shown that women with unexplained infertility had significantly higher median plasma folate concentrations than fertile women. However Gaskins et al. (2015) found that higher serum concentration of folate before ART treatment was associated with higher live birth among subjects of EARTH study using three treatment protocols.
Study design, size, duration: A sub-analysis of data obtained from multicenter, randomized, embryologist-blinded, parallel-group, therapeutic equivalence study of recombinant FSH. 110 women were enrolled using following inclusion criteria: women aged 20-35 years old, tubal and/or male causes of infertility factors, first or second attempt at IVF/ICSI; 18 ≤ BMI ≤ 30 kg/m^2; FSH <10 IU/l, estradiol level <50 pg/ml; AMH≥1.0 ng/ml. No restrictions for folic acid and other food supplements/vitamins were applied before, during and after OS.
Participants/materials, setting, methods: All subjects underwent OS using a GnRH-antagonist protocol and one ART cycle per women. Over the 5-day fixed-dose regimen, the women received 150 IU/day of follitropin alpha, followed by dose adaptation. Baseline serum folate was measured by using a chemiluminescence assay by Architect system (Abbott, USA). Multivariable generalized linear models were used with Poisson distribution and log link function for adjusted oocyte counts, and a binomial distribution and log link function for adjusted clinical outcomes.
Main results and the role of chance: 110 women had a median serum folate concentration of 20.55 ng/ml (interquartile range: 10.8, 32.9 ng/ml). Age, type of follitropin alpha, ovulation trigger, baseline level of estradiol and LH were not associated with both early and clinical ART outcomes in univariate regression models. For each outcome, we fit a full multivariable model including all covariates with univariate p≤0.10 and reduced to a final model retaining covariates with p < 0.05. Women with higher serum folate had significantly lower total oocytes yield (p =0.08), lower number of matured oocytes (p=0.04) and lower fertilized oocytes (p=0.02) after adjustment for BMI, level of AMH, international normalized ratio, duration of stimulation, dose of FSH, ratio serum calcium/magnesium (additionally for male factor in model of fertilized oocytes). Women in highest quartile of serum folate (>=33.0 ng/ml) had 0.23 odds ratio (95% CI: 0.04, 1.34; p=0.046) for biochemical pregnancy, 0.12 odds ratio (95% CI: 0.02, 0.79; p=0.02) for clinical pregnancy, and 0.1 odds ratio (95% CI: 0.01, 0.7; p=0.03) for live birth rate compared with women in the lowest quartile (<10.8 ng/ml) in models adjusted for red blood cells, level of FSH, ratio serum calcium/magnesium (additionally adjusted for level of antithrombin in model of biochemical pregnancy).
Limitations, reasons for caution: Normogonadotropic non-obese study women aged 20-35 years old were unrestricted in use of different supplements, including folic acid and folate. Further pre-conception large-scale studies with known folate status of both parents, including daily doses, serum folate, homocysteine and hormone levels are needed.
Wider implications of the findings: We suggested that baseline higher serum folate concentration was associated with worse ART outcomes. Our findings might be useful for choose of safe dosage of folate supplementation for both fertile women and women undergoing infertility treatment.
Trial registration number: parental study - NCT03088137 (clinicaltrials.gov)

O-190 The mechanism of action of oxytocin receptor antagonists (OTRan) in ART – a study of nolasiban on biomarkers of uterine receptivity in healthy female volunteers

O. Pohl[1], L. Marchand[1], P. Pierzyński[2], C. Blockeel[3], S. Mackens[3], U. Lorch[4], J.P. Gotteland[1]

[1]ObsEva SA, Research and Development, Plan-les-Ouates Geneva, Switzerland ;
[2]Uniwersytecki Szpital Kliniczny, Klinika Rozrodczości i Endokrynologii Ginekologicznej, Białystok, Poland ;
[3]Universitair Ziekenhuis Brussel, Centre for Reproductive Medicine, Brussels, Belgium ;
[4]St George's University of London, Richmond Pharmacology Limited, London, United Kingdom

Study question: How does nolasiban (an OTRan) effect markers of endometrial receptivity such as uterine contractions, and endometrial perfusion and gene expression.
Summary answer: Administration of nolasiban resulted in decreased uterine contractions, increased endometrial blood flow, and modulation of gene expression relevant for endometrial receptivity and implantation.
What is known already: The rate of uterine contractions during embryo transfer (ET) has been shown to be negatively correlated with pregnancy rates, and endometrial blood flow (perfusion) has been shown to be an important predictive parameter for endometrial receptivity. Oxytocin receptors are expressed during human peri-implantation phase in the myometrium, endometrium and uterine blood vessels, and several clinical studies have shown that blocking activation of oxytocin receptors by an OTRan, has the potential to decrease uterine contractions, increase endometrial perfusion and improve pregnancy rates following ET. The highest dose of nolasiban tested in clinical trials is a single administration of 900mg.
Study design, size, duration: A randomized, double-blind, parallel-group study was conducted in 42 healthy, pre-menopausal women aged 18 to 37 years. Following hormonal pre-treatment, on the day corresponding to a Day 5 ET, women received a single oral administration of 900mg or 1800mg nolasiban or matching placebo. Pharmacodynamic assessments up to 24 hours after treatment included ultrasonographic measurements of uterine contraction frequency and endometrial perfusion. Endometrial biopsies were collected at 24 hours.

Participants/materials, setting, methods: Subjects were pre-treated with an identical hormonal preparation as that used for women undergoing frozen-thawed ET (FET). Transvaginal echography at 0, 4, 8 and 24 hours was used to measure uterine contraction frequency, and endometrial perfusion parameters, including vascularity index (VI), flow index (FI) and vascularity flow index (VFI), were measured via 3D power Doppler. Endometrial tissue mRNA expression was analyzed using Next Generation Sequencing with standard analytical methodologies.

Main results and the role of chance: Both 900mg and 1800mg doses of nolasiban had measurable and durable effects on uterine contractions, with a similar decrease in median contraction frequency at 24-hours after treatment. At 1800mg, effects were observed from the 4-hour time point onwards and in post-hoc statistical analyses were at $p<0.10$ at the 4- and 8-hour time points compared to placebo.

Endometrial perfusion parameters showed marked and sustained median increases and were comparable for both doses. The most noticeable increase in VI was between the 8-hour and the 24-hour time points with $p<0.10$ at the 8-hour time point at 1800mg. FI also increased over time and post hoc statistics showed $p<0.10$ at the 24-hour time point for both doses. Similarly, an appreciable increase in endometrial VFI over time was seen at 900mg and 1800mg compared to placebo; $p<0.10$ at the 8-hour time point at 1800mg.

Within 24 hours of 1800mg nolasiban administration, 10 endometrial genes were found to be significantly differentially expressed (adjusted $p<0.05$). Of these, OLFM4, DPP4 and CXCL12 were regulated in the same direction as Window-of-Implantation-associated genes. In addition, three genes (DPP4, CXCL12 and IDO2) have previously been associated with decidualization and endometrial receptivity.

Limitations, reasons for caution: This study was conducted in healthy volunteers without a diagnosis of infertility but pre-treated as for FET. Extrapolation of these results to patients with infertility who are undergoing fresh embryo transfer should be made with caution.

Wider implications of the findings: These data expand the understanding of the mechanism-of-action of OTRan in increasing live birth rates following ET. These results also suggest faster, broader and more potent effects of the nolasiban 1800mg dose compared to the 900mg dose, supporting testing at higher doses and potential alternate regimens in IVF patients.

Trial registration number: 2018-003702-36

O-191 TRIM28 induces follicular arrest and hyperandrogenism

Y. Liu[1], X. Li[1], J. Xu[1], H. Huang[1]

[1]The International Peace Maternity and Child Health Hospital, Shanghai Jiao Tong University School of Medicine, Shanghai, China

Study question: What is the expression pattern of TRIM28 in granulosa cells(GCs) and the role of that in the mechanism of polycystic ovary syndrome?

Summary answer: The elevated TRIM28 levels reduce ERK phosphorylation by upregulating PDE10A, leading to ovarian steroidogenesis dysfunction in GCs and resulting in follicular arrest and hyperandrogenism.

What is known already: Polycystic ovary syndrome (PCOS) is a common endocrinopathy of unknown etiology that affects women of reproductive age. Previous studies have built a convincing argument that an abnormal AR is associated with PCOS and have documented the unique roles of Androgen receptor(AR) Splicing variants(ASVs)) in GCs in the pathogenesis of PCOS. The AR ASV exhibited a genome recruitment pattern differing from that of wild-type AR and dramatically induced the expression of androgen-related genes. Bioinformatics analysis suggested that this abnormal genomic recruitment pattern of AR ASVs is highly similar to that of multiple transcription factors, of which TRIM28 ranks first.

Study design, size, duration: We compared the gene expression pattern of TRIM28 in granulosa cells(GCs) from 139 PCOS women and 120 women with tubal blockage undergoing IVF-ET between June 2014 and July 2018. We used a human granulosa-like tumor cell line(KGN) to explore the molecular mechanism at the in vitro level. We observed the phenotype of animal modes for 20 weeks.

Participants/materials, setting, methods: 139 PCOS women and 120 women with tubal blockage undergoing IVF-ET in our center were recruited. GCs and follicular fluids were collected during oocyte retrieval. KGN cell line was used for in vitro test. The ovarian specific overexpression of Trim28 transgenicm mice were used as animal models. The phenotypic observation lasted for 20 weeks to clarify the role of Trim28 in the pathophysiological changes of PCOS and explore the molecular mechanism involved.

Main results and the role of chance: We found that the TRIM28 in the granulosa cells (GCs) of women with PCOS were significantly elevated compared with those in the control group ($P<0.05$). We modelled our clinical findings by transgenic mice with ovarian-specific overexpression of Trim28 and followed a PCOS-like phenotype of metabolic abnormalities, including obesity, insulin resistance, hyperandrogenism and follicular dysplasia. Transcriptome analysis of KGN cells revealed that a series of genes were significantly enriched in the ovarian steroidogenesis pathway, and the combination analysis of RNA and ChIP sequences revealed that the mRNA expression of PDE10A was significantly upregulated via TRIM28 in GCs of PCOS women as well as in KGN cells with TRIM28 overexpression, compared with that in the control group ($P<0.05$). Since PDE10A hydrolyzes cyclic adenosine monophosphate (cAMP), the cAMP and PKA activation in TRIM28-overexpressing KGN cells were inhibited, which further led to the inhibition of the MAPK-PKA-ERK signaling pathway and ultimately caused steroidogenesis. Our study thus suggests that elevated TRIM28 levels reduce ERK phosphorylation by upregulating the expression of PDE10A, leading to ovarian steroidogenesis dysfunction in GCs and resulting in follicular arrest and hyperandrogenism, and further confirms the critical role of TRIM28 in the pathophysiological changes of PCOS at the in vivo level.

Limitations, reasons for caution: This study still has certain limitations. We did not explore the reasons for the increased TRIM28 in GCs of PCOS patients, for example, whether it was caused by genetic factors or epigenetic factors.

Wider implications of the findings: Our study first clarified the regulatory mechanism of TRIM28 for PDE10A and their role in the multiple phenotypic interpretations of PCOS and successfully constructed the Trim28-ovarian specific overexpression animal models. The above findings provide new basis and guidance for proposing feasible and effective risk prediction programs and clinical intervention measures.

Trial registration number: 2017YFC1001303

O-192 Androgens increase accumulation of advanced glycation end products (AGEs) in granulosa cells by activating endoplasmic reticulum (ER) stress in polycystic ovary syndrome (PCOS)

M. Harada[1], J. Azhary, MK[1], C. Kunitomi[1], A. Kusamoto[1], N. Takahashi[1], E. Nose[1], N. Oi[1], O. Wada-Hiraike[1], Y. Urata[1], T. Fujii[1], Y. Osuga[1]

[1]Faculty of Medicine- University of Tokyo, Dept. of Obstetrics and Gynecology, Tokyo, Japan

Study question: What is the underlying mechanism regulating AGE – receptor for AGEs (RAGE) system in granulosa cells from PCOS patients?

Summary answer: Targeting AGE-RAGE system, that is upregulated in PCOS ovary and induced by testosterone via activation of ER stress, improves reproductive phenotype of PCOS.

What is known already: PCOS is associated with hyperandrogenism. Previously, we demonstrated that androgen activates ER stress in granulosa cells from PCOS patients and mice, and that this contributes to the pathology of PCOS, including ovarian fibrosis and the growth arrest of antral follicles. In addition, recent studies demonstrated the accumulation of AGEs in granulosa cells from PCOS patients contribute to the pathology by affecting a number of cellular processes, such as steroidogenesis, glucose metabolism, and the production of proinflammatory cytokines.

Study design, size, duration: The expression of RAGE was compared between human granulosa-lutein cells (GLCs) obtained from 11 PCOS patients and ten control patients undergoing oocyte retrieval. Ovaries of three PCOS patients and three control patients, harvested at surgery, were evaluated immunohistochemically for AGEs and RAGE. For *in vitro* experiments, GLCs were obtained from pooled follicular fluids. For *in vivo* experiments, a dehydroepiandrosterone (DHEA)-induced PCOS mouse model was used and forty mice were allocated to four treatment groups.

Participants/materials, setting, methods: Human GLCs were incubated with testosterone and RAGE expression and AGEs accumulation were examined, while GLCs were preincubated with an ER stress inhibitor to examine the intermediary role of ER stress. RAGE expression and AGEs accumulation

in human GLCs and ovaries were compared between control and PCOS patients. PCOS mice were treated with an ER stress or RAGE inhibitor, followed by examination of vaginal smears and quantification of atretic antral follicles.

Main results and the role of chance: Treatment with testosterone increased RAGE mRNA and protein expression in cultured human GLCs. Pre-incubation with a clinically available ER stress inhibitor tauroursodeoxycholic acid (TUDCA) abrogated the stimulatory effect of testosterone on RAGE expression. Treatment with testosterone increased AGEs accumulation in GLCs, and this was reduced by pre-treatment with TUDCA, similar to the pattern for RAGE expression. When we knocked down C/EBP homologous protein (CHOP), a transcription factor activated during ER stress, by RNA interference, CHOP-deficient cells demonstrated significantly lower expression of RAGE expression following testosterone treatment, than control siRNA-treated cells, with a concomitant reduction in AGEs accumulation. GLCs harvested from PCOS patients exhibited higher expression of RAGE mRNA and protein than those from control participants. Immunohistochemical analysis revealed that RAGE expression and AGEs accumulation were increased in granulosa cells of the ovaries from PCOS patients. Increased RAGE expression and AGEs accumulation in granulosa cells of PCOS subjects were further confirmed in PCOS model mice. The administration of a RAGE inhibitor (FPS-ZM1) or TUDCA to PCOS mice reduced the expression of RAGE and the accumulation of AGEs in granulosa cells, and this was accompanied by an improvement in estrous cycling and a reduction in the number of atretic antral follicles.

Limitations, reasons for caution: It is not determined whether the concentrations of testosterone usually utilized in human GLC culture studies are appropriate as a model of *in vivo* hyperandrogenism. Furthermore, the concentrations of testosterone in follicular fluid of antral follicles of PCOS women, not of preovulatory follicles, are still unknown.

Wider implications of the findings: Our findings suggest that the hyperandrogenism of PCOS increases the accumulation of AGEs in the ovary by activating ER stress, and that targeting of the AGE–RAGE system, either by using a RAGE inhibitor or a clinically available ER stress inhibitor, may provide a novel therapeutic approach for PCOS.

[7]Imperial College London, Institute of Reproductive and Developmental Biology, London, United Kingdom

Study question: Does mean relative leukocyte telomere length (LTL) or longitudinal change in LTL differ in women with PCOS symptoms or diagnosis in comparison to controls?

Summary answer: In our dataset, women with PCOS do not have shorter LTL, but do show less telomere attrition between ages 31 and 46.

What is known already: Telomeres are DNA-protein complexes that protect chromosome ends from DNA damage and act as a indicator of cellular ageing. In most somatic tissues, a small part of telomeric DNA is lost with every cell division, causing telomere shortening. Current evidence, almost entirely from cross-sectional observations, supports negative associations between LTL and adverse lifestyle and cardio-metabolic risk factors. Women with PCOS are affected by co-morbid conditions that are also associated with shorter LTL, such as obesity and chronic inflammation. To date, few studies have investigated the association between PCOS and LTL and/or LTL shortening with age.

Study design, size, duration: We used a community-based birth cohort (N=5889 women) with clinical follow-up at ages 31 (N=3115) and 46 (N=3280) including measures of LTL at both ages (N=2906 and N=3233). We defined study groups as follows: age 31, both oligo/amenorrhea and hirsutism: "both symptoms" (N=73); age 46, self-reported PCOS diagnosis (DG-PCOS, N=155); self-reported PCOS (both symptoms and/or DG-PCOS: srPCOS, N=207); controls: women without PCOS-related symptoms or diagnosis (age 31: N=1054; age 46: N=1324).

Participants/materials, setting, methods: Mean relative LTL was measured by monochrome multiplex quantitative PCR. The amount of telomeric DNA sequence was quantified relative to a single-copy gene and normalised using a common reference DNA sample. The possible association between LTL and PCOS was analyzed using linear regression models adjusted at both ages for BMI, smoking, alcohol consumption and socioeconomic status. Pearson correlations between LTL and BMI, waist, hip, testosterone and sex hormone-binding globulin were performed at both ages.

Main results and the role of chance: Since LTL was measured using a different reference DNA sample at ages 31 and 46, this was standardized [z score= (LTL–mean (LTL))/SD(LTL)] separately for each measurement.

Unadjusted mean LTL did not differ between women with PCOS symptoms and controls at age 31 (0.01±(SD)1.10 *vs*. 0.07±0.99, P=0.632) or between DG-PCOS women and controls at age 46 (0.03±0.93 *vs*. 0.01±1.02, P=0.860). Similarly, LTL did not differ when comparing srPCOS with controls (at age 31 for srPCOS 0.02±0.99 *vs*. controls 0.07±0.99, P=0.593; at age 46 for srPCOS -0.05±0.95 *vs*. controls 0.01±1.02, P=0.414). After respective adjustments for the aforementioned covariates at age 31 or 46, none of the results changed.

Interestingly, we observed a greater mean difference (MD) of LTL z-scores between ages 46 and 31 in the control group (MD: -0.13±1.10, P<0.001) than in the srPCOS group (MD: -0.01±1.10, P=0.958). The observed difference suggests that the longitudinal change in LTL is markedly less in women with PCOS when compared to controls.

In the srPCOS group there were only weak negative correlations between LTL and BMI (r=-0.17, P=0.019), and LTL and waist circumference (r=-0.19, P=0.009) at age 31 whereas the correlations did not reach significance at age 46.

Limitations, reasons for caution: The symptoms and diagnosis of PCOS were self-reported. The questionnaire at age 46 did not differentiate between women with polycystic ovaries and the syndrome. The study population was relatively young to express significant telomere shortening. The sample size of the PCOS women with telomere measurement data was relatively small.

Wider implications of the findings: We observed less LTL attrition in PCOS women than in controls. Analyses included correction for BMI and lifestyle factors, but before concluding whether there is a causal association between PCOS and LTL, further research is needed to clarify the underlying mechanisms and compare with data from other biomarkers of ageing.

07 July 2020 Parallel 1 17:00 - 18:00

O-194 Human blastocysts show distinct changes in their metabolism between day 5 and 6

D. Sakkas[1], M. Venturas[2], J.S. Shah[1], T. Sanchez[2], D.J. Needleman[2]

[1]Boston IVF, Research, Waltham- MA, U.S.A. ;
[2]Harvard University, Molecular and Cellular Biology and School of Engineering and Applied Sciences, Cambridge, U.S.A.

Study question: Do day 5 and 6 human blastocysts exhibit metabolic changes that can be detected by non-invasive metabolic imaging?
Summary answer: Imaging of NADH and FAD reveals metabolic differences between day 5 and day 6 discarded human blastocysts.
What is known already: Based on their functional role in cell biology, intracellular NADH and FAD have a diagnostic potential as natural biomarkers for cellular redox reactions and energy metabolism. NADH and FAD are auto-fluorescent, and their concentration and local environment can be measured using Fluorescence Lifetime Imaging Microscopy (FLIM). It has previously been shown that FLIM can quantitatively measure distinct stage differences in the metabolic state of preimplantation mouse embryos over the course of development. Human embryos are known to undergo metabolic changes during the 8-16 cell stage however less is understood of the metabolic idiosyncrasies during the later stages of preimplantation.
Study design, size, duration: We performed a prospective observational study with 88 day 5 and 68 day 6 blastocysts (108 patients, mean age 35.3 years). Blastocysts were discarded and donated for research under an approved institutional review board protocol . All, but 2, embryos had a Gardner score of A and/or B for the inner cell mass and trophectoderm and were either full or expanded blastocysts. The vitrified blastocysts were thawed and cultured for 2 hours prior to imaging.
Participants/materials, setting, methods: A FLIM measurement provides 9 metabolic parameters which can be used to analyze the metabolic signatures of individual embryos. We imaged each blastocyst at three different focal planes, enabling three metabolic measurements per embryo. We then compared those metabolic signatures in relation to the day of vitrification of the embryo (day 5 or 6), using multilevel models.
Main results and the role of chance: FLIM was used to compare the metabolic differences between day 5 and 6 discarded human blastocysts. Of the nine metabolic parameters obtained from each blastocyst the 4 for NADH showed no significant difference (P>0.05) when comparing the Day 5 and 6 blastocysts: NADH short (t1) and long (t2) fluorescence lifetime, fluorescence intensity (I), and fraction of the molecule engaged with enzyme (F). In contrast, all 4 FAD parameters showed highly significant differences (P<0.001) between the Day 5 and 6 blastocysts: FAD-t1; FAD-t2, FAD-I and FAD-F. The redox ratio (Intensity of NADH)/(intensity of FAD), was also compared between Day 5 and 6 blastocysts and showed a substantial significant difference (P<0.001). Subsequent analysis comparing Day 5 and 6 blastocysts with similar expansion rates and similar Gardner grade inner cell mass and/or trophectoderm showed the same pattern.
Limitations, reasons for caution: The study was limited by the type of human blastocysts available as they were discarded and donated for research without any knowledge of their clinical outcome. It would also be expected that the blastocysts would be a mixture of euploid and aneuploid.
Wider implications of the findings: Metabolic imaging can non-invasively detect a significant shift in metabolism between Day 5 and 6 human blastocysts. This analysis indicated that Day 5 and 6 blastocysts may be undergoing intricate changes in respiration as they ready for implantation. Further studies examining metabolic signature over time may provide more information.

O-195 NMR metabolomics study of follicular fluids reveals specific signature correlated to ART data in endometriosis patients.

K. Pocate[1], P. Santulli[2], F. Kateb[3], M. Bourdon[2], C. Maignien[2], C. Patrat[1], J.P. Wolf[1], G. Bertho[3], C. Chapron[2]

[1]Hopital Cochin, Department of Histology- Embryology- and Biology of Reproduction, Paris, France ;
[2]Hopital Cochin, Gyneacology-Obstetrics and Reproduction clinical unit, Paris, France ;
[3]Paris Descartes University, Laboratoire de Chimie et Biochimie Pharmacologiques et Toxicologiques- UMR 8601-CNRS- Université Paris Descartes- ComUE Sorbonne Paris Cité- 45 rue des Saint-Pères- 75006- Paris- France, Paris, France

Study question: To evaluate the relation between metabolic follicular fluid (FF) composition and ART outcomes in terms of embryo quality and live birth occurrence in endometriosis patients.
Summary answer: Embryo quality and live birth occurrence seem to be correlated to a specific metabolic signature in endometriosis patients.
What is known already: Among different mechanisms explaining infertility occurrence in endometriosis, oocyte quality alteration has been raised. This last point is still under debate despite of recent studies confirming the deleterious impact of endometriosis on the oocyte competence. Metabolomics studies are increasingly being used to measure alterations of metabolic pathways associated with complex disorders. Among the various sources of study samples in endometriosis, FF is one of the most interesting to analyze in a context of infertility. Very few studies have focused on the metabolic signature of endometriosis FF and its correlation with ART outcomes.
Study design, size, duration: This is a prospective study started on February 2018 and still recruiting (ClinicalTrials.gov NCT03241329). A total of 9 endometriotic patients were included for this analysis.
Participants/materials, setting, methods: Endometriotic patients enrolled in an ART attempt without any male infertility associated factor. After controlled ovarian stimulation, oocyte retrieval was performed by transvaginal aspiration under ultrasound guidance. Each follicle was individually aspirated and only unique oocyte deriving from the same follicle was retained for the evaluation. FF was then centrifuged and stored at -80°C before 1D-^{1}H NMR-based metabolomics analysis. Data were compared to blastocyst quality assessment and to clinical outcome after transfer.
Main results and the role of chance: Analysis was carried out on a total of 26 FF samples for which embryo quality was assessed and on 8 FF samples for which clinical outcome information was available. Univariate analysis revealed that the concentration of various statistically relevant metabolites could be associated with embryo quality. In particular, the metabolic profile of FF resulting in better embryo quality was characterized by a decrease in glucose level associated to an increase in lactate level. Among other discriminant metabolites, citrate, acetate and amino acids, such as tyrosine also appear as being particularly relevant with a lower concentration level observed for good embryos. Finally, live birth occurrence appears to be correlated to the same trend of variation in glucose and lactate levels, but also to an increase in lipids levels such as HDL cholesterol, 2-octenoate and alkane.
Limitations, reasons for caution: Even if the methodology of our study was robust, the analysis was realized using a small number of samples. These preliminary results need to be confirmed on larger series.
Wider implications of the findings: Embryo quality and live birth occurrence seem to be correlated to a specific metabolic signature in endometriosis patients. Our results could be linked to the oocyte quality and could then represent a new and non-invasive tool for the prediction of succeeding chance in pregnancy favorable outcomes.
Trial registration number: not applicable

O-196 Blastocyst quality modulates the generation of an inflammatory microenvironment by decidualized cells

L. Fernandez[1], E. Grasso[1], E. Soczewski[1], M.S. Gori[1], G. Calo[1], V. Hauk[1], G. Martinez[2], M. Irigoyen[2], C. Perez Leiros[1], R. Ramhorst[1]

[1]CONICET. Universidad de Buenos Aires., Instituto de Química Biológica de la Facultad de Ciencias Exactas y Naturales IQUIBICEN. Laboratorio de Inmunofarmacología y Laboratorio de Inmunología Reproductiva de la Fertilidad., Buenos Aires, Argentina ;
[2]Fertilis Medicina Reproductiva, Laboratorio de embriologia, San Isidro, Argentina

Study question: Could soluble factors secreted by blastocyst (blastocyst conditioned media or BCM) control the inflammatory response during the peri-implantation period according to blastocyst quality?
Summary answer: Decidualized cells increased the expression/production of inflammatory cytokines as well as neutrophils migration and activation in response to BCM from impaired development (ID) blastocyst.

What is known already: The decidualization program in humans starts on each menstrual cycle and implies not only phenotypical changes on the endometrial stromal cells, but also in their secretory profile. This secretome includes pro-implantatory factors as well as pro and anti-inflammatory cytokines. Despite blastocyst implantation needs a sterile inflammatory response, it should be later controlled in favour of a tolerogenic microenvironment. In this sense, decidualized cells display the ability to change their secretome according to the quality of the blastocyst.
Study design, size, duration: Human endometrial stromal cell line (HESC) was decidualized with medroxiprogesterona and dbcAMP during 8 days. Then, decidualized HESC cells were stimulated with human blastocyst conditioned media (BCM) obtained from developing blastocysts (normal development or ND) or arrested ones (impaired development or ID). Non decidualized cells were used as control.
Participants/materials, setting, methods: BCM were recovered from 5 days individually cultured blastocyst obtained from IVF/ICSI and classified as normal or impaired development (ND/ID) according to Istanbul consensus. Neutrophils were obtained from peripheral blood from healthy donors. Cytokine expression/production was evaluated by RT-qPCR/flow cytometry/ELISA. Caspase-1 activity was measured using Flica probe. Neutrophils migration towards HESC supernatants was evaluated using a transwell system. ROS production was assessed by CDFH-DA probe. MMPs activity was evaluated by gelatin zymography.
Main results and the role of chance: We observed that ID-BCM stimulation increased caspase-1 activation and IL-1β production by decidualized cells, while ND-BCM reduced IL-1β production ($p<0.05$, ANOVA). When a cytokine profile was evaluated, we observed that ID-BCM increased CCL2 and CXCL12 expression as well as IL-8 secretion, while the production of the anti inflammatory cytokine IL-10 was reduced ($p<0.05$, ANOVA). In contrast, ND-BCM stimulation did not modulate these cytokines. Since IL-8 and CXCL12 are associated to neutrophils recruitment towards the inflammatory sites, we evaluated whether the HESC supernatants were able to modulate neutrophils migration using a transwells system. In this sense, ID-BCM increased neutrophils recruitment. Additionally, when neutrophils were stimulated with HESC supernatants, ID-BCM treatment leaded to higher ROS production ($p<0.05$, Friedman test), suggesting an increased activation of these immune cells. Since menstruation is accompanied by a neutrophils influx, we hypothesize that ID-BCM stimulation induces a "menstruation like" pro-inflammatory microenvironment. Due to the fact that MMPs are the final effectors of menstruation, we tested MMPs activity on HESC conditioned media. In this sense, ID-BCM stimulation increased geletinolitic activity of MMP9 ($p<0.05$, ANOVA).
Limitations, reasons for caution: The present results were obtained using immortalized cell lines and *in vitro* models. Further studies are necessary to elucidate whether the mechanisms operate similarly *in vivo* and rule out any factor not contemplated *in vitro*.
Wider implications of the findings: These results provide new clues about the embryo maternal crosstalk and the natural embryo selection. Decidualized cells respond to blastocyst derived factors according to their quality either controlling or inducing a pro-inflamatory microenvironment. These findings might contribute to a better understanding of reproductive disorders such as *in vitro* implantation failures.
Trial registration number: not applicable

O-197 What can we learn from the first 24 hours of embryo development? A fully automated AI-based algorithm for identifying high-quality blastocysts.

D. Gilboa[1], M. Meseguer[2], R. Maor[1], R. Weiner[1], L. Alon[1], L. Bori[2], L. Alegre[2], D.S. Seidman[3]

[1]AiVF, IVF Research and Development, Tel Aviv, Israel ;
[2]IVIRMA Global, IVF Unit, Valencia, Spain ;
[3]Sheba Medical Center, IVF Unit, Ramat Gan, Israel

Study question: Can an AI-based system that analyses the first 24 hours of embryonic development open, for the first time, a window to the development of the embryo?
Summary answer: Using AI algorithms we have shown that a combination of previously unrecognized features within 24 hours after fertilization can help identify high-quality blastocyst
What is known already: Embryos examined on the first day after retrieval are usually classified as viable or atretic. However, little more can be established regarding their future development, based on routine morphological studies. All AI algorithms developed so far for embryo selection are based on time-lapse video analysis of cleavage stage embryos. Oocyte and zygote stage visual assessment was not used so far for the prediction of embryo quality.
Study design, size, duration: A retrospective analysis of the first 24 hours of embryo development based on 1560 consecutive time-lapse videos from a single IVF center.
Participants/materials, setting, methods: Using computer vision algorithms, we identified unique features, some of which were never before recognized, during the first 24 hours of embryonic development. We then developed an automated AI algorithm to extract and measure these features from time-lapse videos. A deep neural network was developed based on the parameters recognized by the computer vision module for each image. A classifier was used to match these parameters to the endpoint, high-quality blastocysts.
Main results and the role of chance: Our model was able to predict high-grade blastocysts on day 5 using only day-1 time-lapse data with an AUC of 0.665 [95% CI 0.650-0.681] and 10-fold stratified cross-validation of the training set. Our test results showed that the AUC was reproducible. These results are comparable to studies attempting to make similar predictions based on a much longer observation period of cleavage stage embryos.
Limitations, reasons for caution: Future prospective validation of our AI algorithm is required using different patient populations, although the number of embryos analyzed is outstanding.
Wider implications of the findings: Our results broaden the understanding of the potential capabilities for IVF of newly introduced AI systems. We showed that a deep neural net can solve one of the most challenging tasks, distinguishing between top-grade embryos, solely based on unique visual features identified in the first 24 hours after fertilization.
Trial registration number: not applicable

SESSION 50: ANDROGEN TREATMENT IN FERTILITY MANAGEMENT

07 July 2020 Parallel 2 17:00 - 18:00

O-198 A prospective study of testosterone gel treatment in poor ovarian reserve in IVF-ICSI cycles

R. Singh[1], M. Singh[2]

[1]BHOPAL TEST TUBE BABY CENTRE, INFERTILITY, BHOPAL, India ;
[2]BTTB Centre, Infertility, Bhopal, India

Study question: Does transdermal testosterone gel pretreatment improve the outcome in women with poor ovarian reserve undergoing IVF-ICSI Cycles ?
Summary answer: The testosterone gel has a significant impact on the fertility rate in women with a poor response in the IVF cycles.
What is known already: Poor ovarian reserve to external gonadotropin drugs is one of the problems with IVF-ICSI cycles which can lead to cycle stop, access to fewer oocytes and embryos, and finally reduced pregnancy rates.
No effective approach has been found yet to treat poor response to ovarian stimulation.
However, there are possible methods affecting the performance of gonadotropins on the ovaries such as high-dose gonadotropins, growth hormone, glucocorticoids, and low-dose aspirin. Another treatment is the use of low-dose androgens to improve ovarian response to gonadotropins which acts by increasing the intrafollicular androgen and the number of follicle-stimulating hormone (FSH) receptors on granulosa cells.
Study design, size, duration: 52 patients from July 2017 to July 2019, were randomly divided into two groups , 26 patients treated with a

placebo (lubricant gel, control group) and 26 patients treated with testosterone gel (Study group).
Inclusion criteria were : patients for IVF cycles, patients older than 40 years, a cycle with previous poor response, i.e., to obtain 3 or <3 oocytes of the cycles by normal stimulation, AFC <5–7, AMH <0.5–1.1 ng/ml, Fertility outcomes were compared.
Participants/materials, setting, methods: 52 patients were randomly divided into two groups. 26 patients treated with a placebo gel and 26 patients treated with testosterone gel .

Patients who met inclusion (Bologna) criteria were placed in the antagonist cycle group. The patients were randomly divided into two groups each included 26 participants treated with a placebo and testosterone gel . Fertility outcomes were compared between two groups.

The two groups were not statistically different in terms of FSH , AFC, AMH,
Main results and the role of chance: The number of oocytes and embryos in the study (testosterone gel) group were significantly higher than in the control group.

The mean number of oocytes obtained was 3.12 ± 1.14 versus 1.27 ± 1.03 and embryos was 2.10 ± 1.08 versus 0.39 ± 0.48.

The clinical pregnancy rate was 15% (4/26) in the study (testosterone gel) group ,were significantly higher versus than in the control group 04 % (1/26).

In conclusion, there is evidence from this study that the use of transdermal testosterone prior to ovarian stimulation in women who are considered poor responders, and this treatment has shown to significantly improve live birth rates and reduce the doses of FSH required for ovarian stimulation.

Androgen receptors are expressed in granulosa cells at early stages of follicle maturation, it is surprising that such a short treatment up to 20 days of testosterone supplementation could achieve significantly higher live birth rates. Hence, extending testosterone supplementation for a longer period could enhance the pool of follicles sensitive to gonadotrophins and therefore increase the number of oocytes available for retrieval.
Limitations, reasons for caution: Transdermal-testosterone may improve the clinical outcomes for poor-ovarian-reserve.

One limitation is the low number of participants and exact subgroup of poor-ovarian-reserve who would benefit from this treatment still needs to be identified.

Although trends in all parameters appear to favour testosterone supplementation, further investigations are needed to confirm these findings.

Wider implications of the findings: According to the results of our study, the testosterone gel has a positive impact on fertility rate in patients with poor-ovarian-reserve.

The identification of poor responders that could especially benefit from testosterone treatment should be addressed in further studies.

Large studies on larger populations are recommended to be conducted.
Trial registration number: not applicable

O-199 The efficacy and molecular mechanism of dehydroepiandrosterone in diminished ovarian reserve

C. Çakır[1], G. Kuspınar[1], S. Işıklar[1], K. Aslan[2], I. Kasapoglu[2], G. Uncu[2], B. Avcı[1]

[1]Uludag University School of Medicine, Histology and Embryology & Gynecology and Obstetric ART Center, Bursa, Turkey ;
[2]Uludag University School of Medicine, Gynecology and Obstetric ART Center, Bursa, Turkey

Study question: What is the effectiveness and molecular mechanism of dehydroepiandrosterone(DHEA) added to the controlled ovarian hyperstimulation(COH) protocol in diminished ovarian reserve (DOR) in vivo rat model?
Summary answer: DHEA improves ovarian respons by increasing folliculogenesis and suppresses apoptotic process of follicles with modulation of the systemic inflammatory response by reducing COX-2 gene expression.
What is known already: Despite the controversy about its effect and uncertainty about the exact mechanisms, DHEA is added as an adjuvant in over a quarter of IVF treatment protocols in patients with poor ovarian response. DHEA stimulates primordial follicles initiation and preantral follicular development in the gonadotrophin responsive stages. It is believed that DHEA increase ovarian susceptibility to FSH stimulation at the later stage but there has not been an established evidence to support at the follicular/molecular level.
Study design, size, duration: In order to determine the efficacy of DHEA both alone and combination with the COH protocol in the low and normalovarian reserve experimental groups, 75 Spraque Dawley female rats were divided into 15 groups. (Control group, VCD group, VCD+DHEA group, VCD+DHEA+KOH group, VCD+DHEA+SF group, VCD+DMSO group, VCD+DMSO+KOH group, VCD+DMSO+SF group, DMSO group, DMSO+DHEA group, DMSO+DHEA+KOH group, DMSO+DHEA+SF group, DMSO+DMSO group, DMSO+DMSO+KOH group and DMSO+DMSO+SF group).
Participants/materials, setting, methods: The experimental animal model of DOR was composed by 4-Vinylcyclohexene diepoxide (VCD) injections (160mg/kg/day for 15 days). After VCD or DMSO injections, DHEA injections were administered (60mg/kg/day for 45 days). COH protocol was then applied to the subjects. In ovarian tissues obtained from sacrificed subjects, COX-2 gene expression levels were analyzed by RT-qPCR, morphological evaluation and ovarian follicle count were performed by hematoxylin-eosin staining.
Main results and the role of chance: It was determined that VCD injections caused a decrease in the number of follicles at different stages of development ($p<0.05$) and an increase in the number of atretic follicles ($p<0.05$) and COX-2 gene expression levels ($p<0.05$) in the ovarian tissues. While DHEA injections did not affect folliculogenesis and COX-2 gene expression levels in subjects with normal ovarian reserve, it was determined that DHEA injections caused a decrease in atretic follicle counts ($p<0.02$) and an increase in COX-2 gene expression levels in subjects with low ovarian reserve ($p<0.01$). DHEA injections before the COH protocol affected folliculogenesis positively in both low and normal ovarian reserve experimental groups, and thus enhanced the efficiency of the COH protocol. Also, DHEA decreased COX-2 gene expression levels in all subjects($p<0.001$).
Limitations, reasons for caution: The limitations of the study is that clinical outcomes have not been evaluated.
Wider implications of the findings: While evidence of using DHEA in clinical setting is currently uncertain, this study shows that DHEA can modify the ovarian microenvironment and modulate the systemic inflammatory response by reducing COX-2 expression.DHEA treatment potentially may be useful clinically as a means to increase the number of gonadotropin-responsive follicles for ovarian stimulation.
Trial registration number: Not applicable

O-200 Endocrine and histological effects of androgen treatment in female-to-male transsexual patients: a study model of long-term high-dose ovarian androgenization

G. Casals Soler[1], A. Borrás Capó[1], A. Goday Cibeira[1], M. Mora Porta[2], S. Peralta Flores[1], F. Fàbregues Gasol[1], J.M. Calafell Pozo[1], D. Manau Trullàs[1], F. Carmona Herrero[3]

[1]Hospital Clinic de Barcelona, Assisted reproduction unit, Barcelona, Spain ;
[2]Hospital Clinic de Barcelona, Endocrine department, Barcelona, Spain ;
[3]Hospital Clinic de Barcelona, Gynecology department, Barcelona, Spain

Study question: Which are the hormonal and ovarian histological effects of a long-term high-dose androgen treatment using female-to-male transsexual patients (FTMTP) as a study model?
Summary answer: According to this study model, long-term high-dose androgen treatment is associated with sequential preoperative hormonal changes, heterogeneous postoperative endocrine parameters and characteristic ovarian histological features.
What is known already: FTMTP treated with high-doses of androgens for a long period of time constitutes an excellent endocrinological, metabolic and histological study model of ovarian androgenization. The aim of the present investigation is: a) to identify the sequence of endocrinological changes in these patients, from the baseline period prior to the start of androgenization to the postoperative

stage and beyond, with controls up to 6 months after surgery; b) histological ovarian assessment after a long period of treatment with androgens at high doses.
Study design, size, duration: Longitudinal observational prospective study including 60 FTMTP patients treated with long-term high-dose of systemic androgens (testosterone undecanoate, Reandron® 1g every 3 months by intramuscular injection). The study points were three: before starting androgen treatment (point 0); after two years of androgen treatment, performed the day before surgery, which consisted in a laparoscopic hysterectomy and bilateral adnexectomy (point 1); and 6 months after surgery (point 2).
Participants/materials, setting, methods: We performed serum hormonal tests including AMH, FSH, LH, estradiol, androgenic profile (androstenedione, testosterone, SHBG) and fasting insulin in each point of the study. Ultrasonographic scans were performed in 32 patients at point 0 and 1 of study. The histological examination was performed in histological sections stained with hematoxylin and eosin. The stromal structure, the thickness of the *tunica albuginea* and the developmental stages of the follicles were evaluated, counting follicles of each category separately.
Main results and the role of chance: The mean age (±SD) was 27.81±5.81 years old (range 20-34). Five patients presented previous polycystic ovary syndrome (PCOS) criteria, with a transvaginal ultrasonography with ≥20 follicles <10mm, ovarian volume ≥10 mm^3 and oligomenorrhea. All patients became amenorrheic after starting the hormonal treatment. At point 1 of the study, all the patients showed hirsutism, no follicular activity by ultrasonography, high testosterone serum levels (781,5 ng/ml ± 325,9) and other serum hormonal parameters in the reference ranges: AMH (3,23±1,4 ng/ml), FSH (5,95±1,97U/L), LH (4,7±3,45 U/L) and estradiol (46,8±24,9 pg/ml). The histological follicular population study demonstrated 88% of primordial follicles, 3.1% of primary follicles, 0.7% of secondary follicles, 4.9% of antral follicles and 3.4% of atretic follicles. We must highlight a high presence of luteinization of stromal cells (68.5% of cases) and only two cases with stromal hyperplasia (1.8%). The thickness of the tunica albuginea was heterogeneous (mean=0.55±0.22 mm; range 0.15-1.45). These ovarian samples share some characteristics with PCOS ovaries although they do not reproduce their complete histological criteria (Hughesdon, 1982). Hormonal assessment showed high heterogeneity at point 3 of study (mean ± SD; range): FSH 52.0±36.0 U/L (0.4-102.4), LH 26.5±21.59 U/L (0.1-68.3) and estradiol 36.2±7.9 pg/ml (27-45).
Limitations, reasons for caution: The sample size is limited. We could not include a control group of non-androgenized patients due to ethical reasons. Ovarian samples from surgery for other indications did not present adequate characteristics to be considered as controls due to histological changes secondary to different associated pathologies.
Wider implications of the findings: We demonstrated that long-term high-dose systemic treatment with androgens is associated with: a) sequential hormonal changes during the preoperative period and heterogeneous postoperative data, possibly due to a hypothalamus and/or pituitary gland inhibition in a selected group of patients; b) characteristic follicular and stromal changes in the ovarian histological study.
Trial registration number: Not necessary

O-201 Association between levels of testosterone /DHEAS at initiation of ovarian stimulation for in vitro-fertilization and the probability of pregnancy: a systematic review and meta-analysis

V. Christoforaki[1], J. Bosdou[1], G. Lainas[1], T. Lainas[2], A. Kalpatsanidis[1], A. Mouza[1], G. Grimbizis[1], E. Kolibianakis[1]

[1]Aristotle University of Thessaloniki- Medical School, Unit for Human Reproduction- 1st Department of Ob/Gyn, Thessaloniki, Greece ; [2]EUGONIA, Assisted Reproduction Unit, Athens, Greece

Study question: Is the probability of pregnancy associated with levels of testosterone/ dehydroepiandrosterone-sulphate (DHEAS) at initiation of ovarian stimulation for in-vitro fertilization (IVF)?
Summary answer: At initiation of ovarian stimulation, a significant negative association exists between testosterone and live birth, whereas a non-significant association exists between DHEAS and clinical/biochemical pregnancy.
What is known already: It has been shown that androgen action is required for normal follicular growth and progression beyond pre-antral stage. Androgens exert direct autocrine and/or paracrine effects that regulate follicular development, by augmenting follicle stimulating hormone (FSH) receptor expression in granulosa cells. Until today, several studies have examined the association between endogenous androgen and achievement of pregnancy, with conflicting, however, results, that have not been yet systematically reviewed.
Study design, size, duration: A systematic review and meta-analysis was conducted after performing a literature search in MEDLINE, CENTRAL until October 2019. The main outcome was the association between levels of testosterone / DHEAS and the probability of pregnancy. Meta-analysis was conducted by pooling data to calculate standardized mean differences (SMD) with 95% confidence intervals (CI), using random effects model.
Participants/materials, setting, methods: Thirteen eligible studies, including 3977 patients, published between 1992 and 2017 were identified. In these studies, testosterone and DHEAS levels were assessed prior to initiation of stimulation among women who after embryo transfer achieved or not pregnancy. Three out of the thirteen studies were prospective, eight were retrospective and in two studies the design was unclear.
Main results and the role of chance: Inhibition of premature luteinizing hormone (LH) surge was performed using gonadotrophin-releasing-hormone (GnRH) agonists (n=9 studies), GnRH-antagonists (n=2 studies), either GnRH-agonists or antagonists (n=1 study), while this information was not reported in one study. Ovarian stimulation was performed with recombinant-FSH (n=6 studies), urinary FSH (n=4 studies), both recombinant and urinary FSH (n=2 studies), while this information was not reported in one study.

Significantly lower testosterone levels were present in patients who achieved live birth compared to those who did not (SMD: -0.21, 95%CI: -0.38 to -0.04, p=0.02, one study, 731 patients).

Testosterone levels were not significantly different between patients who achieved clinical pregnancy and those who did not (SMD: -0.17, 95%CI: -1.27 to +0.93, p=0.76, eight studies, 2016 patients) as well as between those who had positive pregnancy test compared to those who did not (SMD: -0.16, 95%CI: -0.43 to +0.11, p=0.24, four studies, 1230 patients).

DHEAS levels were not significantly different between patients who achieved clinical pregnancy and those who did not (SMD: +0.05, 95%CI: -0.09 to +0.18, p=0.53, six studies, 942 patients) as well as between those who had positive pregnancy test compared to those who did not (SMD: -0.01, 95%CI: -0.73 to +0.71, p=0.98, one study, 120 patients).
Limitations, reasons for caution: Heterogeneity was present regarding patient population, as well as the type of ovarian stimulation protocol used, which could not be meaningfully explored by subgroup analysis, due to the limited number of eligible studies.
Wider implications of the findings: The current study does not suggest that there is a positive association between testosterone / DHEAS levels at initiation of stimulation and pregnancy achievement, questioning the rationale behind testosterone and DHEAS pre-treatment in patients undergoing ovarian stimulation for IVF.

O-202 The transcriptomic profile of endometrial receptivity in recurrent miscarriage

L. Craciunas[1], O. Pickering[1], J. Chu[1], M. Choudhary[2], J. Zurauskiene[3], A. Coomarasamy[1]

[1]University of Birmingham, Tommy's National Centre for Miscarriage Research, Birmingham, United Kingdom ; [2]Royal Victoria Infirmary, Assisted Conception Unit, Newcastle, United Kingdom ; [3]University of Birmingham, Centre for Computational Biology, Birmingham, United Kingdom

Study question: What is the transcriptomic profile of the endometrium in women who suffered unexplained recurrent miscarriage and can it predict the fate of the subsequent pregnancy?

Summary answer: Endometrium biopsied from women who suffered high order recurrent miscarriage has a distinct transcriptomic profile and the differences may predict the fate of subsequent pregnancies.

What is known already: Embryo chromosomal abnormalities represent the most common cause of first trimester miscarriage in addition to a broad range of maternal health problems. Genomic studies based on the products of conception reported decreasing rates of chromosome abnormalities as the order of miscarriage increased, with a significant turning point after four or five miscarriages, suggesting the cause of miscarriage more likely to be non-chromosomal in higher order miscarriages. Endometrial transcriptomics aim to describe the full range of RNA transcripts that are produced at the level of the endometrium with an aim to develop a new test of endometrial receptivity.

Study design, size, duration: This was a multicentre cohort study performed in the Tommy's National Centre for Miscarriage Research in Birmingham, Saint Mary's Hospital in Manchester and Royal Devon & Exeter Hospital, United Kingdom. The study was conducted between December 2017 and December 2019. It included 24 women diagnosed with unexplained recurrent miscarriage based on strict inclusion criteria to rule out known causes and risk factors for miscarriage, while increasing the risk of an unidentified endometrial receptivity problem.

Participants/materials, setting, methods: Endometrial biopsies were obtained during implantation window from 18-35 years old women, not pregnant and regularly menstruating, diagnosed with unexplained recurrent miscarriage by undertaking standard investigations according to the ESHRE guidelines. They were excluded for miscarriage risk factors such as smoking, obesity or hyperprolactinemia. The RNA transcripts abundances were quantified using Kallisto. R packages tximport and DESeq2 were used to summarize count estimates at the gene level and to analyse the differential gene expression.

Main results and the role of chance: When compared to controls (two or three miscarriages), women who suffered four or more miscarriages had 19 differently expressed genes after adjustment for multiple comparisons. They were related to biological processes such as immunity (HLA-DMA, CCR8, ALOX5), energy production (ATP12A), hormone secretion (CGA), adhesion (CHAD, ADGRF2, AQP5, TBCD, CTNND1, NKD2) and cell proliferation (NCCRP1).

Important differences in the transcriptomic profiles were identified when women who suffered a subsequent miscarriage were compared to women who had a live birth following the endometrial biopsy. The number of significantly differently expressed genes was 421. Their gene ontology mapped to processes relevant to embryo implantation and early stages of pregnancy such as biosynthetic process (129 genes), signal transduction (124 genes), response to stress (113 genes), immune system process (84 genes), cell differentiation (75 genes), catabolic process (67 genes), cell death (66 genes), cell proliferation (59 genes), homeostatic process (41 genes), cytoskeleton organization (40 genes), cell adhesion (38 genes) or reproduction (26 genes).

Limitations, reasons for caution: This was a first discovery study to evaluate endometrial receptivity using transcriptomics in a relatively small selected population of women who suffered unexplained recurrent miscarriage. The findings reported here have not been validated in an independent sample set yet.

Wider implications of the findings: Abnormal transcriptomic profiles may explain variations in endometrial receptivity and build up on the evidence to support non-chromosomal causes for higher order miscarriages. Validation of the biological changes identified prior to a subsequent miscarriage or live birth may aid in developing a prediction test for use in clinical practice.

Trial registration number: NCT03442335

O-203 Systematic review and meta-analysis of prevalence of microbiota in ART cycles and recurrent pregnancy loss

S. Robati[1], E. Chronopoulou[1], E. Theodorou[1], P. Serhal[2], W. Saab[2], V. Seshadri[2]

[1]Institute for Women's Health- University College London, Faculty of Population Health Sciences, L0ndon, United Kingdom ;
[2]The Centre for Reproductive & Genetic Health CRGH, Population Science and Women's Health, London, United Kingdom

Study question: Does microbiota influence miscarriage rates in ART cycles and contribute to recurrent miscarriage?

Summary answer: This meta-analysis has demonstrated the importance of screening for microbiota, including Bacterial Vaginosis (BV) and Chlamydia Trachomatis (CT).

What is known already: Approximately 15% of pregnancies end up in miscarriage, contributing to one of the most common adverse pregnancy outcomes. Most causes remain unknown, although a complex interplay of different factors are thought to be involved and the presence of infection plays a pivotal role. Microbiota affects all facets of reproduction including pregnancy loss; however, few studies have been conducted to quantify the prevalence of each microbiome following ART (assisted reproductive technology) and its role with recurrent miscarriage.

Study design, size, duration: Systematic review and meta-analysis of published controlled studies. Searches were conducted from January 1999 to June 2019 on MEDLINE and EMBASE using the following search terms: miscarriage OR recurrent miscarriage OR microbiome (bacterial vaginosis (BV), chlamydia, herpes simplex virus (HSV), human papillomavirus (HPV), cytomegalovirus (CMV) and toxoplasma or toxoplasmosis) AND IVF. Studies were limited to those published in English.

Participants/materials, setting, methods: A total of 225 full-text articles were assessed for eligibility from 310 records identified through database searching. 30 studies were included in the quantitative synthesis (meta-analysis). References were based on title and abstract and assessed utilising the Newcastle–Ottowa Quality Assessment Scales.

Main results and the role of chance: For patients undergoing IVF treatment, a significant association was observed with early spontaneous miscarriage for Bacterial Vaginosis (BV) (RR 1.56, 95% CI 1.14–2.21), which supports existing literature. Chlamydia Trachomatis (CT) had two studies which limited clinical significance and Herpes Simplex Virus (HSV) did not show any statistical significance for miscarriage following IVF (RR 1.28, 95% CI 0.85-1.92). There were no studies for the other microbiota. There was no significant relationship between microbiota infection and recurrent miscarriage; however, meta-analysis was carried out for the association between CT and Cytomegalovirus (CMV) with recurrent miscarriage (OR 1.30, 95% CI 0.61-2.78 and OR 2.58, 95% CI 0.84-7.90 respectfully). There were insufficient studies for the remaining microbiota to perform a meta-analysis.

Limitations, reasons for caution: There is a paucity of data for specific micriobiota. Some sample sizes were too small to find any significant association with miscarriage and further study is necessary.

Wider implications of the findings: This study has shown the importance of screening before ART treatment and for women with recurrent miscarriages. There may be a role for specific commensals including Lactobacillus that may improve the intrauterine environment to aid with implantation. Being the first meta-analysis within this field is valuable for patient counselling.

Trial registration number: not applicable

O-204 The metabolomic profile of endometrial receptivity in recurrent miscarriage

L. Craciunas[1], J. Chu[1], O. Pickering[1], L. Mohiyiddeen[2], W. Dunn[3], A. Coomarasamy[1]

[1]University of Birmingham, Tommy's National Centre for Miscarriage Research, Birmingham, United Kingdom ;
[2]Central Manchester University Hospitals, Saint Mary's Hospital, Manchester, United Kingdom ;
[3]University of Birmingham, School of Biosciences, Birmingham, United Kingdom

Study question: What is the metabolomic profile of the endometrium in women who suffered unexplained recurrent miscarriage and can it predict the fate of the subsequent pregnancy?

Summary answer: Endometrium biopsied from women who suffered high order recurrent miscarriage has a distinct metabolomic profile and the differences may predict the fate of subsequent pregnancies.

What is known already: Embryo chromosomal abnormalities represent the most common cause of first trimester miscarriage in addition to a broad range of maternal health problems. Genomic studies based on the products of conception reported decreasing rates of chromosome abnormalities as the order of miscarriage increased, with a significant turning point after four or five miscarriages, suggesting the cause of miscarriage more likely to be non-chromosomal in higher order miscarriages. Endometrial metabolomics aim to describe

the full range of metabolites identified in a tissue sample obtained from the endometrium with an aim to develop a new test of endometrial receptivity.
Study design, size, duration: This was a multicentre cohort study performed in the Tommy's National Centre for Miscarriage Research in Birmingham, Saint Mary's Hospital in Manchester and Royal Devon & Exeter Hospital, United Kingdom. The study was conducted between December 2017 and December 2019. It included 24 women diagnosed with unexplained recurrent miscarriage based on strict inclusion criteria to rule out known causes and risk factors for miscarriage increasing the risk of an unidentified endometrial receptivity problem.
Participants/materials, setting, methods: Endometrial biopsies were obtained during implantation window from 18-35 years old women, not pregnant and regularly menstruating, diagnosed with unexplained recurrent miscarriage by undertaking standard investigations according to the ESHRE guidelines. They were excluded for miscarriage risk factors such as smoking, obesity or hyperprolactinemia. The metabolite composition and relative concentrations of samples were analysed applying ultra-high performance liquid chromatography-mass spectrometry. Raw data were processed applying XCMS and statistical analysis was applied using the software MetaboAnalyst.
Main results and the role of chance: There were distinct metabolomic profiles between the endometrial samples obtained from women with higher order miscarriage defined as more than four recurrent miscarriages and more than five recurrent miscarriages, respectively. More biological differences were identified when the cut-off for the extreme group was set at five miscarriages and the analysis showed groups of metabolites from the same metabolite class, supporting the class-specific changes with more confidence. These groups of metabolites related to cardiolipins, ceramides and glycerophospholipids. Cardiolipins are mitochondrial cell membrane lipids and indicate mitochondrial stress and morphological changes. Ceramides are generally believed to be lipotoxic, while glycerophosphoinositols are considered to be signalling molecules.

Important biological changes were identified in the metabolomic profiles of women who suffered a subsequent miscarriage compared to those who had a live birth following the endometrial biopsy. The most relevant metabolite classes were triacylglycerides (fatty acid storage molecules), purine and pyrimidine metabolism and ether glycerophospholipids.
Limitations, reasons for caution: This was a first discovery study to evaluate endometrial receptivity using metabolomics in a relatively small selected population of women who suffered recurrent miscarriage. The findings reported here have not been validated in an independent sample set yet.
Wider implications of the findings: Abnormal metabolomic profiles may explain variations in endometrial receptivity and build up on the evidence to support non-chromosomal causes for higher order miscarriages. Validation of the biological changes identified prior to a subsequent miscarriage or live birth may aid in developing a prediction test for use in clinical practice.

O-205 The precise identification of the window of implantation using the molecular tool ER Map® in ART cycles significantly improves clinical outcomes

M. Enciso[1], J. Aizpurua[2], B. Rodriguez-Estrada[1], I. Jurado[1], M. Ferrandez-Rives[1], E. Rodriguez[3], E. Pérez-Larrea[3], A.B. Climent[4], K. Marron[5], J. Kennedy[5], J. Sarasa[1]

[1]iGLS, Research and Development, Alicante, Spain ;
[2]IVF-Spain, Gynaecology, Alicante, Spain ;
[3]IVF Donostia, Gynaecology, San Sebastian, Spain ;
[4]IVF-Spain, Statistics, Alicante, Spain ;
[5]Sims IVF Clinic, IVF Unit, Dublin, Ireland

Study question: Does the identification of the window of implantation using the endometrial receptivity test ER Map® improve ART outcomes?
Summary answer: The use of ER Map® test for endometrial receptivity evaluation and personalised scheduling of embryo transfer significantly improves pregnancy rates.
What is known already: The endometrium reaches a receptive status for embryonic implantation around days 19-21 of the menstrual cycle. During this period, known as the window of implantation (WOI), the endometrium shows a specific gene expression profile suitable for endometrial function evaluation. ER Map® is a molecular diagnostic tool able to accurately predict endometrial receptivity status by analysing the gene expression profile of an endometrial biopsy by high-throughput RT-qPCR. In this study, the experience of the clinical application of ER Map® for WOI identification and personalised scheduling of embryo transfer in subfertile couples is presented in detail.
Study design, size, duration: This is a retrospective study analysing endometrial function and ART outcomes of 2256 patients undergoing endometrial receptivity assessment by ER Map® between March 2016 and September 2019. Results obtained when single embryo transfers were scheduled either on the moment of endometrial receptivity (WOI timeframe) as recommended by ER Map®, or deviating from this recommendation are analysed and compared.
Participants/materials, setting, methods: Patients referred for ER Map® analysis were included in the study. Endometrial biopsy samples obtained in a HRT cycle at P_4+5.5 were ER Map® tested and classified into 'Receptive", 'Pre-receptive" or 'Post-receptive". Based on ER Map® results, a recommendation for embryo transfer was performed. Single blastocyst transfers (sET) were performed in all cases. Clinical outcome measures were: positive β-HCG rate [βR], clinical pregnancy rate [CPR] and pregnancy loss rate [PLR].
Main results and the role of chance: ER Map® analysis of endometrial receptivity status showed that 771 out of 2256 patients (34.2%) studied had a displaced WOI.

Analysis of ART outcomes showed a significantly higher clinical pregnancy rate in sETs scheduled within the WOI predicted by ER Map® compared to transfers that deviated more than 12h from ER Map® recommendation (βR 56.09% vs 41.54%, X^2 test p=0.02; CPR 44.35% vs 23.08%, X^2 Test p <0.001). Pregnancy rates were even lower when the deviation from the WOI identified by ER Map® exceeded 24h (βR 56.09% vs 26.92%, X^2 test p=0.012; CPR 44.35% vs 19.23%; X^2 test p=0.004). The deviation of embryo transfers from the WOI predicted by ER Map® had also an impact on the progression of pregnancy. A significant increase in pregnancy loss (~2-fold) was detected in the group of transfers that deviated from ER Map® recommendation compared to transfers performed within the ER Map® WOI (PLR 41.4% vs 21.05%, X^2 Test p <0.022).

This study provides strong evidence that ER Map® endometrial receptivity evaluation can reliably identify the WOI and improve clinical outcomes. Personalisation of progesterone duration pre-treatment before transfer renders significantly improved ART results, increasing the likelihood of pregnancy and reducing the risk of miscarriage.
Limitations, reasons for caution: ER Map® test can serve as a valuable tool to improve ART results, however, to determine the true extent of any clinical benefits, other types of investigations, such as non-selection studies and randomized controlled trials, will also be necessary.
Wider implications of the findings: The application of ER Map® for the identification of cases of WOI displacement and personalised embryo transfer scheduling is an effective strategy for improving ART outcomes. Not only patients suffering from implantation failure but also couples experiencing recurrent miscarriage can benefit from the accurate identification of the WOI.
Trial registration number: Not applicable

O-206 Recurrent pregnancy loss: diagnostic workup after two or three pregnancy losses? A systematic review of the literature and meta-analysis.

M. Van Dijk[1], A. Kolte[2], J. Limpens[3], E. Kirk[4], S. Quenby[5], M. Van Wely[1], M. Goddijn[1]

[5]University Hospital Coventry- Warwick Medical School., Division of Reproductive Health, Warwick, United Kingdom

Study question: Do abnormal test results for definite or probable risk factors for RPL occur with equal frequency in women with two versus women with three or more pregnancy losses?

Summary answer: No difference in prevalence in uterine abnormalities and APS was found, a difference in prevalence of chromosomal abnormalities, thrombophilia and thyroid disorders cannot be excluded.

What is known already: Recurrent pregnancy loss (RPL) occurs in 1 – 3% of all couples trying to conceive. No consensus exists when to perform testing for risk factors in couples with RPL. Some guidelines recommend testing if a patient has had two pregnancy losses whereas others advise to test after three losses. Before trying to conceive, couples and clinicians attempt to find an explanation for their pregnancy losses and a treatment that will prevent a recurrence, especially in cases with modifiable risk factors, such as thyroid disorders and APS. Is it necessary to wait before the next pregnancy loss will occur?

Study design, size, duration: A systematic review of literature and meta-analysis was performed.

Participants/materials, setting, methods: Relevant studies were identified by a systematic search in OVID Medline and EMBASE from inception. A search for recurrent pregnancy loss was combined with a broad search for terms indicative of number of pregnancy losses, screening/testing for pregnancy loss or the prevalence of known risk factors. Meta-analyses were performed in case of adequate clinical and statistical homogeneity. The quality of the studies was assessed using the Newcastle-Ottawa scale.

Main results and the role of chance: From a total of 1985 identified publications, 21 were included in this systematic review and 19 were suitable for meta-analyses. For uterine abnormalities (7 studies, OR 1.00, 95%CI 0.79 – 1.27, I^2=0%) and for antiphospholipid syndrome (3 studies, OR 1.04, 95%CI 0.86 – 1.15, I^2=0%) we found low quality evidence for a lack of a difference in prevalence of abnormal test results between couples with two versus three or more pregnancy losses. We found insufficient evidence of a difference in prevalence of abnormal test results between couples with two versus three or more pregnancy losses for chromosomal abnormalities (10 studies, OR 0.78, 95%CI 0.55 – 1.10), inherited thrombophilia (5 studies) and thyroid disorders (2 studies, OR 0.52, 95%CI: 0.06 – 4.56).

Limitations, reasons for caution: A methodological limitation of this study is the definition of the study groups. On average, 15-20% of women with two losses will experience a loss in the next pregnancy some of the women, some will be in the other group if evaluated at a different time point.

Wider implications of the findings: The results of this study may support investigations after two pregnancy losses in couples with RPL, it should be stressed that additional studies of the prognostic value of investigations used in RPL are urgently needed. An evidenced-based treatment is currently not available in the majority of cases.

Trial registration number: Not applicable

SESSION 52: AI. A NEW TOOL TO ASSESS ART OUTCOMES AND HELP PATIENTS?

07 July 2020 Parallel 4 17:00 - 18:00

O-207 Patient-oriented counselling: predicting live birth probability (LBP) at each step of the In Vitro Fertilization (IVF) process via machine learning.

V. Grzegorczyk Martin[1], T. Fréour[2], C. Avril[1], A. De Bantel - Finet[1], P. Barrière[2], J.L. Pouly[3], M. Grynberg[4], I. Parneix[5], J. Roset[1], T. Grzegorczyk[6]

[1]Clinique Mathilde, Centre d'Assistance Médicale à la Procréation, rouen, France ; [2]CHU de Nantes, Service de Biologie et Médecine de la Reproduction, Nantes, France ; [3]CHU Clermont Ferrand, Unité de Fécondation In Vitro Département de Gynécologie Obstétrique et Reproduction Humaine Polyclinique de l' Hotel-Dieu, Clermont Ferrand, France ; [4]Hôpital Antoine-Béclère, Médecine de la reproduction et préservation de la fertilité, Clamart, France ; [5]Polyclinique Jean Villar, Centre d'AMP - IFREARES Bordeaux, Bruges, France ; [6]Teranalytics, Data management, Boston, U.S.A.

Study question: How does a machine learning tool for live birth prediction accuracy evolve to counsel couples as demographic, ovarian stimulation, laboratory and transfer data become available?

Summary answer: The weight of individual parameters is not static but evolves at each step of IVF process, contributing to higher accuracies in live birth prediction (C-index).

What is known already: Several predictive models have been developed to help ART clinicians in counselling patients and improve decision-making process. The first validated models, proposed by Templeton et al. in 1996, then improved by Nelson et al. in 2011, integrated demographic and clinical parameters before starting IVF. In 2016, Mc Lernon et al. proposed a new predictive tool based on additional information collected during the first IVF attempt providing an individualized estimate of a couple's cumulative chances of live birth.

To our knowledge, no predictive model exists that dynamically adjusts the LBP throughout the IVF process, as new data become available.

Study design, size, duration: We designed our study on retrospective data of 9587 IVF cycles between 2016-2017 from four IVF centers. Only cycles with verified, consistent and complete data up to final outcome were included.

Parameters were split into four categories following the IVF process: (1) demographic (patient baseline characteristics), (2) ovarian, (3) laboratory and (4) transfer data.

Participants/materials, setting, methods: We implemented a univariate and multivariate evolutive logistic regression, validated with Random Forest, with iterative parameter selection based on 5% significance level. No parameters were included or excluded by default. Validation was internally based on a 70%-30% split. Results are reported as odd ratios and C-index.

LBP were re-calculated by fitting a new model at the addition of each of the four categories, finally yielding probabilities for each fresh or frozen embryo transfer.

Main results and the role of chance: Accuracy of the model in predicting live birth progressively increased from 0.64 to 0.72 as ovarian stimulation, laboratory and embryo transfer parameters were respectively added.

Female age remains strongly predictive of LBP at all steps. After fresh embryo transfers, LBP decreases linearly with increasing female age, whereas its impact becomes significant beyond 37 years for frozen transfers (OR=0.59; 95%CI=0.4-0.85).

Female BMI influence is constant throughout all steps (OR=0.98; 95%CI=0.97-0.99).

Among infertility causes, endometriosis showed the worst impact on LBP.

AFC and AMH are significant predictors when only baseline characteristics are included in the model, but their impact is not statistically significant anymore when the number of retrieved oocytes becomes available.

High gonadotrophin dose negatively impacts LBP in fresh embryo transfers (OR=0.52; CI=0.42-0.64).

Endometrial thickness >7mm positively impacts LBP at the transfer step (OR=1.07; CI=1.04-1.10).

As an example, a 38 year-old woman whose baseline characteristics give her 22% LBP for her first fresh transfer if AMH is 2.5ng/mL, has 22% recalculated chances if 3 oocytes are retrieved and 28% if 8 are collected. If that same woman has an AMH of 1.5ng/ml, her LBP drops to 17%, but increases to 21% and 27% if 3 and 8 oocytes are retrieved, respectively.

Limitations, reasons for caution: Our models need to be further evaluated by performing an external validation: infertile population in France might be slightly different than in other countries (ie: BMI, ethnicity, etc). The limited number of cycles results from deliberate stringent quality control process, whereby only verified, consistent, and complete cycle data were kept.

Wider implications of the findings: The prospect of this work is to develop a practical and evolutive tool to help clinicians accompany their patients by always providing the latest personalized estimates of LBP, before and throughout the IVF intervention, at each fresh and/or frozen embryo transfer.

Trial registration number: not-applicable

O-208 Is IVF making more male embryos and does maternal AMH play a role in this?

K. Hammer[1], C. Cherston[1], S. Vagios[1], C. Sacha[1], D. Pepin[2], C. Bormann[1], M. Kumar Kanakasabapathy[3], P. Thirumalaraju[4], H. Shafiee[5], M. Morris-Sabatini[1]

[1]Massachusetts General Hospital, OBGYN-Reproductive Endocrinology & Infertility, Boston, U.S.A. ; [2]Massachusetts General Hospital, Pediatric Surgical Research Laboratories-Department of Surgery, Boston, U.S.A. ; [3]Harvard Medical School- Brigham and Women's Hospital, Department of Medicine, Boston, U.S.A. ;

[4]Harvard Medical School, Harvard-MIT Division of Health Sciences and Technology, Boston, U.S.A. ;
[5]Harvard Medical School, Department of Medicine, Boston, U.S.A.

Study question: Does anti-mullerian hormone (AMH) predict neonatal sex if undergoing in vitro fertilization?
Summary answer: Increasing AMH levels correlate with an increased trend for male births, likely related to rate of developmental progression of male embryos by day 5.
What is known already: A sex skew toward male neonates after IVF has been described, but it is unclear why this skew exists. This phenomenon may be related to speed at which a male embryo develops to the blastocyst stage leading to an increase in their selection for transfer. We propose that maternal AMH also plays a role in early embryonic development. AMH is known for its role in sexual differentiation and as a marker for ovarian reserve. AMH receptor has been heavily identified in male placentae and fetal membranes and likely impacts early embryonic development.
Study design, size, duration: Retrospective data analysis of 658 IVF cycles from January 2015 to December 2019 at an academic institution in the United States. Data include SART primary outcomes, PGT outcomes, artificial intelligence (AI) data on embryo selection and sex by either PGT or neonatal outcome. We hypothesize that a higher AMH level will lead to more male high-quality embryos on day 5 of embryo culture.
Participants/materials, setting, methods: SART data included women ages 27-44 with AMH levels drawn within 1 year of IVF. PGT cycles additionally included EmbryoScope data using an AI algorithm trained to select the highest quality embryo by morphology for transfer on day 3 and day 5 of development. Results were analyzed by AMH level within quartiles for the following endpoints: ratio male:female neonate sex, ratio male:female PGT result, sex of day 3 and day 5 embryo selected using AI.
Main results and the role of chance: SART contained 658 singleton newborns, 53.8% (n=354) were male and 46.2% (n=304) female. AMH correlated with male neonate; for every 1ng/mL increase in AMH the odds for a male neonate increased 5.4%, p=0.017. Quartile analysis demonstrated that at or above the seventy-fifth percentile, AMH=5.11ng/mL, was associated with male sex; male to female 60.7% (n=99) vs 39.3% (n=64). AMH less than the seventy-fifth percentile had a male to female ratio 51.5% (n=255) vs 48.5% (n=240), p=0.04.

PGT-A cycles, n=209, had more female than male embryos, 52,1% (368/706 embryos) female vs 47.9% (368/706 embryos) male. AI analysis of the highest quality embryo demonstrated a difference in sex ratio between day 3 and day 5. Day 3 cohort favored female embryos at higher AMH levels than male embryos, female (median 2.3, IQR 1.4-3.8) vs male (median 1.3-3.0), p=0.042. Day 3 embryos and AMH above the seventy-fifth percentile demonstrated a trend towards female sex, male 35.7% (n=10) vs female 64.3% (n=18), p=0.136. Day 5 embryos had comparable AMH values for both sexes, male median 2.1 (IQR 1.4-3.7) and female median 2.1 (IQR 1.3-2.9), p=0.45. AMH above the seventy-fifth percentile had an increased trend toward male embryo selection 67.9% (n=19) male vs 32.1%(n=9) female, p=0.23.
Limitations, reasons for caution: This is a retrospective review of SART data combined with data from a verified artificial intelligence algorithm to identify the highest quality embryos during development. More work is needed to elucidate how AMH exposure of the oocyte may differently impact the development of male vs female embryos.
Wider implications of the findings: AMH levels in the follicle may have implications for early embryo development kinetics. Providers must account for sex differences in embryo development so as not to artificially skew the sex ratio when selecting embryos for transfer.
Trial registration number: not applicable

O-209 Time to pregnancy for women using a fertility awareness based mobile application to plan a pregnancy

J. Pearson[1], S. Rowland[1], C. Favaro[1], E. Berglund-Scherwitzl[1], R. Scherwitzl[1], K. Gemzell-Danielsson[2], J. Harper[3]

[1]Natural Cycles Nordic AB, Luntmakagatan 26, Stockholm, Sweden ;
[2]Karolinska Institute, Head Department of Women´s and Children´s Health, Stockholm, Sweden ;
[3]UCL Institute for Women's Health, Department of Reproductive Health, London, United Kingdom

Study question: What is the time to pregnancy for users of the Natural Cycles fertility awareness based mobile application to identify the fertile window?
Summary answer: Women <35 years, with no anovulation, regular cycles and who regularly logged sex (52% of cohort) had a 12-month pregnancy probability of 96%.
What is known already: Women trying to get pregnant are encouraged to identify their fertile window using methods such as their menstrual cycle dates, basal body temperature, changes in cervical mucus and lutenising hormone surge identification. But these methods can become time consuming and stressful. Using an app which can calculate the fertile window using an algorithm may be easier and more accurate. This is one of the first studies to examine the time to pregnancy for women using an app that identifies the fertile window.
Study design, size, duration: This observational study included 5376 women with an age range of 18 to 45 years. They used the app in Plan pregnancy mode between September 31st 2017 and August 31st 2018 to allow at least 12 months of potential usage up to the cutoff date of September 1st 2019.
Participants/materials, setting, methods: The time to pregnancy was analysed related to age, gravidity, BMI, cycle length variation, average cycle length, and behavioural characteristics such as frequency of sexual intercourse via hazard ratios (HRs) using Cox regression adjusted for fixed covariates.
Main results and the role of chance: 3166 women achieved pregnancy within 13 cycles, while 570 women were still trying to get pregnant at the end of the observation period. Overall the one-year pregnancy probability was 83% (95% CI: 82%-84%). The mean time to pregnancy for the whole cohort was 3.3 cycles (95% CI: 3.2-3.4). Women <35 years, with no anovulation, regular cycles and regularly log sex (52% of cohort) had a 12 month pregnancy probability of 96% and a mean time to pregnancy of 2.4 cycles (95% CI: 2.2-2.6). Lower pregnancy probability was associated with the following exposures: ages 35 to 45 (HR 0.69, 95% CI: 0.61-0.78), high cycle length variation (HR 0.89, 95% CI: 0.77-1.01) and sexual intercourse logged on less than 10% of days (HR 0.84, 95% CI: 0.71-1.01). Anovulatory cycles were also associated with a worse outcome with a one-year pregnancy probability of 72%.
Limitations, reasons for caution: Users had higher educational level and lower BMI than would be expected in the general population. Close to 50% had characteristics associated with sub-fertility such as age > 35 years, highly variable cycle length or anovulatory cycles. Sex logging data was incomplete which limited the conclusions that could be made.
Wider implications of the findings: Fertility awareness apps have an important role in educating women and their partners about fertility and facilitating discussions around the topic. In the future smart algorithms may facilitate early identification of couples who may benefit from infertility assessment.
Trial registration number: 2016/2037-31

O-210 Interactive information provision during IVF/ICSI treatment by using an app: A randomized controlled trial

M. Keijsers[1], T. Timmers[2], I. Van Rooij[1], J.M.J. Smeenk[1]

[1]Elisabeth Twee Steden Hospital, Obstetrics & Gynecology, Tilburg, The Netherlands ;
[2]Interactive Studios, software development, Rosmalen, The Netherlands

Study question: An application (app) has been developed providing patients with information in an interactive way; will the use of this tool result in a change of knowledge, self-reliance and care consumption?
Summary answer: Patients in the app group achieved a higher level of knowledge and were more satisfied with treatment compared to the control group.
What is known already: Patients undergoing an ivf/icsi treatment experience a lack of knowledge, which causes (unnecessary) stress during their treatment. Furthermore, they receive a lot of information in a limited timeframe in the clinic often resulting in an insufficient uptake of relevant details. Patients would like to see an improvement in providing information. Routinely providing comprehensible and structured information, in particular about the practical aspect of the treatment, in a patient controlled way could be a solution.
Study design, size, duration: A single center randomized controlled trial was conducted. The app group had access to the informative and personal app,

including informative videos and quiz questions.The control group received the current/normal form of information provision. Each patient received four questionnaires at fixed timepoints prior to, during and after treatment. The questonnaires focussed respectively on information provision, self-reliance, care consumption, level of knowledge and finally the satisfaction of care during treatment was evaluated.

Participants/materials, setting, methods: In the period from April 2018 to September 2019, 51 patients were included into the study. Native patients, so without any experience with the use of gonadotrophins and with a medical indication for IVF/ICSI treatment were invited to participate in a randomized controlled trial prior to their intake regarding the IVF/ICSI treatment. Twenty-two patients were included in the control group and twenty-nine patients in the app group.

Main results and the role of chance: The groups were found not to differ significantly on baseline characteristics and outcome parameters. The patients in the app group scored higher on the QPP-IVF questionnaire (indicating satisfaction) than the patients in the control group, although this did not reach significancy (52,89 versus 47,92, p=0,13). Two days after the ivf intake in the clinic both the control group (from 17,33 to 23,25, p=0,22) and the app group (from 20,74 to 26,58, p=0,02) scored higher in the relative level of knowledge compared to baseline findings. Only the increase in the app group was found to be significant. Five days after the ovum pick up, a significant increase in the level of perceived knowledge is also observed in the app group (from 20,74 to 26,89, p=0,05), but not in the control group (from 17,33 to 26,00, p=0,48). No significant differences were found on self-reliance and care consumption (p>0.05).

Limitations, reasons for caution: The limited sample size of the pilot study is a reason for caution. The observed differences need to be replicated in a larger study and in a multicentred design.

Wider implications of the findings: Knowledge on the use of a patient journey app is limited within IVF/ICSI. The preliminary results indicate that the app could help patients in the uptake of information at their own pace, resulting in more knowledge and satisfaction. This could also have a beneficial effect on care consumption and costs.

Trial registration number: NA

SELECTED ORAL COMMUNICATIONS
SESSION 53: CONTROVERSIES IN ART
07 July 2020 Parallel 5 17:00 - 18:00

O-211 Commercial influences on assisted reproductive technology: a scoping review

W. Lipworth[1], M. Wiersma[1], N. Ghinea[1], A. Newson[1], I. Kerridge[1], C. Waldby[2], W. Ledger[3], R. Norman[4]

[1]University of Sydney, Sydney Health Ethics, University of Sydney, Australia ; [2]Australian National University, Research School of Social Sciences, Canberra, Australia ; [3]University of New South Wales, Obstetrics & Gynaecology, Sydney, Australia ; [4]University of Adelaide, Robinson Research Institute, Adelaide, Australia

Study question: How are commercial influences on assisted reproductive technology (ART) understood, debated and studied in the academic literature?

Summary answer: Commercial influences raise a numerous ethical, organisational, economic and clinical issues. These are discussed in diverse contexts, not limited to direct discussions of commercialisation

What is known already: While advances in technologies have increased the range of ART options available to patients, concerns exist about the steps taken by ART providers to ensure that their businesses are successful, profitable and sustainable (henceforth "commercial influences" on ART). Distinguishing the key issues associated with these commercial influences is complicated by the diversity of ways and contexts in which they are discussed, and there have been no systematic attempts to draw these together.

Study design, size, duration: This scoping review used the methodological framework first proposed by Arksey and O'Malley, and later refined by Levac and Peters. It involved five key stages: 1) identifying the research question; 2) identifying relevant studies; 3) study selection; 4) charting the data; and 5) collating, summarising and reporting results.

Participants/materials, setting, methods: Articles were included if they addressed one or more of the following topics: 1. What are the factors that shape the commercial organisation of ART? 2. How are commercial influences currently identified, appraised, regulated and managed? 3. How should commercial influences be addressed, by whom, and with what guidance? The search strategy was developed based on keywords and index terms related to commercialisation of ART in PubMed based on Medical Subject Headings (MeSH) terms.

Main results and the role of chance: Commercial influences on ART are a frequent topic of discussion and critique in the academic literature, however these discussions are widely dispersed and often implicit in discussions of 1. The pricing of ART services, and variability in these costs 2. The number and timing of interventions, particularly when it comes to the use of more invasive (and expensive) interventions in patients who might benefit from less invasive treatments and patients in whom success is unlikely 3. The expansion into non evidence-based interventions 4. The ways in which interventions are marketed and justified to patients 5. The workings of international markets and 6. Other commercial interests, such as joint ownership of diagnostic, counselling and hospital services and relationships with other health-related industries.

Limitations, reasons for caution: A scoping review is a semi-systematic literature review that aims for thematic saturation rather than aiming to collect the full range of articles on a topic. In cannot, therefore, draw quantitative conclusions about the literature. Our search was also limited to articles published in English.

Wider implications of the findings: The implications of the commercialisation of ART cannot be understood without systematically considering a wide range of ethical, organisational, political, economic, scientific and clinical issues, across a diverse range of literatures. We provide a novel "map" of these issues that can help to guide debate on this highly contentious topic.

Trial registration number: Not applicable

O-212 Expanded carrier screening in medically assisted reproduction: An ethical exploration of a new screening option in the light of professional and parental responsibilities

S. Van der Hout[1], W. Dondorp[1], G. De Wert[1]

[1]Maastricht University, Health- Ethics & Society, Maastricht, The Netherlands

Study question: May professionals recommend that applicants of assisted reproduction undergo expanded carrier screening, and that identified carrier couples apply for pre-implantation genetic testing to avoid the birth of an affected child?

Summary answer: While an offer of ECS should be non-directive, carrier couples of very serious disorders should have access to MAR only if they apply for PGT.

What is known already: Expanded carrier screening (ECS) entails a screening offer for multiple recessive disorders simultaneously, and allows testing of couples regardless of ancestry. A growing number of European fertility clinics offer ECS on a routine basis. However, little attention has been given to the ethics of ECS in the context of medically assisted reproduction (MAR). MAR-professionals have indicated a need for ethical guidance, as an offer of ECS addressing MAR-patients raises ethical questions that do not arise in other carrier screening contexts: the involvement of MAR-professionals in creating the child implies that both professional and parental responsibilities should be taken into account.

Study design, size, duration: In this ethics study we explore the morally relevant aspects of the scenario of offering ECS to MAR-patients, focusing on possible tensions between considerations of reproductive autonomy and parental/professional responsibility. This study is part of a larger project in which we will use the findings to conduct an exploration of relevant stakeholder views. The overall aim is to contribute to a robust normative framework that can guide the practice of ECS in MAR.

Participants/materials, setting, methods: This is a desk research study bringing together the scientific literature relevant to the possible (wider) introduction of ECS in MAR and debates conducted in philosophical and applied ethics literature on the nature and scope of relevant principles including

'reproductive autonomy', 'professional responsibility' and 'responsible parenthood'. We use the method of 'wide reflective equilibrium' as a framework for our analysis. This method has a proven value for the normative analysis of bioethical problems.

Main results and the role of chance: MAR-professionals have a responsibility to take account of the welfare of the child that they are causally and intentionally involved in creating. ESHRE has recommended that they should refrain from providing assistance when there is a high risk that the child will have a seriously diminished quality of life. What follows from this norm with regard to offering ECS to MAR-patients? May (or should) professionals recommend, or even insist, that patients have ECS, and make use of pre-implantation genetic testing (PGT) or other preventive options when both partners are identified as carriers? We recommend that this depends on a) the level of genetic risk; and b) the severity of the disease under consideration. If MAR-patients have an a priori low carrier risk, ECS should be offered in a non-directive way and facilitate autonomous reproductive decision-making. However, if both partners are identified as carriers of a serious genetic disorder, professionals may well be justified in urging them to actively consider PGT, or even make access to MAR conditional on the patients' use of preventive options. We conclude that the preventive options created by new genomic testing possibilities are not morally indifferent, but may bring along new professional and parental responsibilities.

Limitations, reasons for caution: This is an ethical exploration aimed at contributing to further debate about the responsible introduction of ECS in MAR.

Wider implications of the findings: Our exploration of the relationship between respect for autonomy and acknowledging professional and parental responsibilities for the welfare of the future child has a wider relevance for the ethics of (shared) decision-making in the highly dynamic field of MAR as a whole.

Trial registration number: Not applicable

O-213 Ethical justifications of Spanish Fertility Society to preserve anonymity of gamete donation

R. Nunez - Calonge[1], M. Muñoz[2], F. Abellan[3], I. Cuevas[4], L. Feito[5], A. De la Fuente[6], L. Martínez[7], D. Mataro[8], M. Roca[9]

[1]URA, Ethics and Reproduction, Madrid, Spain ;
[2]IVIRMA, Medical Director, Alicante, Spain ;
[3]Sociedad Española de Fertilidad, Legal, Madrid, Spain ;
[4]Hospital General, IVF Laboratory, Valencia, Spain ;
[5]Faculty of Medicine- Complutense University, Public Health & Maternal and Child Health, Madrid, Spain ;
[6]Instituto Europeo de Fertilidad, Medical Director, Madrid, Spain ;
[7]Hospital Virgen de las Nieves, Reproduction, Granada, Spain ;
[8]Eugin Clinic, Reproductive Endocrinology and Infertility, Barcelona, Spain ;
[9]Barcelona University, Psychology, Barcelona, Spain

Study question: What is the view of Spanish Society of Fertility (SEF) regarding ethical aspects of the removal of anonymity in gamete donation?

Summary answer: SEF recommends disclosure to the donor-conceived children their biological origin preserving the anonymity since there are no convincing ethical arguments for removal.

What is known already: Although most gamete donations in the world are made anonymously, a growing number of countries have questioned the morality of preserving anonymity, and laws are being enacted that allow children born by donation to identify donors.

The main criticisms of the anonymity of gamete donation focus on the primary interest of donor-conceived children, and more specifically on health and interest in forming their own identity. On the other hand, those who support anonymity argue that its practice respects the interests of the donor as well as the parents' wishes to determine the best interest of offspring.

Study design, size, duration: Reflecting concern about the anonymity of gamete donation, the Spanish Society of Fertility convened a focus group with key figures in ethics, law and reproductive medicine to identify scientific, psychological, legal and ethical arguments supporting the anonymous gamete donations. The project was set-up as a qualitative study to call in to question the justifications that are often thought to ground a right to know one's genetic origins and took place between May and October 2019.

Participants/materials, setting, methods: One of the objectives of the focus group was to deliberate about the ethical justifications that support the right to know the genetic origins, mainly based on the protection of health and the right to identity, but also taking into account other values that affect the different participants in the donation For this, we used the deliberative method to deal with conflicts, as it seeks to protect the values that may be at stake.

Main results and the role of chance: Spanish Society of Fertility has produced an Anonymity in Donations Framework Document, divided into five distinct parts: demographic, clinical, psychological, social, ethical and legal aspects. From an ethical perspective, the following arguments regarding gamete donation anonymity were suggested:

Health of children: Spanish policy, despite its requirement of anonymity, explicitly indicates that donor-conceived individuals should have access to non-identifiable information about the donor, including medical information, so, the anonymous donation is not incompatible with providing relevant medical information.

Sense of identity: there is no solid empirical evidence to show that children conceived by the donor in general suffer "genealogical confusion".

Other values examined were: autonomy of the parents and the right to privacy, genetic inheritance, donor confidentiality, justice, responsibility, quality and economic value.

Following the bioethical deliberation mentioned above, and after having examined the main values that become part of the two extreme courses (anonymity of the donation against its suppression), the best intermediate course would be the one that tried to safeguard the greater number of values involved, namely, donor-conceived individuals are morally entitled to access general (non-identifying) information about their origin.

Limitations, reasons for caution: Although there is no evidence of any conflict in Spain for the rule of anonymity, the opinion of the patients, donors and offspring, would be lacking.

Wider implications of the findings: Before introducing mandatory disclosure of the donor´s identity, the commitment should be to ensure that this change entails advantages for those involved, which have not been demonstrated so far. Strategies should be adopted to implement education programs that do not stigmatize the fact of being born through donor gametes.

Trial registration number: Not applicable

O-214 First sperm and egg bank in Latin America with open identity donors: a five-year study on patients' and donors' preferences between anonymous and open-identity donation.

P. Regalado[1], V. Rawe[1]

[1]REPROBANK, Research, Buenos Aires, Argentina

Study question: Would gamete donors and patients choose open-identity given the chance? Several countries worldwide have laws regulating anonymity in gamete donation, mostly European and North American with opposing standpoints between them.

Summary answer: Ours results show many patients demanding open identity and half of gamete donors willingly donating this way, concurring with international tendency to unveiling donor identity.

What is known already: In Latin America few countries have laws regulating Assisted Reproductive Techniques (ART) and anonymity donation is set by default. The lack of empirical data is alarming: having non-official statistics, national surveys or publications addressing open identity vs anonymous donation. A tendency toward unveiling donor identity to offspring is increasing in Europe and North America. However, in Latin America few countries have laws regulating ART and anonymity donation is set by default. Our study is rich and pioneer for Latin American, it shows our cultures demand to allow access to genetic origins by lifting anonymity and leave the choice to offspring.

Study design, size, duration: Report of 5 years of experience of the first open identity program (PIA) in Argentina, offering both anonymous and open identity donor sperm samples and later extended to eggs. We intended to discover donors' and patients' choice on open vs anonymous donation, reasons and motivations for choosing either. We gathered information from all donors and patients that participated or went through ART.

Participants/materials, setting, methods: The sample includes 192 donors (132 sperm and 60 egg), 2391 ART patients and over 150 parents of open identity donors´ offspring. Descriptive, correlational and inferential statistics were

applied with parametrical and non-parametrical analysis. Also, we surveyed the sample with two *ad hoc* questionnaires regarding reasons or setbacks for choosing open or anonymous donations, opinions on current legislation on the matter, future plans on identity revelation to offspring, among other queries.

Main results and the role of chance: Statistics show that open identity donation was chosen by 55% of egg donors, 48.5% of sperm donors and 29% of ART patients. Regarding donors, more egg than sperm donors chose open identity, however the difference was not statistically significant. Regarding patients, results showed statistically significant differences based on type of family structure: open identity donation is chosen in 1 out of 10 heterosexual couples, 3 out of 10 lesbian couples, and 4 out of 10 single women. More in depth results are discussed in relation to patients' and donors' general reasons, attitudes and motivations toward open identity and anonymity. Also, post-treatment parents with open identity offspring past choice satisfaction is addressed.

An international wide controversy has existed since sperm donation became a part of ART. Anonymity continues to depend on judicial regulations. Empirical research needs to guide laws based on ethical and social-need grounds. The past decade has shown an international tendency towards removing anonymity or allowing access to genetic origins. Anonymity in many countries continues to be defended while social movements and organizations of donor offspring continue to demand the human right to access genetic origins. Research on open identity vs. anonymity mostly reflects European and North American cultures.

Limitations, reasons for caution: Samples were gathered from a single gamete bank because it is the only one in the country offering an open identity program. Samples don't represent argentine ART patients. However, it does show a tendency in favor of what has been found in other countries.

Wider implications of the findings: Our findings are rich and pioneer for Latin American, evidencing a cultural demand to address anonymity. Few countries in Latin America have ART laws. Research is fundamental for future legislations.

Trial registration number: not applicable

SESSION 54: MODERN TECHNIQUES PROMOTE VARIETY IN FERTILITY NURSING RESEARCH

07 July 2020 Parallel 6 17:00 - 18:00

O-215 The Effect of Hypnofertility on Cortisol Levels, Fertility Preparedness and Pregnancy Rates in Women Undergoing InVitroFertilization: A Randomized Controlled Study

S. Fata[1], M. Aluş Tokat[1]

[1]Dokuz Eylul University, Obstetric and Gynecological Nursing, Izmir, Turkey

Study question: Does Hypnofertility have remarkable effect on cortisol levels, fertility preparedness and pregnancy rates?

Summary answer: Hypnofertility is a powerful and effective mind-body program and aims to improve relaxatation, regulate hormone secretion and increase the pregnancy rates.

What is known already: It is found that there is a negatively correlation between stress levels and fertilization rates, pregnancy rates, total births, live births. There is information in the literature that controling of cortisol levels is important and can give idea about stress experienced before starting assisted reproductive treatment. Health professionals can be enterprise some applications to reduce the stress and cortisol levels. One of the methods that can reduce stress is Hypnofertility. Hypnofertility is a powerful and effective mind-body program with aim to relax couples, improve the preparedness to treatment process and therewithall increase the pregnancy rates.

Study design, size, duration: It was randomized controlled trial conducted in Dokuz Eylül University InVitroFertilization (IVF) Center in Turkey between December 2017-March 2019. The 61 women with unexplained infertility (30 women for intervention group and 31 women for control group) were reached. The women were applied intervention or control procedure in four face-to-face session (first treatment day, second control day, OPU, embryo transfer) and one mobile session (from embryo transfer day to pregnancy test day) throughout IVF treatment cycle.

Participants/materials, setting, methods: Interventions based on Hypnofertility including affirmations, visualization, imagination and relaxation were applied to women undergoing with IVF treatment from the first day of treatment to the day of pregnancy test. The standart IVF center follow up process was provided to control group. The cortisol level was evaluated trough saliva sample (four times), for determining preparedness of women the Fertility Preparedness Scale (three times) was applied and pregnancy result was evaluated by blood beta HCG test.

Main results and the role of chance: The group equivalence on baseline socio-demographic and infertility characteristics was shown in similar (X^2: 0.007, p: 0.06; X^2: 4.419, p: 0.93). There was no significant difference between the two groups in terms of fertility preparedness evaluated at baseline (t=0.930, p=.35). Although there was higher improvement in fertility preparedness in intervention group (second session p=0.04, third session p=0.01), the results of repeated measures, showed no difference in total in terms of group*time (F=2.177, p=.13). Saliva samples collection time of both groups were similar (p=.84; p=.41; p=.68; p=.50, respectively). When the cortisol levels of the women in the intervention and control groups were evaluated, a statistically significant difference was found in terms of group*time interaction (F=4.187, p=.00). It was observed that the interventions decreased the cortisol levels of the women in the intervention group compared to the control group (p=.00). Cortisol levels of the intervention group gradually decreased during the treatment period (p=.01). The last measurement has the lowest results in spite of the most stressful days of treatment (the embryo transfer day). Even though interventions relieved the women during treatment process, there was no the expected effect on pregnancy outcomes (X^2: 0.098, p=.75).

Limitations, reasons for caution: The main limitation of this randomized controlled trial was the limited number of samples. Since the cost of each measurement of cortisol level in saliva measured in the study was high, and the support obtained from University Scientific Research Project Coordination Unit was limited.

Wider implications of the findings: Although interventions based on Hypnofertility not effect pregnancy clinical outcomes, they reduced the cortisol levels of women. Also the fertility preparedness was improved in clinically meaningful level.

Trial registration number: NCT04141436

O-216 Assessment of a French web-based patient decision aid (ptDA) of ertility preservation (FP) for women with breast cancer

A.C. Benoit[1], G. Moutel[2], R. Morello[3], G. Grandazzi[2], A. Mayeur[1], M. Grynberg[1]

[1]Antoine Beclere University Hospital, Reproductive Medicine and Fertility Preservation, Clamart, France ;
[2]Normandie University, Inserm U1086- ANTICIPE, Caen, France ;
[3]University Hospital- Caen, Biostatistics and Clinical Research Unit, Caen, France

Study question: Does a French web-based ptDA in addition to standard counselling by a specialist in reproductive medicine improve informed choice of women with breast cancer?

Summary answer: The web-based ptDA we have developed improves patients' knowledge and informed choice without influencing their attitude towards FP and decrease the level of decisional conflict.

What is known already: Chemotherapy may cause infertility in young survivors of breast cancer, impairing their quality of life in the long term. Various FP techniques increase the likelihood of survivors becoming genetic mothers. The complex emotional situation, the need to make the right decision in a short space of time and conflicting ideas about life and death may mean that the decision about FP is a difficult one to take. Weighing up the risks and benefits of FP options may seem a mammoth task. Use of a ptDA could be increase patients' knowledge of treatment options and congruency between informed values and care.

Study design, size, duration: The study was a single-center randomized controlled trial conducted in the FP department of an academic hospital in France from September 2018 to November 2019. After being referred by oncologic

centers to specialists in reproductive medicine for fertility counselling, women were randomly assigned to the control group with usual care or to the intervention group with use of the web-based ptDA before and during counselling.
Participants/materials, setting, methods: A total of 125 women aged 18 to 40, with a primary diagnosis of breast cancer, who have not yet started any cancer treatment and able to read, write and speak French were included and randomized to the control group (n=65) or the intervention group (n=60). We have compared the decision-making process between control group and intervention group by quantitative data collected about fertility-knowledge, attitudes towards FP, and decisional conflict after the FP consultation.
Main results and the role of chance: Better knowledge was found in the intervention group (8.6/10 (±1.34)) compared to the control group (6.49/10 (±1.89)). In both groups, patients had a positive attitude towards FP (96%). The final decision was not influenced by membership in one group or another. Thus, at the end of the FP consultation, 73.6% (92/125), i.e. 69.2% (45/65) of patients in the control group and 78.3% (47/60) of patients in the intervention group, chose to keep their oocytes, embryos and/or ovarian tissue. The proportion of informed choice was statistically higher in the intervention group than in the control group (respectively 75% versus 38.5%, p<0.001). In addition, the level of decision-making conflict among patients in the intervention group was lower than in the control group (respectively 14 (±12.5) versus 21.9 (±15.7), p<0.01).
Limitations, reasons for caution: Investigators were not be blinded to the intervention, which represents a limitation. Furthermore, the study was specifically focused on women with breast cancer. Therefore, the results are not applicated to other malignancies.
Wider implications of the findings: The present study led to the development of the first French language ptDA of FP. Our results suggest that a French web-based ptDA has the potential to help supporting women with breast cancer to make informed fertility-related decisions and might decrease decisional regrets.
Trial registration number: NCT03591848

O-217 Addressing the psychosocial and informational needs of men with severe male factor infertility (MFI) with a peer-support platform

E. Lowndes Stevenson[1], K. Baker[2], K. McEleny[3]

[1]Duke University Medical Center, School of Nursing, Durham NC, U.S.A. ; [2]Duke University Medical Center, Department of Urology, Durham, U.S.A. ; [3]Newcastle upon Tyne Hospitals NHS Trust, Newcastle Fertility Center, Newcastle-upon-Tyne, United Kingdom

Study question: What do men with MFI desire in order to address their psychosocial and educational needs during the fertility process?
Summary answer: Men indicate desiring digital health communication and anonymous digital platforms to meet their psychosocial and informational needs.
What is known already: Men with MFI experience higher levels of psychological challenges such as depression and sexual dysfunction than fertile men. Men respond differently than their partners to the infertility diagnosis. Our previous research found that men employed avoidance strategies/did not disclose infertility status to social networks, experienced affective symptoms (sadness, shock, disbelief, denial), and lacked access to evidenced-based information in part because of their margination within the fertility process, secondary to the female-facing nature of fertility healthcare.
Study design, size, duration: This IRB-approved prospective qualitative study recruited men seeking a MFI consultation with a urologist between 2018 and 2019. Men over 18 years of age with primary or secondary MFI were phone interviewed after providing informed consent. Each digitally recorded interview lasted between 15 and 40 minutes and was transcribed verbatim. Nineteen participants were recruited (until data saturation reached).
Participants/materials, setting, methods: Inclusion criteria were men (≥ 18 years old) seen for a new patient MFI consultation having received a MFI diagnosis during the preceding 12 months and could read/write English. Exclusion criteria were a history of vasectomy or stated absence of a fertility concern despite a fertility related diagnosis. Nineteen men were recruited from a fertility urology clinic in a large academic medical center. Interviews were conducted by phone. Data were analyzed using content analysis.
Main results and the role of chance: Mean age was 35.3 years. Results indicated that participants prefer technology based communication to receive health information (i.e. 'mychart') because of the ease, access, and efficiency. Participants were not amenable to alternative medical structures (i.e. group sessions for emotional support), but were interested in anonymous digital platforms to meet psychosocial needs. In response to these data, as well as previous study team data, our team developed an internationally-focused and non-commercial peer-support platform (https://all-about-fertility.com/) to allow men with MFI to be able to disclose to others with MFI and seek anonymous emotional support online, whilst also receiving accurate and unbiased medical information to support their fertility journey and decision-making. Contributions from global Reproductive Health/Science experts provides men with confidence when seeking health information.
Limitations, reasons for caution: As the results are based on qualitative data from 19 men with MFI, the results cannot readily be generalized to larger populations. Implementation of the peer-support platform is still being optimized and its usefulness and impact to meet stated goals will be evaluated/reported in the coming years.
Wider implications of the findings: Men with MFI have unmet psychosocial and informational needs. Development of a peer-support platform is a positive step in addressing some of these needs and has the potential to have a wide reach into areas with limited support (geographically, economically).
Trial registration number: n/a

O-218 A preparatory information movie for the first oocyte aspiration in addition to care as usual: protocol for the POAM randomized controlled trial

L. Dias[1], P. De Loecker[2], T. D'Hooghe[1], K. Peeraer[3], E. Dancet[1]

[1]KU Leuven, Regeneration and Development, Leuven, Belgium ; [2]GZA Ziekenhuizen campus Sint-Augustinus, Gynaecologie - Verloskunde - Fertiliteit, Wilrijk, Belgium ; [3]UZ Leuven, Regeneration and development, Leuven, Belgium

Study question: Can a preparatory information movie on oocyte aspiration (POAM) decrease the anxiety of women on the day of their first oocyte aspiration? A protocol for a randomized controlled trial.
Summary answer: This RCT protocol provides a framework to examine the effect of a preparatory information movie on oocyte aspiration on women's anxiety and other secondary outcomes.
What is known already: Limited success rates of the fertility clinic trajectory could be increased by preventing discontinuation, a couple's decision to stop treatment despite financial stability and ongoing wish for a child. The main reason for discontinuation is distress, which increases during an IVF cycle, with anxiety peaks on the days of oocyte aspiration and pregnancy test. Moreover, pre-treatment anxiety predicts discontinuation from especially the first IVF cycle. Detailing procedural steps of out-patient clinic invasive procedures decreases patient's anxiety. Information leaflets however often increase anxiety because they can be very complicated. An educational movie simply showing what will happen can overcome this problem.
Study design, size, duration: In the POAM-RCT 190 women are randomized (1:1 allocation ratio; computerized randomization) during a recruitment period of 19 months to the parallel groups of 'care as usual' (a one-hour face-to-face information session 1-3 months prior to the start of treatment on all procedural steps of an IVF cycle, also summarized on a take-home leaflet) or 'care as usual supplemented with the Preparatory information on Oocyte Aspiration Movie (POAM)'.
Participants/materials, setting, methods: The setting for this monocentric interventional single-masked RCT is the fertility clinic of the GZA Ziekenhuizen, a private hospital in Belgium. Dutch speaking women with Dutch speaking male partners who are about to start their first IVF cycle (with or without ICSI or PGT) are eligible. Women who already experienced an IVF cycle and therefore know the patient journey on the day of the oocyte aspiration are not eligible.
Main results and the role of chance: In case of randomization to the intervention group, couples receive the day prior to their first oocyte aspiration, in addition to 'care as usual', a secured link to the POAM (5-minute movie visualizing the patient journey on the day of oocyte aspiration detailing which procedures will happen when, in which room, in the presence of which persons) by email.

The primary outcome of this RCT is women's state anxiety assessed with the reliable STAI-state questionnaire. Secondary patient-related outcomes are men's

state anxiety and also women's and men's infertility-specific distress on the day of the oocyte aspiration, assessed with the Infertility-Distress Scale. Previous research in the field of reproductive medicine showed that men are significantly less distressed if they receive an information leaflet before a diagnostic sperm test. Finally, women's and men's intervention evaluation are assessed by questioning how often they watched the movie and whether or not they would recommend it.

Secondary clinical outcomes that will be followed-up in the electronic medical records are clinical pregnancy, miscarriage, IVF delay, IVF discontinuation and cumulative pregnancy. The evidence on whether women's anxiety affects (cumulative) clinical pregnancy rates and miscarriage rates is conflicting.

Limitations, reasons for caution: A potential limitation of this RCT is selection bias, as women who are more anxious or stressed will be less likely to participate. Randomization aims to adjust for this effect. Another potential limitation is the single-masked character of the RCT as only the statistician will be masked during data processing.

Wider implications of the findings: With this RCT, we expect to demonstrate the value of additional information using a preparatory movie in couples undergoing their first oocyte aspiration. If these couples are positively affected, this technique should be implemented in each fertility clinic. We also want to show the value of publishing a study protocol.

Abstract text

ART is a fast moving and innovative area of medicine. And while innovation can be a force for good, offering patients improved chances of success, too often new drugs, treatments or equipment are introduced with little robust evidence that they will improve outcome. For regulators this presents a difficulty: how best to encourage innovation while protecting the patient?

More high-quality research including Randomised Controlled Trials, meta-analyses, and follow-up of patients is needed. But where do we go if these are not readily available now?

The UK's Human Fertilisation and Embryology Authority (HFEA) is ~30 years old and has led the way in regulation in this sector. Our experience of licensing mitochondrial donation suggested a different way of thinking about regulation and innovation, where good regulation provides the conditions that encourage innovation while ensuring every patient has access to the right information, at the right time.

We in the fertility sector in the UK are concerned that many patients are being frequently offered, and charged for, optional extras to their treatment which claim to improve their chances of having a healthy baby. These additional therapies and techniques are collectively known as treatment 'add-ons'. They cover a range of interventions including genetic tests, drugs, surgery and equipment. The problems posed by treatment add-ons are well known but crucially, the evidence base for most add-ons is not robust. Over recent years, there has been a significant increase the number of clinics, both in the UK and elsewhere, offering additional treatments – in 2019, 77% [DH1] of clinics in England offered at least one add-on according to their websites.

This talk will focus on the actions the HFEA is taking to encourage more responsible innovation in the way in which clinics offer treatment add-ons, and the way in which patients can understand the risks and benefits involved. The ultimate aim has always been to balance scientific and medical advancement with individual rights and needs. Our add-ons work touches on the quality of evidence, patient information and informed consent.

Given our limited powers on the introduction of new treatments, we cannot simply set conditions of the use of add-ons. In January 2019, the HFEA published a consensus statement signed by an additional 10 signatory bodies which sets out the principles of responsible innovation which we believe should guide professionals in the UK. The HFEA is continuing to work on a range of initiatives designed to set standards and inform patients about the use of treatment add-ons in the UK. The HFEA has published information for patients on some of the add-ons being offered in the UK based on an annual review by our independent Scientific and Clinical Advances Advisory Committee of relevant published research. The HFEA has tightened its guidance for clinics to require that any information provided to patients by clinics on the safety and effectiveness of any add-on explicitly references the HFEA website. In future we envisage that new treatments or technologies under development will only be offered to patients outside of a research setting once safety and effectiveness have been demonstrated. More high-quality research including Randomised Controlled Trials, meta-analyses, and follow-up of patients is needed. We want to move towards a more consistent and transparent approach to the use of treatment add-ons in fertility services.

O-222 When will we start transplanting prepubertal testis tissue?

C. Wyns[1]

[1]*n/a, n/a, BRUSSEL, Belgium*

Abstract text

Testicular tissue transplantation in humans was already performed back in 1889 by Brown-Sequard to treat hypogonadism. However, grafting the tissue to restore the reproductive potential has never been reported.

Efforts to preserve the fertility of prepubertal boys facing fertility-threatening therapies by cryopreserving their immature testicular tissue have motivated researchers to develop methods to give these young patients a hope to father their own genetic child. In this regard, auto-transplantation of cryostored tissue can be considered if there is no risk of cancer cell contamination of the tissue i.e. not in case of haematological cancers or metastasizing tumours.

The proof of principle of the technique was recently obtained with the birth of GRADY in macaques but many research questions remain before pilot trials can be considered in humans where most often only small amounts of tissue are available for future use.

Xenotransplantation experiments with human prepubertal testicular tissue in nude mice showed an important loss of spermatogonia in grafts, regardless of prior cryopreservation, justifying optimization of the avascular transplantation procedure.

High DNA fragmentation by TUNEL was observed in the first days following grafting suggesting that cell damage is likely due to hypoxia before vascular supply of oxygen to the grafted tissue is in place. In this regard, finding the most appropriate graft size to reduce tissue necrosis and cell loss is a first matter of concern. Only one study compared graft outcome for different tissue sizes and no differences were observed up to 16mm³. Attempts to shorten the ischemic period

before revascularization of the graft were also made by culturing the tissue fragment before grafting in media containing vascular endothelial growth factor (VEGF) as this method increased the number of seminiferous tubules with elongating spermatids in bovine. Unfortunately, this could so far not be confirmed for human prepubertal tissue although a potential benefit was suggested in a report of two cases.

However, controlled local drug delivery of VEGF covering the time period needed for the stabilization of the neo-vasculature could be more efficient. Therefore, nanoparticles (NPs) containing growth factors e.g. VEGF, platelet-derived growth factor (PDGF) and necrosis inhibitors have been developed as well as tissue embedding matrices allowing proper migration of endothelial cells. Higher recovery rates of undifferentiated spermatogonia in autografts were reached in an alginate hydrogel and further improvement was achieved with NPs controlled drug delivery.

Incomplete and abnormal differentiation of spermatogonia in xenografts of human prepubertal testicular tissue was also observed, most likely due the phylogenetic distance between mice and human, but not only. Indeed, graft development seems also influenced by its hormonal environment as autografting experiments in marmosets showed less advanced germ cell development in hemi-castrated than castrated animals. While it was reported that human prepubertal Leydig cells show maturation features based on the presence of key enzymes of steroidogenesis and ultrastructural modifications after xenografting, only few studies have investigated the impact of the hormonal environment on the spermatogonial stem cell niche in grafts. Some questions still need to be addressed: what would be the real impact of the post-chemotherapeutic hypergonadotropic hypogonadic state of candidate patients for autotransplantation on transplant outcome, and would hormone requirements of the transplanted tissue depend on the age of the patient at cryopreservation? Furthermore, and so far, the absence of a valid preclinical model for human prepubertal testicular tissue transplantation precludes to answer the question of the time needed to achieve complete spermatogenesis in grafts and thus the optimal moment for sperm retrieval.

O-224 Indications for tubal surgery

A. Watrelot[1]

[1]*Hospital Natecia, gynecologic surgery, Lyon, France*

Abstract text

Interest in tubal surgery has decreased progressively in the last decades due to IVF/ICSI results which have dramatically increased in the same time.However IVF access is not easy in many countries and more and more patients wish , if possible, to conceive naturally. Therefore once may ask what is the place for tubal surgery in 2020.

First of all it is important to consider the tubal pathology: the most common pathology is the one affecting the distal part of the tube . Everybody knows today the detrimental effect of hydrosalpinx on fertility and IVF results.

In this case, salpingectomy is often proposed but with a careful selection, a conservative treatment by salpingoplasty may produce very good results in term of spontaneous pregnancy.

A "new" chapter in distal tubal pathology represented by the subtle tubal abnormalities is raising (such as paratubal cysts, sacculation,accessory tubes),and we have more and more evidence that these minor abnormalities should be diagnosed and treated allowing spontaneous pregnancy in more than 50% of cases.

lastly , proximal surgery keeps good indication after sterilization when the patients wishes to restaure her fertility. datas suggest that microsurgical recanalization of the tube through robot or microsurgery gives better outcome in term of pregnancy than IVF/ICSI.

Therefore we consider that tubal surgery, in the hands of trained team, has a role to play ,providing that a good diagnosis is established, a careful selection of patients is made and a complete information is delivered to patients . Nevertheless, nowadays, few surgeons are trained in tubal surgery, except in Far East countries(such as India and China) where tubal surgery is still very popular.

We should probably think to re-promote the teaching of tubal surgery in the initial training of young surgeons, in order not to compete with IVF /ICSI but to provide an additional tool which may be beneficial in some infertile patients

SELECTED ORAL COMMUNICATIONS

SESSION 58: IMPROVING SPERM CRYSOPRESERVATION OUTCOMES

08 July 2020 Parallel 4 08:30 - 09:30

O-225 Does cryopreservation affect live birth outcome in surgically retrieved sperm: – an analysis of a decade of nationwide data

J. Lewin[1], **E. Yasmin**[1]

[1]*University College London Hospital, Gynaecology, London, United Kingdom*

Study question: Is there a difference in live birth rate after ICSI between cryopreserved and fresh surgically-retrieved sperm?

Summary answer: There was no difference in live birth rate between cryopreserved and fresh sperm used in ICSI over 10 years analysed from all UK fertility centres

What is known already: Multiple small studies have been conducted comparing success rates from fresh and cryopreserved surgically-retrieved sperm for use in ICSI. A 2014, meta-analysis showed no significant difference in live birth rate. Most included studies were small and subsequent studies have demonstrated conflicting results. Concerns are raised about the effect of cryo-protectants and freezing/thawing techniques on function and structure of sperm such as DNA fragmentation and acrosomal reaction.

Study design, size, duration: Annual data pertaining to ICSI cycles from all IVF centres in the UK were obtained from the UK Human Fertilisation and Embryology Authority (HFEA). The time period studied included all years from 2007 to 2017 inclusive. Data from 235,296 ICSI cycles were therefore obtained.

Participants/materials, setting, methods: By law all clinics in the UK offering assisted reproductive technology treatments must collect accurate data from all cycles including pregnancy outcome, which is then submitted to the HFEA. We obtained anonymised data from the HFEA on live births per cycle of treatment according to sperm and egg source from 2007-2017. We compared live birth outcomes between cryopreserved and non-cryopreserved sperm from different sources using Chi square, ANOVA and Pearson correlation coefficient where appropriate.

Main results and the role of chance: A total of 235,296 ICSI cycles were performed in the UK between 2007 and 2017 inclusive. Data obtained from these cycles included the number of cycles and live births/ per cycle of treatment for each year categorised by source of egg and sperm (donor or partner) and further divided by method of sperm retrieval (ejaculate, epididymal or testicular) and whether the used sperm were fresh or cryopreserved. Any sub-group with <5 cycles/live births were listed as <5 to protect patient anonymity, so these were excluded from analysis, including all data from 2007 and from donor gamete cycles. 197,836 ICSI cycles were therefore included, which resulted in 61,344 live births over the 10-year period. Of these cycles 184,246 used ejaculated sperm, 5249 epididymal and 8341 testicular, which had live birth rates of 30.93%, 32.94% and 31.60% respectively. There was no difference in the live birth rate between fresh and frozen ejaculated (30.94% vs 29.78%, p=0.208), epididymal (32.59% vs 33.20%, p=0.64) or testicular (31.59% vs 31.64%, p = 0.97) sperm. There was no difference between any of the groups when analysed by one-way

ANOVA (p=0.089), and no statistically significant correlation between the year and the live birth rate for any group.
Limitations, reasons for caution: ICSI cycles using donor oocytes were excluded from analysis due to low numbers. The primary diagnosis (obstructive or non-obstructive azoospermia) was not known in patients undergoing surgical retrieval of testicular sperm and a sub-group analysis between live outcome in obstructive and non-obstructive azoospermia would have provided important clinically relevant information.
Wider implications of the findings: The lack of difference in live birth outcomes in different sources of partner sperm allays some of the concerns about using frozen sperm for ICSI especially in surgically retrieved sperm. This analysis can serve as evidence to counsel patients undergoing surgical retrieval of sperm.
Trial registration number: not applicable

O-226 Novel Technologies for Single-Sperm Vitrification with Cryotop and Cell Sleeper: A Follow-Up Study

Y. Endo[1], S. Mitsuhata[1], M. Hayashi[1], Y. Fujii[1], H. Motoyama[1]
[1]Kurashiki Medical Clinic, IVF Center, Kurashiki, Japan

Study question: Do the novel sperm vitrification devices (Cryotop and Cell Sleeper) efficiently vitrify small numbers of spermatozoa?
Summary answer: Single-sperm recovery was successful with both devices; fertilization and embryo cleavage occurred normally, embryo transfer was successful, and four babies were liveborn.
What is known already: We developed the effective single-sperm vitrification methods by using the nonbiological carriers Cryotop (Kitazato, Tokyo, Japan) and Cell Sleeper (Nipro, Osaka, Japan) and were the first to report the successful delivery of infants from the individually vitrified sperm from a man with nonobstructive azoospermia (Endo et al., 2011, 2012). Since the publication of our reports, however, there have been few reports of live birth after the use of sperm from men with extremely severe male infertility. Because the population of such men is quite limited, insemination with donor sperm is a common option in such cases.
Study design, size, duration: This was a retrospective study. From January 2010 to December 2018, vitrification of small numbers of spermatozoa was performed for 9 men with azoospermia after testicular biopsy and for 3 men with cryoptozoospermic semen. The ICSI treatments were performed in 16 cycles for sperm from Cryotops and 14 cycles for those from Cell Sleepers.
Participants/materials, setting, methods: Vitirification: All motile specimens were vitrified before the day of oocyte pickup. Two to 14 spermatozoa were loaded into cryoprotectant solution in each device (Cryotop and Cell Sleeper), which was placed in liquid nitrogen vapor. Subsequently, they were stored in a cryogenic tank. Warming: On the day of oocyte retrieval, Cryotops and Cell Sleepers were taken out of the tank. Sperm were retrieved with intracytoplasmic sperm injection (ICSI) needles and used in ICSI procedures.
Main results and the role of chance: A total of 475 sperm in 55 Cryotops and 171 sperm in 18 Cell Sleepers were vitrified. During ICSI, 30 Cryotops and 16 Cell Sleepers were warmed, and the sperm recovery rate was 83% (218/264) and 91% (135/148), respectively ($P < 0.05$). After warming, 34% (75/218) of sperm from Cryotops and 15% (20/135) from Cell Sleepers were motile, and the difference was significant ($P < 0.01$). A total of 87 Cryotop sperm and 74 Cell Sleeper sperm were used in ICSI and injected into oocytes individually. The normal fertilization rate was significantly higher in the Cryotop group than in the Cell Sleeper group (48% [42/87] vs. 32% [24/74]; $P < 0.05$), but the rate of embryo cleavage did not differ (88% [37/42] vs. 96% [23/24]). Fresh and frozen embryos from both groups underwent 16 and 10 transfer cycles, respectively, and 16 embryos from the Cryotops group and 11 from the Cell Sleeper group were transferred to patients. The rates of pregnancy were 13% (2/16) with Cryotop group and 20% (2/10) with Cell Sleeper group. Finally, 2 healthy babies from Cryotop group and 2 from Cell Sleeper group were born.
Limitations, reasons for caution: Fewer than 0.7% (12/1837) of patients undergoing oocyte pickup required the novel technologies of single-sperm vitrification during the experimental period in Kurashiki Medical Clinic (Okayama, Japan). Further clinical follow-up studies will provide more information about which device has more clinical benefit for single-sperm vitrification.
Wider implications of the findings: Our findings suggest that Cryotop and Cell Sleeper methods would be suitable and clinically useful for men with severe male infertility who hope to have biological children. Furthermore, our effective sperm storage methods contributed to reduce the time-consuming and exhausting search for individual sperm in the laboratory.
Trial registration number: not applicable

O-227 comparison of permeable cryoprotectant free vitrification by droplet method versus rapid freeze using glycerol in abnormal semen sample

S. Ranganathan[1], S. Reddy[1], M. Daniel[1], S. Srinivasan[1]
[1]Sri Ramachandra Institute of Higher education and Research, Reproductive Medicine, Chennai, India

Study question: Is permeable cryoprotectant free vitrification using droplet method of abnormal semen sample a good alternative to conventional rapid freeze using glycerol?
Summary answer: The permeable cryoprotectant free sperm vitrification protocol tested in this study renders considerably better recovery rates of abnormal semen sample compared to rapid freezing.
What is known already: Semen cryopreservation in contemporary practice is conventional rapid freezing; however, more recently, vitrification has also been used. The rapid freeze method has been associated with a decline in sperm quality with negative effects on both structural and functional sperm features. One of the recently emerged technology within the field of cryobiology is spermatozoa vitrification.This method is based on rapid cooling of cells by immersion into liquid nitrogen and, thereby, is the key to reducing the chance of forming big ice crystals. Vitrification is still yet to be explored, since only limited studies shows its efficacy in abnormal semen sample.
Study design, size, duration: This study included 80 oligozoospermic sperm samples from patients seeking ART treatment between 2018-2019. The effects of permeable cryoprotectant free vitrification protocol on functional sperm quality parameters in comparison to fresh and rapid freeze using glycerol samples were assessed.
Participants/materials, setting, methods: All samples were divided into three aliquots : fresh(F), vitrification, warming(V), rapid freeze(R). Sperm total motility, progressive motility, vitality and spontaneous acrosome reaction were assessed and compared between both the groups.
Main results and the role of chance: Results showed better preservation of sperm features after vitrification compared to conventional rapid freeze. Permeable cryoprotectant free vitrification using droplet method presented a significantly higher percentage of total motile, progressively motile and live spermatozoa compared to rapid freezing. The percentage of sperms undergoing premature capacitation was lower in frozen thawed vitrified samples compared to rapid freeze samples. The total motility in V group was 37.79±11.98 and R group was 36.28±11.90. Progressive motility in V group was 22.01±8.45 and R group was 18.31±8.18. The vitality in V group was 51.56±12.31 and R was 49.95±12.22. Acrosome reacted sperms were significantly high in R group with 43.29±9.96 compared to V group 31.93±8.72. Acrosome intact sperms were significantly high in V group with 65.21±8.86 compared to R group 54.09±9.44. The analysis of sperm quality parameters studies revealed that the V group preserved the sperm quality much better than the R group, indicating that samples are better preserved through vitrification than rapid freezing.
Limitations, reasons for caution: This study has been done only on oligozoospermic sperm samples. It is necessary to compare these results in surgically retrieved sperm samples to evaluate the influence of the application of this methodology in routine clinical practice.
Wider implications of the findings: The sperm vitrification protocol described here guarantees better maintenance of sperm quality parameters than conventional rapid freeze and can prove to be a better and economical alternative to preserve sperm samples from patients seeking ART treatment. Further it opens new doors in IVF and ICSI.
Trial registration number: not applicable

O-228 Sperm banking before gonadotoxic treatment: is it worth the effort?

E. Reiser[1], K. Vomstein[1], T. Kriesche[1], B. Böttcher[1], G. Pinggera[2], B. Toth[1]

[1]Medical University Innsbruck, Department of Gynecological Endocrinology and Reproductive Medicine-, Innsbruck, Austria ;
[2]Medical University Innsbruck, Department of Urology, Innsbruck, Austria

Study question: Do cancer patients already show impaired sperm quality prior to gonadotoxic treatment?
Summary answer: Sperm quality was already impaired prior to gonadotoxic treatment.
What is known already: Cryopreservation of semen is a well-established method as chemotherapy, surgery and radiotherapy have deleterious effects on spermatogenesis. However, patients suffering from malign, as well as benign diseases show impaired semen characteristics already prior to gonadotoxic treatment. Therefore, this study aims to compare semen quality between different cancer types and benign diseases. Furthermore, the usage rate of cryopreserved semen is reported to be as low as 8% for assisted reproductive treatments (ART) and was also analyzed in our study cohort.
Study design, size, duration: Within this retrospective study, the semen quality and the utilization of cryopreserved semen, was assessed in a total of 264 patients suffering from cancer and benign diseases prior to any gonadotoxic therapies. Patients were referred to the Department of gynecological endocrinology and reproductive medicine, Innsbruck, Austria between 01/2008 and 07/2018. Pre-treatment semen analyses were studied and compared in accordance with the WHO guidelines. In addition, the usage of cryopreserved semen for ART was evaluated.
Participants/materials, setting, methods: Pre-treatment semen analyses were studied and compared in accordance with the WHO guidelines in 264 patients with testicular cancer, hematological malignancies and benign diseases prior to any gonadotoxic therapies. In addition, the usage of cryopreserved semen for ART was evaluated.
Main results and the role of chance: Patients with testicular cancer (TM) showed a lower sperm concentration (12 *106/ml) compared to hematological malignancies (HM) (28.5 *106/ml, p=0.0029) and benign diseases (Ben) (29 *106/ml, p=0.0008). Within the TM group, the group of seminomas (8.5 *106/ml) presented the lowest sperm counts. Although most of the individual mean values were within the WHO reference limits, only 38 % of TM and 45 % of sarcoma patients had a normozoospermia. In the other groups (HM, Ben) only 60 % of the patients showed a normozoospermia. No correlation between sperm quality and Ann- Arbor stadium, TSH- values or BMI was present. Only 5 (1.9 %) patients used their frozen semen for a total of 9 ART cycles, which resulted in 5 live births.
Limitations, reasons for caution: The low use rate might be explained by the short follow up time after cryopreservation and patients' age. The storage of semen for fertility preservation is currently not covered by health insurance in Austria compared to other countries, where storage costs play a minor role.
Wider implications of the findings: Depending on the underlying disease, patients show different sperm quality, with TM and HM patients having the lowest sperm concentrations. Due to the low usage rate of cryopreserved semen, a control sperm test should be part of the follow-up cancer care - to avoid costly storage.

SESSION 59: NEW MORPHOKINETIC INSIGHTS OF EMBRYO DEVELOPMENT

08 July 2020 Parallel 1 10:00 - 11:45

O-229 Improving embryo selection by development of laboratory-adapted Time-lapse model

I. Blais[1], S. Lahav-Baratz[1], M. Koifman[1], I. Feferkorn[1], M. Dirnfeld[1,2]

[1]Lady Davis Carmel Medical Center, Division of Reproductive Endocrinology and IVF- Department of Obstetrics and Gynecology, Haifa, Israel ;
[2]Technion – Israel Institute of Technology, Ruth and Bruch Rappaport Faculty of Medicine, Haifa, Israel

Study question: Is it applicable to develop morphokineric algorithm for a specific IVF laboratory, can it provide more information for embryo selection in addition to general models?
Summary answer: A model based on laboratory-specific morphokinetics was found to be complementary to the general models and an important tool for improving single embryo selection.
What is known already: Generally applicable algorithms for selection and mainly deselection of embryos from a cohort are routinely used in IVF labs. It was shown that clinical and laboratory conditions influences embryo morphokinetics. In order to avoid the differences between labs, the general algorithms were developed by using large range of cells division timing. It is recommended that laboratories develop a model that uses the specific embryo division timing obtained under local conditions. However, it was not reported whether a specific model can be developed in a lab that embryos were already selected for transfer by using the general models.
Study design, size, duration: During 2013-2018, 12,944 embryos were incubated in our EmbryoScope (Vitrolife), using the general models for embryo selection. There were 1879 KID (known implantation data) embryos, of which, 425 were positive KIDs. For the outcome, we set three endpoints for KID definition: gestational sacs (GS), clinical pregnancy (CP), and live birth (LB). Comparison between positive and negative KID embryos for cell division timings was analyzed separately for ICSI and IVF, at patient's age 18-41 years old.
Participants/materials, setting, methods: Implanted and non-implanted embryos were analyze for statistical differences in cell division timing and cell cycles intervals. We used EmbryoScope Stats software for model building. The timing parameters were tested for their contribution to the scoring in the model. The algorithms were tested for the area under the receiver operating characteristic curve (AUC) in KID embryos for developing Day 2,3 and 5 models. The stability of the algorithms structure was verified by performing calibration-validation procedures.
Main results and the role of chance: Since significant differences in cell division timings were found between implanted and non-implanted embryos, we were able to develop a laboratory-adapted model. The algorithms were developed for selection of Day 2, 3 and 5 ICSI embryos. AUC at most cases were higher than 0.65 which indicates that these models are valid in our laboratory. In addition, these values for AUC were obtained across all GS, CP and LB KID embryos databases tested. An increase in the predictability of the models was observed from Day 2-3 to Day 5 models. AUC test results ranged around 0.658, 0.671 for Day 2, Day 3 respectively and 0.872 for Day 5 model. Our results show that although embryos were selected for transfer using the general models, specific laboratory model is contributory for better selection of embryos. It may improve embryo selection and increase the number of single embryo transfers.

Developing a laboratory-specific model requires many stages of sorting and characterization. It demands accurate annotation and statistical analysis for every parameter alone and in combination, to evaluate which parameter should be included in the model. Many conclusions can be drawn about the model-building process, which may facilitate and improve the process in other laboratories.
Limitations, reasons for caution: Laboratory specific in house model is an important tool that helps selecting embryos for transfer, but should be used with caution and in combination with other selection method such as general models and embryo classical morphology evaluation by the embryologists.
Wider implications of the findings: We recommend developing in-house model for embryo selection in addition to the general models. This may enable single embryo transfers with more confidence, reducing multiple pregnancies and the number of transfers required to achieve pregnancy. The experience we gained in the process may be of assistance to other laboratories.

O-230 Trophectoderm specification: compaction, polarisation and inner and outer cells occur simultaneously in the human preimplantation embryo

A. Demtschenko[1], W. Essahib[1], G. Verheyen[2], K. Sermon[3], H. Tournaye[2], H. Van de Velde[1]

[1]VUB, Reim, Brussels, Belgium ;
[2]Uz Brussel, crg, Brussels, Belgium ;
[3]VUB, Rege, Brussels, Belgium

Study question: How is the trophectoderm lineage specified in the human preimplantation embryo?

Summary answer: Outer cells at the fully compacted embryo stage display characteristics of trophectoderm cells such as apical polar distribution of p-ERM and nuclear GATA3/YAP1/TEAD4 protein expression.

What is known already: In mice, the first indication of inner cell mass (ICM) and trophectoderm (TE) segregation occurs three days post fertilisation (dpf3). After compaction, asymmetric divisions give rise to inner and outer blastomeres that ubiquitously express transcription factor TEAD4 and sequester polarity markers (p-ERM), and TE lineage specifiers (YAP1, GATA3) to outer blastomeres. This is considered the onset of TE lineage segregation in the mammalian embryo. Studies regarding this event in the human embryo are absent and extrapolations from the mouse model cannot be a surrogate for studies in the human embryo.

Study design, size, duration: Human embryos used in this study, were donated to research as a surplus of IVF-ICSI treatment at our IVF-center after the cryo-storage expiration date of 5 years with informed consent. The project was approved by the institutional ethical committee and the federal committee for research on human embryos.

Participants/materials, setting, methods: Cryopreserved human 8-cell stage embryos, donated to research, or zygotes created for research after informed consent were warmed (Vit Kit -Thaw, Irvine Scientific, USA) and cultured until dpf5 according to standard laboratory procedures of the associated IVF-clinic. Time course immunofluorescence was performed on fixed embryos at predefined stages for TEAD4, YAP1, GATA3, p-ERM as well as F-actin and Hoechst for imaging (LSM800, ZEISS) and the manual estimation of individual blastomere counts per embryo (ImageJ).

Main results and the role of chance: The compaction process of the human embryo is interrupted by cleavage divisions this results in a fully compacted embryo at dpf4.These fully compacted embryos are comprised of a total of 16±3 cells, n=21, of which 76%, n=16/21 contain 1±1 inner blastomere in their core excluded from the exterior. The nuclei of the outer blastomeres are positive for TE-specifier YAP1 (69±22%, n=8) and begin to co-express TE-transcription factor GATA3 (15±22%, n=8). The apical membranes of the outer blastomeres appear polarised by p-ERM staining (100%, n=8) and TEAD4 is expressed ubiquitously (100%, n=8). While inner cells also express TEAD4 they remain apolar and rarely express YAP1. This inner/outer pattern is maintained in the blastocyst ICM and TE. All nuclei of TE cells of dpf5 blastocysts are positive for YAP1/GATA3 and TEAD4 and apical membranes of TE cells show polar distribution of p-ERM. Whereas the ICM remains apolar, TEAD4 positive, GATA3 negative, and very rarely contains YAP1 positive cells.

Limitations, reasons for caution: In spite of available functional data on the interaction between YAP1 and TEAD4 and their effect on GATA3 expression and embryo development in the mouse and the bovine model, functional experiments in the human embryo still need to confirm the link between polarity, nuclear TEAD4/YAP1/GATA3, TE specification and blastocyst formation.

Wider implications of the findings: The same molecular determinants are involved in the TE lineage segregation of mice and humans, but their expression differs according to the morphological development of the respective species. In contrast to the stepwise model of the mouse, compaction, polarisation and inner and outer cells occur gradually in the human embryo.

Trial registration number: not applicable

O-231 Embryos excluding multinucleated cells during blastocyst formation increase their reprodutive potential

A. MUNUERA PUIGVERT[1], S. Novo[1], L. Almenara[1], A. García-Faura[1], B. Marquès[1], F. García[1], C. Castelló[1], M. López-Teijón[1]

[1]Institut Marquès, Reproductive Medicine Service, Barcelona, Spain

Study question: Has the inclusion or exclusion of blastomeres in multinucleated embryos any effect on embryo development and clinical outcomes on IVF treatments?

Summary answer: Embryos excluding multinucleated cells during blastulation appear to have the capacity for self-correction that allows them to keep intact their ability to become healthy babies.

What is known already: The effects of multinucleation on embryo development and on clinical outcomes are unclear. Some studies have correlated multinucleation with low embryonic development, low implantation potential and aneuploidies increase. However, there is still a debate about transferring multinucleated embryos, as some other studies have observed that multinucleation is equally present in euploid and aneuploid embryos. Moreover, there are live births reported from multinucleated embryos. One of the theories about these discrepancies is the location of the multinucleated cells once the blastocyst is formed. In this way, these cells may be part of the inner cell mass, the trophectoderm or be excluded.

Study design, size, duration: Retrospective study involving 20,779 embryos from 5,621 cycles performed between 2014 and 2019. Two main groups were considered: Control Group (CG;N=16,897), embryos without multinucleation and, Multinucleation Group (MNC;N=3,879), embryos showing at least one multinucleated blastomere. Embryos transferred belonging to MNC Group (N=307) were subdivided according to the multinucleated cell location after blastulation: MNC-1 (N=142), no cells excluded; MNC-2 (N=73), mononucleated cells excluded; MNC-3 (N=46), multinucleated cells excluded. All groups were homogeneous.

Participants/materials, setting, methods: All the embryos were cultured until blastocyst stage using one-step culture media. We used the time-lapse technology to follow up the location of the multinucleated cells and we had to exclude from the study those transferred embryos that could not be monitored (N=46). Single embryo transfer was performed to all patients and the clinical outcome rates were compared between groups performing the statistical analysis Chi-square test.

Main results and the role of chance: Our results showed that despite presenting a significantly lower rate of blastocyst formation (MNC=20.0%; CG=58.0%; p<0.05), the transfer of multinucleated embryos that were able to reach the blastocyst stage at D5/6 had remarkable reproductive success.

Blastocysts that were able to exclude multinucleated cells (MNC-3) achieved higher clinical outcomes respect those including multinucleated cells (MNC-1 and MNC-2). Pregnancy rate in MNC-3 (63.0%) was significantly higher than in the other groups (MNC-1=50.7%; MNC-2=41.1%; p<0.05). The clinical pregnancy rate in MNC-3 (56.5%) was higher than MNC-1 (41.5%) and MNC-2 (32.9%), being statistically significant with MNC-2 (p<0.05).

Miscarriage rate of MNC-3 was lower than the other groups but the differences were not significant (MNC-1=16.2%; MNC-2=9.6%, MNC-3=6.5%).

It was in the live birth rates when MNC-3 (48.9%) showed the highest significant differences regarding the other two groups (MNC-1=24.8%, MNC-2=22.2%; p<0.05).

Moreover, we found that embryos excluding multinucleated cells (MNC-3) reached equivalent clinical outcome results to CG (with 4210 blastocysts transferred): pregnancy rate: 63.0% vs. 60.8%; clinical pregnancy rate: 56.5% vs. 50.6%; live birth rate: 48.9% vs. 34.4%.

Limitations, reasons for caution: There is a wide difference on sample size between MNC and CG groups. 14.7% of the MNC transferred embryos had to be excluded from the study because they could not be well monitored under time-lapse viewer.

Wider implications of the findings: We consider that MNC should be classified according to their ability to locate multinucleated cells. The exclusion of multinucleated cells could be part of some error detection mechanism. Embryos that are able to discard them while reaching the blastocyst stage have the same reproductive potential as blastocyst without multinucleation.

Trial registration number: Doesn't apply

O-232 Deep learning using embryo preimplantation videos can automatically predict the potential of human embryos to blastulate and implant

Y. Ken-Tor[1], N. Zabari[1], A. Szeskin[1], A. Tamar[1], D. Richter[2], Y. Or[3], Z. Shoham[3], A. Hurwitz[4], I. Har-Vardi[2], M. Gavish[1], A. Ben-Meir[4], A. Buxboim[5]

[1]Hebrew university, Computer science, Tel Aviv, Israel ;
[2]Soroka University Medical center, Fertility and IVF Unit- Department of Obstetrics and Gynecology, Beer Sheeva, Israel ;
[3]Kaplan Medical Center, Fertility and IVF Unit, Rehovot, Israel ;
[4]Hebrew University Hadassah Medical Center, Fertility and IVF Unit- Department of Obstetrics and Gynecology, Jerusalem, Israel ;
[5]Hebrew university, The Alexender Grass Center for Bioengineering- School of computer Science and Engineering, Tel Aviv, Israel

Study question: Does the morphodynamic data in preimplantation human embryo videos can be analyzed using deep learning algorithms to predict the potential to reach blatulation and implantation.

Summary answer: Blastulation prediction on test-set embryos, reached area under the ROC curve 0.73 at 72 hour. prediction on of day-5 transferred test-set embryos, outperformed manual KIDScore™-D5.

What is known already: In IVF treatments, early identification of embryos with high implantation potential is required for shortening time to pregnancy while avoiding clinical complications caused by multiple embryo pregnancy. Current classification tools are based on manually annotated morphological and morphokinetic parameters. However, manual annotation introduces inter-observer and intra-observer variability and provides a discrete representation of preimplantation development while ignoring dynamic features that may be associated with embryo quality. Deep learning AI, which offers a powerful toolbox for carrying out automated and standardized classification tasks involving expansive datasets, is gradually incorporated into the health care system worldwide and IVF clinics specifically.

Study design, size, duration: 16,000 3D videos of preimplantation embryos were annotated for morphological and morphokinetic parameters. 6,200 were blastulation-labelled and > 5,500 were implantation-labelled. Each embryo video file was associated with maternal information and clinical metadata. The classification was evaluated using fivefold cross-validation and using an uncontaminated test set consisting of 20% of the labeled embryos. Generality was verified via leave-one-clinic-out and leave-one-age-group out cross-validation.

Participants/materials, setting, methods: Embryos were cultured in nine time-lapse incubators during the past six years in four medical centers across Israel. We developed fully automated and standardized classifiers by training time point sensitive deep neural networks directly on video frames. Using machine learning we combined the frame scores into a single embryo score for blastulation or implantation prediction. Using SHAP values we identified key time points for prediction and impactful video frames.

Main results and the role of chance: Blastulation prediction on test set embryos increased monotonically with the time of prediction measured from ICSI, reaching area under the ROC curve (AUC) 0.73 at 72 hours, 0.88 at 96 hours and 0.94 at 110 hours. Blastulation prediction was further demonstrated using high-quality embryos that reached 8 cells.

KID predictive strength increased with time of prediction as evaluated for the same cohort of day-5 transferred test-set embryos. AUC increases slowly from 48 to 84 hours and more rapidly from 84 hours onward. Our deep learning prediction is as accurate as KIDScore-D3 on day-3 and more accurate than KIDScore-D5 on day-5 as evaluated for the same test-set embryos.

Both blastulation and implantation results were consistent with fivefold cross-validation, leave one-clinic-out and leave one-age-group out from the training session, supporting generality.

Using SHAP analysis we identified key temporal points that can direct blastulation and implantation prediction without including the rest of the video. we trained again the embryo-learning blastulation and implantation classifiers using only the key temporal points. The new models reached comparable AUC for both goals supporting the importance of a few time points.

Limitations, reasons for caution: Prediction accuracy is limited due to lacking critical information about endometrial receptivity and using a homogenous dataset of embryos that were retrospectively preselected for transfer according to established morphological and/or morphokientic criteria.

Wider implications of the findings: Deep learning provides full automation and standardization of embryo classification and improves accuracy. Our classifiers mark the first step towards the development of a decision support tool. This framework opens the door for clinical implementation of deep learning classification tools that will improve conception rates while shortening time to pregnancy.

Trial registration number: not applicable

O-233 Direct cleavage in late stages of embryo progession does not affect in vitro development, ploidy nor the reproductive potential of human embryos

J. Masso Hernaez[1], S. Novo[1], V. Moens[1], À. García-Faura[1], B. Marquès[1], F. García[1], C. Castelló[1], M. López-Teijón[1]

[1]Instituto Marques, Reproductive Medicine Service, Barcelona, Spain

Study question: What are the effects of direct cleavage (DC) on embryo development and preimplantation genetic testing (PGT) results?

Summary answer: The results for embryos that present DC and develop into good quality blastocysts (GQB) are equivalent to those that do not present DC.

What is known already: After the appearance of time-Lapse technology, various studies based on morphokinetics have identified the presence of direct cleavage in 14% - 26.1% of all evaluated embryos. These embryos present a significant reduction in blastocyst formation, euploidy rate and implantation potential compared to control groups without DC. However, depending on the cycle where DC is observed, the impact may not be so negative.

Study design, size, duration: A retrospective study including 11168 embryos from 3175 cycles between January 2018 to October 2019. Two groups were defined: a DC-negative group (DC-) containing 10051 embryos without DC in any of their division cycles and a DC-postive group (DC+) including 1117 embryos with at least one DC in any of their first three cycles. DC+ group was subdivided into DC+1 (n=493), DC+2 (n=476) and DC+3 (n=148) based on the cycle in which DC was observed.

Participants/materials, setting, methods: For all cycles intracytoplasmatic sperm injection technique was performed and the resulting embryos were cultured in time-lapse incubators to blastocyst stage using one-step culture media. Blastocyst, good quality blastocyst (GQB), multinucleation and ploidy rates were compared between both groups, with and without DC. Furthermore, groups DC+1, DC+2 and DC+3 were also compared among each other. The chi-square test was used for statistics.

Main results and the role of chance: At least one DC event was observed in 10% of embryos on culture day 2 or 3. This rate was lower compared to values published previously by others laboratories. The *in vitro* development rate of DC+ embryos up to day 5/6 (42.4%) was significantly lower than the DC- embryos (73,6%) ($p<0.05$). Presence of multinucleated cells was more frequent in DC+ embryos (487/1117; 43.6%) than DC- embryos (1411/10051; 14%) ($p<0.05$). GQB rate was significantly lower the earlier DC happened (DC+1 46/493; 9.3%, DC+2 106/476; 22.3%, DC+3 66/148; 44.6%; $p<0.05$). It is noteworthy that DC+3 GQB rate was similar to the control group (5298/10051; 52.7%) ($p=0.0601$). When only considering embryos biopsied on day 3, DC+ embryos had lower euploidy rates (8/84; 9.5%) than DC- ones (316/1036; 30.5%) ($p<0.05$). However, on day 5/6 biopsy, the euploidy rate was equivalent (DC+ 30/82; 36.6% vs DC- 497/1300; 37.9%; $p=0.8569$), as was pregnancy rate (DC+ 7/12; 58.3% vs DC- 228/325; 70.2%; $p=0.5786$) and ongoing pregnancy rate (DC+ 5/12; 41.7% vs DC- 185/325; 56.9% $p=0.4531$). Differences in mosaicism rates were not significant (DC+ 10/82; 12.2% vs DC- 237/1300; 18,2%; $p=0.2168$).

Limitations, reasons for caution: Due to their decreased potential depending on the moment of DC, the number of DC+ embryos biopsied and/or transferred was lower compared to DC-. A larger sample in the study group is necessary to confirm the above results.

Wider implications of the findings: Embryos with early DC+ should never be the first option for transfer. From our results, in cases where PGT is indicated, biopsy must be performed on day 5/6. If an embryo is capable of developing into a GQB, events that are linked to bad prognosis may have been resolved.

Trial registration number: not applicable

O-234 Application of the embryo-uterus statistical model for prediction of implantation after day 3 embryo transfer by using time-lapse morphokinetics and female age

E. Van Marion[1], E. Baart[1], E. Van Santbrink[2], M. Avo Santos[2], J. Laven[1], M. Eijkemans[3]

[1]Erasmus University Medical Centre Rotterdam, Division of Reproductive Endocrinology and Infertility- Department of Obstetrics and Gynaecology, Rotterdam, The Netherlands ;

[2]Reinier de Graaf Groep, Division of Infertility- Department of Obstetrics and Gynaecology, Voorburg, The Netherlands ;

[3]University Medical Centre Utrecht, Biostatistics and Research Support, Utrecht, The Netherlands

Study question: Can we develop a robust and clinically applicable time-lapse morphokinetic model, which predicts embryo implantation potential after single embryo transfer (SET)?

Summary answer: A prediction model based on the time interval between the four- and five-cell stage and female age showed adequate performance on an independent data set.

What is known already: Over the past years, time-lapse embryo culture is increasingly used as a semi-quantitative tool to research the timing of embryo development and the correlation with implantation. Studies with different sample sizes and statistical approaches have led to either centre specific or generally applicable models to support embryo selection. The predictive capability of time-lapse selection algorithms may be influenced by patient characteristics, type of data included in the analysis and the used statistical methods. Earlier studies excluded double embryo transfer (DET) cycles of which only one embryo implanted, introducing bias in the data.
Study design, size, duration: This is a retrospective study of couples (n= 707) undergoing an *in vitro* fertilization (IVF) cycle with or without intracytoplasmic sperm injection (ICSI) at the Erasmus University Medical Centre between January 2012 and June 2019. Embryo transfer was either SET or DET. This resulted in 785 transferred embryos that reached at least the five-cell stage. Embryo selection was not guided by time-lapse morphokinetics but was performed on day 3 according to classic morphological criteria.
Participants/materials, setting, methods: Embryos were cultured in the EmbryoScope™ and retrospectively annotated for developmental time points up to the 8-cell stage. The final prediction model was established by using the Embryo-Uterus model (EU) (Roberts, Stat Med 2007:p156) with the number of gestational sacs as the outcome variable. Correlations between embryos that implanted simultaneously were included in the model. The model was externally validated on time-lapse data from 1269 fresh embryo transfers performed at the Reinier de Graaf hospital.
Main results and the role of chance: We performed manual backward selection using $P < 0.3$ for inclusion in a multivariable EU-regression analysis with the following parameters: female age, time to three-cell stage (t3), time-interval between the two- and the three-cell stage (t3-t2), time to four-cell stage (t4), time-interval between the four- and the five-cell stage (t5-t4), and the ratio of the time-interval between the three- and the five-cell stage and the two- and the five-cell stage (t5-t3/t5-t2). As the relationship between these parameters and gestational sacs was non-linear, they were included using cubic splines. All variables were entered in the Embryo part of the model. This resulted in a final model including female age and t5-t4, yielding the probability of clinical pregnancy after SET, with the optimal timing of t5-t4 between 10-14 hours. An embryo that needs less time between t5-t4 shows a steeper decrease in implantation potential than if it needs longer. This was consistent for all female ages. The area under the receiver operating characteristic curve (AUC) of the final model was 0.624. The model was capable of predicting clinical pregnancy in the external dataset with an AUC of 0.639 and showed adequate calibration with a slope of 1.235.
Limitations, reasons for caution: Although the model shows good calibration and validation, prospective validation is needed to establish clinical applicability. Embryo transfer (ET) was performed on day 3. For clinics performing day 5 ETs the model can be relevant for poor responders or patients that do not want to culture until day 5.
Wider implications of the findings: We were able to minimize selection bias by analysing both SETs and DETs irrespective of the number of implanted embryos and selecting embryos for transfer by morphology alone. This model can be used to counsel couples on their pregnancy chances before embryo transfer, and as a decision tool for cryopreservation.
Trial registration number: not applicable

O-235 Does calcium ionophore treatment have any effect on embryo kinetics?

I. Keles[1], B. Balaban[2], A. Isıklar[2], S. Ertaş[2], B. Urman[2], B. Ata[1], K. Yakin[3]

[1]Koc University Hospital, Assisted Reproduction Unit, ISTANBUL, Turkey ; [2]American Hospital of Istanbul, Assisted Reproduction Unit, Istanbul, Turkey ; [3]Koc University, Obstetrics and Gynecology, Istanbul, Turkey

Study question: Is oocyte activation with calcium ionophore associated with morphokinetic parameters in cleavage and blastocyst stage embryos?
Summary answer: Embryos that were grown from activated oocytes did not show any difference in terms of morphokinetic parameters.
What is known already: Alterations in calcium signalling may be one of the underlying reasons for defects in cell growth and clevage. It has been shown in humans that calcium fluctuations were detected with a peak shortly before cell division and these calcium oscillations disappeared in arrested embryos. Clinical use of calcium ionophore treatment after intracytoplasmic sperm injection (ICSI) demonstrated an improvement in fertilization, cleavage and blastulation rates in couples with fertilization failures or severe male factor infertility. However, there is no data available on the morphokinetic evaluation of embryos developed following activation.
Study design, size, duration: This retrospective cohort study included 798 embryos from 484 couples undergoing ICSI from 2018-2020. We used propensity score matching to compare the morphokinetic parameters of embryos that were developed following ICSI with or without oocyte activation via ready to use calcium ionophore.
Participants/materials, setting, methods: The indication for oocyte activation was either severe male factor infertility or previously failed/low fertilization(≤ 25%). After excluding women ≥40-year of age, the study group comprised 121 women and the control group 363 . Groups were re-analysed according to female age and ICSI indication . All embryos were cultured in a timelapse incubator in the same single step medium and annotated at t2, t3, t4, t5, t8 and tB time points by a single embryologist.
Main results and the role of chance: The mean female age was 33.7 years (19-40). Morphokinetic measurements showed normal distributions. The mean annotation time points for "t2, t3, t4, t5, t8 and tB" in the control versus study group were in the following order: 26.8 vs 26.9, 35,0 vs 35.2, 38.4 vs 38.3, 46.6 vs 47.0, 56.1 vs 55.5, 104.9 vs 103.8 hrs ($p>0.05$ for all). When adjusted according to female age and ICSI indication, no difference was detected between two groups for any time points.
Limitations, reasons for caution: This was a single center retrospective study reporting on a limited number of ICSI cycles in which calcium ionophore treatment was deemed necessary.
Wider implications of the findings: Calcium ionophore treatment of oocytes to improve fertilization and/or clinical outcome in selected patients does not have a significant impact on embryo kinetics.
Trial registration number: Not Applicable

SESSION 60: LONG TERM HEALTH, OBSTETRICS AND NEONATAL OUTCOMES RELATING TO INFERTILITY TREATMENT

08 July 2020 Parallel 2 10:00 - 11:45

O-236 Pregnancy, Delivery, and Neonatal Outcomes Among Women with Congenital Adrenal Hyperplasia: A population based study on 9.1 million pregnancies

A. Badeghiesh@gmail.com[1], H. Baghlaf[2], E. Suarthana[1], M. Dahan[1]

[1]Mcgill University, Obstetric and Gynecology department, Montreal, Canada ; [2]University of Toronto, Obstetrics & Gynecology, Toronto, Canada

Study question: What are the pregnancy, delivery and neonatal outcomes in congenital adrenal hyperplasia (CAH) patients?
Summary answer: CAH patients have a two-fold higher risk of; chorioamnionitis, maternal infection and cesarean section also fetal increases in small for gestational age and congenital malformation
What is known already: Congenital adrenal hyperplasia (CAH) is a cluster of inherited enzymatic defects of adrenal steroid biosynthesis. Deficiencies of each enzyme required in the steroid biosynthesis pathway are well known, and these deficiencies are all inherited as autosomal recessive disorders. Women with CAH have decreased fertility because of oligo-ovulation. Conception requires a combination of proper therapeutic compliance, careful endocrine monitoring, and often ovulation induction. There are significant gaps about pregnancy, delivery and neonatal outcomes among CAH patients. The purpose of this study is to investigate these outcomes.
Study design, size, duration: We conducted a retrospective population-based cohort study utilizing data from the Health Care Cost and Utilization Project-Nationwide Inpatient Sample database (HCUP-NIS) over 11 years from 2004 to 2014. We created a cohort of all deliveries between 2004 and 2014 inclusively. Within this group, all deliveries to women with CAH were identified as part of the study group (n=299), and the remaining deliveries were categorized as non-CAH births and comprised the reference group (n=9,096,489).

Participants/materials, setting, methods: Analysis was performed to identify the prevalence of pregnant women with CAH over the study duration. Demographic and clinical characteristics were compared between women with and without CAH using Chi-square test. All confounding variables were adjusted for using multivariate logistic regression, based on any significant differences between the two groups generating adjusted odds ratios (aOR).

Main results and the role of chance: There were 9,094,499 deliveries during the study period. 299 pregnant women were found to have CAH. Compared to the control group, CAH subjects were likely to be: older (p<0.001), white (p<0.001), have higher incomes (p<0.001), have private medical insurance (P<0.001), be obese (p<0.001), have a previous cesarean section (p<0.001), chronic hypertensive (7.4% versus 1.8%, p<0.001), pre-gestational diabetics (5% versus 0.9%, p<0.001), and have thyroid disease (11.7% versus 2.5%, p<0.001). Chorioamnionitis was higher in CAH compared to controls (aOR 2.67, 95% CI 1,17 -6.06). The rate of caesarian section (aOR 2.10, 95% CI 1,44 – 3.07) and maternal infection (aOR 2.63, 95% CI 1,22 -5.63) were higher in CAH. Rates of pregnancy induced HTN, preeclampsia, eclampsia, gestational diabetes, preterm delivery, preterm premature rupture of membranes and postpartum hemorrhage did not differ between CAH group and the control group.

At birth, 8% and 2.2% of the neonates were found to be small for gestational age (SGA) in CAH and control groups respectively (aOR 3.37 95% CI 1.86 - 6.11). Congenital anomalies were encountered in 2.7% of the CAH group compared to the control group (0.4%) (aOR 5.24 95% CI 2.31 - 11.90)

Limitations, reasons for caution: This retrospective analysis utilizes an administrative database, with its inherent limitations. Significant medical history or adverse pregnancy outcomes may be more often reported in patients with more significant conditions or outcomes

Wider implications of the findings: CAH patients are at risk of: chorioamnionitis, maternal infection and cesarean section. CAH is associated with small gestational age infants possibly related to chronic maternal steroid use. The rate of congenital malformations likely related to elevated androgens in female offspring and chronic glucocorticoid used in pregnancy was about 2.7%.

Trial registration number: not applicable

O-237 Vitamin D concentration at term in newborn-mother pairs with and without polycystic ovary syndrome: association with perinatal outcome

M. Kollmann[1], B. Obermayer-Pietsch[2], G. Pregartner[3], E. Lerchbaum[4], S. Feigl[1], P. Klaritsch[5]

[1]Division of Obstetrics and Maternal Fetal Medicine, Department of Obstetrics and Gynecology- Medical University of Graz, Graz, Austria ;
[2]Endocrinology Lab Platform- Department of Obstetrics and Gynecology and Division of Endocrinology and Metabolism, Department of Internal Medicine- Medical Uniersity of Graz, Graz, Austria ;
[3]Institute for Medical Informatics- Statistics and Documentation IMI, Medical University of Graz, Graz, Austria ;
[4]Division of Endocrinology and Metabolism, Department of Internal Medicine- Medical University of Graz, Graz, Austria ;
[5]Division of Obstetrics and Maternal Fetal Medicine, Department of Obstetrics and Gynecology, Graz, Austria

Study question: Do mothers with/without PCOS have different vitamin D levels at term, how are vitamin levels reflected in their offspring, and are vitamin levels associated with an adverse perinatal outcome?

Summary answer: Vitamin D levels did not differ significantly in women with/without PCOS and their respective offspring. Vitamin D deficiency was not associated with adverse perinatal outcome.

What is known already: Studies suggest that non pregnant women with PCOS may be at elevated risk of vitamin D deficiency. Furthermore, there is evidence suggesting that vitamin D may also play an important role during pregnancy. Data regarding vitamin D deficiency during pregnancy in PCOS patients and its association with perinatal outcome is scarce.

Study design, size, duration: Prospective cross-sectional study

Participants/materials, setting, methods: We included 79 women with PCOS according to the ESHRE/ASRM 2003 definition and 354 women without PCOS and an ongoing pregnancy ≥ 37 + 0 weeks of gestation who gave birth in our institution between March 2013 and December 2015. Maternal serum and cord blood vitamin D levels were analysed at the day of delivery.

Main results and the role of chance: Maternal vitamin D levels did not differ significantly in women with PCOS and without PCOS (p=0.998), nor did the vitamin D levels of their respective offspring (p=0.692). Vitamin D deficiency (< 20 ng/mL) was found in 26.9% and 22.5% of women with and without PCOS (p=0.430). There was a strong positive correlation between maternal and neonatal vitamin D levels in both investigated groups. Linear regression estimates of cord blood vitamin D levels are about 77% of serum vitamin D concentrations of the mother. Compared to healthy controls, the risk for maternal complications was increased in PCOS women (48% versus 65%; p=0.009), while there was no significant difference in neonatal complications (22% versus 22%; p=1.0). However, vitamin D levels were similar between mothers and infants with and without perinatal complications.

Limitations, reasons for caution: Fetal cord blood was used for the analysis of fetal hormonal levels.

Wider implications of the findings: Although the share of women and infants with vitamin D deficiency was high in women with and without PCOS, it seems that the incidence of adverse perinatal outcome was not affected. The long-term consequences for mothers and infants with a vitamin D deficiency have to be investigated in future studies.

Trial registration number: NCT02106676

O-238 Early ovarian ageing and long-term health consequences: Is number of oocytes harvested in ART associated to an earlier and increased risk of age-related diseases?

M.W. Christensen[1], U.S. Kesmodel[2], K. Kirkegaard[3], H.J. Ingerslev[2]

[1]Århus University Hospital, Obstetrics and Gyneacology, Aarhus N, Denmark ;
[2]Aalborg University Hospital, Fertility Unit, Aalborg, Denmark ;
[3]Aarhus University Hospital, Obstetrics and Gyneacology, Aarhus N, Denmark

Study question: Do young women with early ovarian ageing defined as unexplained, repeatedly few oocytes harvested in ART have an increased risk of age-related diseases?

Summary answer: At follow-up young women with idiopathic early ovarian ageing had an increased risk of age related diseases compared to young women with normal ovarian ageing.

What is known already: Early and premature menopause is associated with an increased risk of cardiovascular diseases (CVD), osteoporosis and death. Identifying women at risk may thus allow early preventive health initiatives. Repeatedly few oocytes harvested in well stimulated assisted reproductive technology (ART) cycles is a likely predictor of advanced menopausal age when seen in young women and may thus serve as an early marker of accelerated general ageing. Oocyte harvest in ART as a measure of ovarian ageing and thus as a risk predictor of age-related morbidity and mortality has not been investigated previously.

Study design, size, duration: A register-based national historical cohort study. Young women (≤ 37 years) having their first ART-treatment in a Danish fertility clinic (public or private) during the period 1995-2014 was divided into two groups dependent on ovarian reserve status: early ovarian ageing(EOA) (n=1,234) and normal ovarian ageing(NOA) (n=18,614). Number of oocytes harvested in first and subsequent cycles was used as a marker of ovarian reserve. Several national registers were applied to assess morbidity and mortality.

Participants/materials, setting, methods: EOA was defined as ≤ 5 oocytes in minimum two well-stimulated cycles and NOA as ≥8 oocytes in minimum 1 cycle. Known causes influencing the ovarian reserve (endometriosis, surgery, chemotherapy etc.) was reason for exclusion. Primary outcome was overall-disease risk defined as either: CVD, osteoporosis, type-2 diabetes, cancer, all-cause death, Charlson Comorbidity index, cataract, Alzheimer's or Parkinson's disease or early retirement benefit. Cox regression models were used to assess the disease risk after first ART-cycle.

Main results and the role of chance: Median follow-up time from first ART-cycle to first disease event was 6.1 years (10/90 percentile 1.0/12.9) and 6.7 years(10/90 percentile 1.0/14.1) in the EOA -and NOA group respectively. Women with EOA had an increased risk of overall- disease when compared to women with a normal oocyte yield (Adjusted HR 1.26, 95 % CI 1.10;1.43). Stratifying on diseases categories, the EOA group had a significantly increased risk for cardiovascular diseases (adjusted HR 1.39, 95 % CI 1.15; 1.67),

osteoporosis (adjusted HR 2.36, 95 % CI 1.48;3.74), Charlson comorbidity index (Adjusted HR 1.28, 95 % CI 1.06;1.54) and early retirement benefit (adjusted HR 1.52, 95 % CI 1.06;2.19).

Limitations, reasons for caution: Due to register limitations we were unable to identify the reason why no oocytes had been collected in case of cancelled cycles and we may have missed women with the most severe forms of EOA. Neither did we have information on the total doses of gonadotropin given in each cycle.

Wider implications of the findings: These findings indicate that oocyte yield may serve as marker of later accelerated ageing when unexpected, repeatedly few oocytes are harvested in young women. Counselling on life-style factors as a phrophylactic effort against cardiovascular and other age related diseases may be essential for this group of women.

Trial registration number: The study was approved by the Danish Data Protection Agency (J.nr 1-16-02-319-14)

O-239 The worldwide epidemic of Vitamin D deficiency: are we contributing by using inaccurate and unreliable measurement methods?

E.E. Lara Molina[1], J.M. Franasiak[2], A. Devesa-Peiro[3], M. López-Nogueroles[4], M. Florensa[5], M. Martin[5], D. Amoros[6], A. Ballesteros[7], A. Pellicer[8], P. Diaz-Gimeno[9]

[1]IVI RMA Global Barcelona, Egg Donation, Barcelona, Spain ;

[3]Valencia University, Gynecology and Obstetrics, Valencia, Spain ;
[4]Biomedical Research Institute La Fe, Analytical Unit, Valencia, Spain ;
[5]IVI RMA Global Barcelona, IVF laboratory, Barcelona, Spain ;
[6]IVI RMA Global Barcelona, General laboratory, Barcelona, Spain ;
[7]IVI RMA Global Barcelona, Reproductive Unit, Barcelona, Spain ;
[8]IVI RMA Global Rome, IVI RMA Global President, Rome, Italy ;
[9]Biomedical Research Institute La Fe, IVI Foundation IVI RMA Global, Valencia, Spain

Study question: Is Vitamin D deficiency diagnosis biased by which measurement technique is utilized?

Summary answer: 25-hydroxyvitamin D (25OHD) serum concentrations are significantly lower when measured via Enzyme-Linked Immunosorbent Assay (ELISA) compared to Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS).

What is known already: Vitamin D deficiency is widely reported in general population and in women undergoing ART, but lack of accuracy when measuring its metabolites remains as an unresolved issue. 25OHD is the most abundant vitamin D metabolite in the circulation, and is proposed to be the best indicator of vitamin D status. Although LC-MS/MS for serum 25OHD measurement is theoretically a more accurate and reliable technique than immunoassay-based methods, these are faster and less laborious, and are more commonly used for Vitamin D assessment in the general practice.

Study design, size, duration: 34 healthy women participating in our egg donation program were included during four months in this prospective, non-interventional cohort study. Serum samples were collected for quantification of 25OHD concentrations with the use of LC-MS/MS procedure and with ELISA. 25OHD levels according to IOM guidelines (<20, 20-30, and >30 ng/mL) were evaluated according each method results.

Participants/materials, setting, methods: Serum was obtained in each subject, and then separated into two samples. 25OHD concentrations in one of the samples were measured via LC-MS/MS using a UPLC-TQ-S Xevo Waters system with a Waters Acquity BEH C18 (1,7µm 2,1 x100mm) column. A Vitamin D Enzyme-Linked Immunosorbent Assay (ELISA) kit (ab213966) Abcam for the quantitative determination of 25OHD was used for the other sample. A paired Wilcoxon test was performed for contrasting the mean differences between both techniques.

Main results and the role of chance: All the cases were included and studied during autumn and winter months. None of them had taken vitamin D oral supplements during the last six months before sampling. Mean value for 25OHD concentrations in serum was 36.96±15.78 ng/ml when measuring via LC-MS/MS, and significantly lower when ELISA method was used (20.74 ± 21.73 ng/ml, p-value=1.255e-05). According to IOM guidelines, there was no Vitamin D deficiency in our studied population of 34 healthy women on reproductive age when LC-MS/MS is utilized, and most of them were in the sufficiency range of >30 ng/ml (n=23; 67.65%). In contrast, this population could be classified in the insufficiency range according to mean values obtained via ELISA method, most of them showing concentrations bellow <20ng/ml (n=23; 67.65%).

Limitations, reasons for caution: The study population was a rather homogenous group of young, healthy women. These findings need to be confirmed in a larger, more diverse patient population**.**

Wider implications of the findings: Utilizing ELISA to measure serum vitamin D levels results in an overestimation of vitamin D deficiency and may explain the increased prevalence in the population. Thus, LC-MS/MS should be considered as a more reliable procedure to measure Vitamin D in research and clinical practice.

Trial registration number: not applicable

O-240 Polycystic Ovary Syndrome as an independent risk factor for gestational diabetes and hypertensive disorders of pregnancy: A population-based study on 9.1 million pregnancies

G. Mills[1], A. Badeghiesh[2], E. Suarthana[2], H. Baghlaf[2], M. Dahan[3]

[1]McGill University, Ob GYN, Montreal, Canada ;
[2]McGill University, Ob Gyn, Montreal- QC, Canada ;
[3]McGill University, McGill University Health Center Reproductive Center, Montreal- QC, Canada

Study question: Does polycystic ovary syndrome (PCOS) confer an independent risk for the development of gestational diabetes (GDM), gestational Hypertension (GHTN), and pre-eclampsia (PEC)?

Summary answer: PCOS confers a two-fold higher risk of developing GDM, a 50% increased risk for of developing GHTN, and a 30% increased risk of developing PEC.

What is known already: Despite significant evidence of an increased prevalence of maternal pregnancy complications in women with PCOS, there remain significant gaps in understanding how PCOS affects the development of GDM, GHTN, and PEC. This is most likely due to the complex, multifactorial etiology of PCOS, its range of potential confounders for pregnancy complications, and the variable methodology of studies that have been conducted. To date, the largest meta-analysis on this subject includes 11, 565 women with PCOS analyzed for their risk of GDM and 5896 patients analyzed for their risk of PEC.

Study design, size, duration: We conducted a retrospective population-based cohort study utilizing data from the Health Care Cost and Utilization Project-Nationwide Inpatient Sample database (HCUP-NIS) over 11 years from 2004 to 2014. We created a cohort of all deliveries between 2004 and 2014 inclusively. Within this group, all deliveries to women with PCOS were identified as part of the study group (n=14,882), and the remaining deliveries were categorized as non-PCOS births and comprised the reference group (n=9,081906).

Participants/materials, setting, methods: The analysis was performed to identify the prevalence of pregnant women with PCOS over the study duration. Baseline clinical and demographic characteristics between both groups were compared. Logistical regression analyses were conducted to explore associations between PCOS and maternal metabolic outcomes through the estimation of odds ratio (OR) and 95% confidence intervals (CI). The regression models were adjusted for the potential confounding effects of maternal demographic, preexisting clinical characteristics, and concurrently occurring characteristics.

Main results and the role of chance: At baseline, more pregnant women with PCOS had obesity (22.3% vs. 3.5% p<0.001), chronic hypertension (8.4% vs. 1.8% p<0.001), pre-gestational diabetes (4.1% vs. 0.9% p<0.001), and thyroid disease (12.6% vs. 2.4% p<0.001). Women with PCOS were more likely to have undergone IVF treatment (2.4% vs. 0.1% p<0.001), have multi-gestation pregnancies (5.9% vs. 1.5% p<0.001), and more multiple gestations in the PCOS cohort were the result of IVF treatment than the Non-PCOS cohort (12.3% vs. 2.3% p<0.001).

In singleton pregnancies, women with PCOS were more likely to develop gestational diabetes (aOR 2.17, 95% CI 1.99-2.35), pregnancy-associated HTN (aOR 1.41 95% CI 1.29-1.54 p<0.001), gestational hypertension (aOR 1.48, 95% CI 1.31-1.66), pre-eclampsia (aOR 1.31, 95% CI 1.15-1.50), and superimposed pre-eclampsia (aOR 1.34, 95% CI 1.07-1.67) after controlling for confounding effects (age, race, income level, insurance type, obesity, IVF use, previous C/S, chronic HTN, pre-gestational diabetes, thyroid disease, smoking,

and recreational drug use). In multiple gestation pregnancies, PCOS only conferred an increased risk of developing GDM (aOR 2.33 95% CI 1.92-2.83 p<0.001). However, there was a non-significant trend towards an increased risk for developing pregnancy-associated HTN (aOR 1.92 95% CI 0.99-1.42 p=0.058) in the multiple gestations group.

Limitations, reasons for caution: This retrospective analysis utilizes an administrative database, relies on the accuracy of individuals reporting and coding data. Remote diagnoses of PCOS or mild phenotypes may not have been reported. Significant medical history and/or adverse pregnancy outcomes may be more often reported in patients with more significant conditions and outcomes.

Wider implications of the findings: PCOS is an independent risk factor for the development of GDM, GHTN, and PEC. It is important to consider the risk of all other co-existing metabolic conditions in women with PCOS, as these risks are additive and can significantly increase the risk of adverse complications in pregnancy.

Trial registration number: not required

O-241 GNRH antagonist administration to decrease risk of OHSS in GNRH agonist cycles triggered with HCG

G. Mills[1], S.Y. Dahan[1], M.H. Dahan[1]

[1]McGill University Health Centre, Obstetrics and Gynecology, Montreal, Canada

Study question: Does administration of a gonadotropin-releasing hormone antagonist after HCG trigger in GnRH agonist cycles with significant stimulation reduce the risk of developing ovarian hyperstimulation syndrome?

Summary answer: Addition of GnRH antagonist for 7-10 days to cabergoline treatment after hCG-trigger in agonist cycles reduces the risk of moderate/severe OHSS compared to cabergoline alone

What is known already: In ART cycles that cannot or have not undergone a GnRH agonist trigger, such as in GnRH agonist cycles or when OHSS signs and symptoms appear in low risk cycles after administration of hCG, secondary risk reduction strategies can be employed. Currently, the two main secondary OHSS risk reduction strategies are to avoid fresh embryo transfer to prevent endogenous production of hCG, and administration of the dopamine agonist, cabergoline. However, when using these strategies, the risk of moderate and severe OHSS remains present.

Study design, size, duration: A retrospective cohort study of 171 IVF patients at the McGill University Health Centre treated with GnRh-agonist protocols and with unexpected exuberant response to stimulation from 2011-2019 was performed. Women received triggering with 5000IU urinary hCG or 250mcg recombinant hCG, and were converted to freeze all cycles.

Participants/materials, setting, methods: Patients were allocated to one of two groups. The NO-ANT group (n=123) received cabergoline (Pfizer, Montreal, Canada) 0.5 mg daily, and the ANT group (n=48) received cabergoline treatment and GnRH antagonist (ganirelix, Orgalutran® 0.25 mg/0.5 ml, Merck, Canada). Treatment in both groups lasted for 7 days starting on the oocyte retrieval day. If moderate or severe OHSS occurred, GnRH antagonist was continued for 10 days. No fresh embryo transfers were performed.

Main results and the role of chance: 171 patients were identified as being at risk for developing OHSS after receiving an hCG trigger as part of an agonist cycle. There were no differences between the two groups (No-ANT vs. ANT, respectively) in terms of; age (36.2±2.8 vs. 35.8±3.2 years *p=0.42*), basal serum FSH levels (8.1±2.3 vs. 7.9±2.3 IU/L *p=0.61*), or AFC (12.2±2.4 vs. 11.6±1.9, *p=0.12*). The ANT group had more oocytes collected (18.6 vs. 17.1 *p=0.03)*, more 2PN embryos (14.3 vs. 12.2 *p<0.001)*, and more frozen blastocysts (4.4 vs. 3.9 *p=0.04)*.

The NO-ANT group had more cases of moderate and severe OHSS (52% vs 25% *p = 0.001*, and 25% vs 10% *p = 0.03,* respectively), more occurrences of free pelvic fluid (74% vs. 35% *p<0.001),* and more bloating and discomfort (91% vs. 65% *p<0.001)* than patients in the ANT group. The number of peritoneal ascites drainages/cases of severe OHSS were lower in ANT group (0.4 vs. 1.2 *p=0.01*).

The ANT group had lower serum hemoglobin (14.2±1.4 g/dl vs. 15.1±1.3 g/dl *p<0.001)*, higher serum albumin (29.4±3.4g/L vs. 23.6±2.9g/L *p<0.001)*, higher serum sodium (132.9±2.6 vs. 132.0±2.2 mEq/L *p=0.02*), and lower serum potassium levels (4.6±0.7 vs. 5.2±1.0 mEq *p<0.001*) than the NO-ANT group.

Limitations, reasons for caution: As a retrospective cohort study, there may be some amount of selection and misinformation bias that cannot be accounted for. This study has a relatively small sample size, suggesting the possibility of a type I error. However, given the levels of significance between group outcomes, however, this risk remains low.

Wider implications of the findings: Addition of GnRH antagonist for 7-10 days to routine cabergoline treatment after an hCG trigger in agonist cycles may reduce the risk of developing moderate and severe OHSS compared to cabergoline alone. Further studies are warranted to determine if GnRH-antagonists can be used as a treatment for OHSS once started.

Trial registration number: Not Applicable

O-242 Artificially prepared frozen embryo transfer cycles are associated with an increased risk of preeclampsia.

C. Roelens[1], A. Racca[1], S. Mackens[1], L. Van Landuyt[1], L. Gucciardo[2], M. De Vos[1], H. Tournaye[1], C. Blockeel[1]

[1]UZ Brussel, Centre for Reproductive Medicine, Jette, Belgium ;
[2]UZ Brussel, Department of Obstetrics and Prenatal Medicine, Jette, Belgium

Study question: Is the development of preeclampsia (PE) following frozen embryo transfer (FET) related to the method of endometrial preparation?

Summary answer: Hormonal replacement therapy (HRT) FET cycles are associated with a significantly higher risk of developing PE when compared with natural cycle (NC) FET.

What is known already: PE is a multisystem disorder encountered in approximately 2-5% of pregnancies and a leading cause of maternal and perinatal mortality and morbidity. Although assisted reproductive technology (ART) is an established risk factor for the development of PE, the exact underlying mechanism has not been elucidated. Recent studies have shown a correlation between endometrial preparation before FET and the development of PE during a subsequent pregnancy. The impact of the absence of a corpus luteum on the hormonal environment and vascular adaptations in early pregnancy has been hypothesized as a possible contributing factor in the development of PE after HRT-FET cycles.

Study design, size, duration: We performed a retrospective cohort study at a tertiary university-based hospital encompassing 537 unique patients who had a pregnancy following FET between 2010 and 2019 and delivered in the same institution. 324 patients underwent FET in a NC while 213 performed a HRT cycle. A sample size calculation was performed and showed that 396 patients were needed to detect with 90% power a difference of 8.9% between study and control group.

Participants/materials, setting, methods: The primary outcome was the incidence of PE defined as the development of hypertension after 20 weeks of gestation associated with one or more new-onset conditions: proteinuria, maternal or uteroplacental dysfunctions. Multivariable regression analysis was performed to account for confounding factors knowing to affect the occurrence of PE, including: NC versus HRT, body mass index (BMI), ethnicity, previous history of hypertension during pregnancy and mean arterial pressure (MAP) at the first prenatal consultation.

Main results and the role of chance: No difference was found in the following baseline demographic and clinical characteristics between NC and HRT FET cycles: maternal age, BMI, nulliparity, smoking habits, associated medical conditions, partners age, developmental stage of the embryo, multiple pregnancy, term at delivery and birth weight. Patients suffering from PCOS and ovulation disorders were more commonly represented in the HRT group as compared with the NC group (41.3% versus 6.2%, p<0.001). African ethnicity was more frequent in the HRT group (15.9% versus 8.9% for HRT and NC respectively, p=0.021). Patients undergoing a HRT cycle delivered more often by caesarean section as compared with the NC group (42.7% versus 29%, p=0.001). MAP at the first prenatal consultation was significantly higher in HRT FET cycles (87.9 mmHg ± 17.8 and 82.9 mmHg ± 14.9 for HRT and NC respectively, p=0.001).

The incidence of PE was significantly lower in NC FET cycles (3.7% versus 11.3% for respectively NC and HRT FET cycles, p=0.001). Univariate and multivariate logistic regression analyses were performed in order to account for relevant confounding factors. After confounder adjustment the incidence of PE was significantly lower in the NC FET group (NC versus HRT: aOR 0.35, 95% CI 0.17-0.74, p=0.006).

Limitations, reasons for caution: Although the study adjusted for potential confounding factors, the results remain limited by the retrospective nature of the study and its potentially associated bias.
Wider implications of the findings: The higher incidence of PE in HRT versus NC FET cycles found in our population adds further weight to the existing data on this topic. These significant findings should urge practitioners to preferentially perform FET in a natural cycle instead of a HRT cycle in ovulatory patients.
Trial registration number: not applicable

O-243 High anti-Müllerian hormone levels are associated with preterm delivery in patients with polycystic ovary syndrome

K. Hu[1], F.T. Liu[2], R. Li[2]

[1]Peking University Third Hospital, Center for Reproductive Medicine- Department of Obstetrics and Gynecology, Beijing, China ;
[2]Peking University Third Hospital, Center for Reproductive Medicine, Beijing, China

Study question: Is the serum AMH levels associated with the risk of preterm delivery in PCOS patients?
Summary answer: High anti-Müllerian hormone levels are associated with preterm delivery in patients with polycystic ovary syndrome.
What is known already: Anti-Müllerian hormone (AMH) levels are higher in patients with polycystic ovary syndrome. Accumulating evidence indicates that AMH has an impact on the physiology of the female reproductive system. Increased AMH levels in PCOS patients are associated with PCOS severity and greater ovarian stimulation during IVF treatment. During pregnancy, serum AMH levels are also higher in PCOS than non-PCOS patients, and the elevated AMH levels observed in PCOS patients have an impact on the endocrine system of the fetus.
Study design, size, duration: This is a retrospective cohort study. A total of 25165 in vitro fertilization (IVF) cycles with AMH data performed from January 2017 to July 2018 in Peking University Third Hospital were available for analysis in this study..
Participants/materials, setting, methods: Among the 25165 cycles, 10718 were fresh embryo transfer (ET) cycles, and 14447 were frozen-thawed embryo transfer (FET) cycles. There were 136 preterm deliveries and 1777 term deliveries in the fresh ET group and 145 preterm deliveries and 1685 term deliveries in the FET group. In PCOS patients, 423 term deliveries and 45 preterm deliveries.
Main results and the role of chance: Serum AMH levels were not different between the term delivery and preterm delivery groups in the entire cohort (3.8 vs 4.1 ng/mL, P >0.05). In patients diagnosed with PCOS, those with preterm delivery had higher AMH levels than were found in those with term delivery (9.3 vs 6.9 ng/mL, P <0.01). Preterm deliveries predominated in PCOS patients with AMH levels above the 75th percentile (9.75 ng/ml) (adjusted P <0.0001, adjusted OR=4.0 (95%CI 1.94, 8.08), adjusted for age, BMI, indicated delivery associated complications, embryo transfer number, cesarean or vaginal delivery, fresh ET or FET, gravidity times, parity times, and sex of the infant) and frozen-thawed embryo transfer (FET) patients with AMH levels higher than the 90th percentile (10.10 ng/ml) (adjusted P <0.05, adjusted OR=2.0 (95%CI 1.16, 3.36), adjusted for age, BMI, indicated delivery associated complications, diagnosis (PCOS or non-PCOS), embryo transfer number, cesarean or vaginal delivery, fresh ET or FET, gravidity times, parity times, and sex of the infant). Indicated-delivery associated complications and male infants were risk factors for preterm delivery (adjusted P =0.01, adjusted OR=3.0 (95%CI 1.29, 6.87), adjusted P =0.02, adjusted OR=2.3 (95%CI 1.18, 4.58)). Serum AMH levels were not significantly associated with gestational diabetes or pre-eclampsia.
Limitations, reasons for caution: The main limitation of this study is its retrospective study design and lack of sample size calculation. Some patients with repeated IVF failure may get pregnant more than one year after AMH measurement, which may be different from the exact AMH levels during the cycle of successful pregnancy.
Wider implications of the findings: Our results will guide clinicians to better manage the process of pregnancy in these patients. It will be interesting for further studies to investigate the potential mechanisms underlying these effects.
Trial registration number: not applicable

Study question: What is the role of nuclear receptor (NRs) and their interaction with cofactors in mouse spermiation?
Summary answer: Our data establish that gene repression mediated in Sertoli cells by NCoR-bound RARA/RXRB heterodimers is instrumental to spermiation in mouse.
What is known already: The activity of nuclear receptors is thought to be mediated by interaction with coactivators or corepressors. In the absence of their cognate ligands, it is admitted that NRs bound to the DNA response elements located in their target genes recruit corepressors and inhibit mRNA expression. The physiological impact of NR-mediated gene repression is poorly characterized. We have shown previously that loss-of-function mutants of RARA or RXRB display spermiation defects.
Study design, size, duration: To address this question, we have generated and analyzed the phenotypes of mice expressing a mutant form of *all-trans* retinoic acid (ATRA) receptor alpha (RARA) which specifically disrupts corepressor binding without affecting agonist-dependent coactivator binding (RARA I396E mutation). We have additionally generated mice in which *NCor1* and *NCor2* were knocked out specifically in Sertoli cells.
Participants/materials, setting, methods: Histological analysis of testes from RARA-I396E expressing mice and also of testes from NCor1 and NCor2 compound double mutants in Sertoli cells were performed together with in situ hybridization techniques, immunofluorescence and transcriptome analyses.
Main results and the role of chance: We demonstrate here that this specific mutations impair spermiation (i.e., the release of mature spermatids by the seminiferous epithelium (SE) of the testis), a hallmark of the phenotype observed upon ablation of RARA or of RXRB in Sertoli cells. Moreover, the combined, Sertoli cell-specific, ablation of the two genes encoding the corepressors NCor1 and NCor2 mimics the spermiation defect observed in RARA-I396E expressing mice. Transcriptome analysis revealed deregulation of a specific set of genes, some of which may control spermatid release. This strongly suggests that gene repression mediated in Sertoli cells by NCoR-bound RARA/RXRB heterodimers is controlling spermiation. It is likely that this repressing activity occurs when the level of ATRA available in the SE is low, which corresponds to stages I to VI of the SE cycle, just prior to spermiation.
Limitations, reasons for caution: Since our present results were obtained in mice, their relevance for human spermatogenesis remains to be demonstrated.
Wider implications of the findings: Pharmacological studies strongly support a role of the ATRA signaling pathway in human spermatogenesis. The evidence provided in this work might suggest that changing RARA activity by

pharmacological approaches in humans might be used to help patients with spermiation defects and to design new male contraceptive strategies.
Trial registration number: Not Applicable

O-245 MicroRNA-targeting in spermatogenesis: Over-expressions of microRNA-23a/b-3p and its affected targeting of the genes ODF2 and UBQLN3 in sperm of patients with oligoasthenozoospermia

M. Abu-Halima[1], B. Ayesh[2], L. Becker[1], M. Hammadeh[3], A. Keller[4], M. Eckart[5]

[1]Saarland University, Institute of Human Genetics, Homburg/Saar, Germany ; [2]al-Aqsa University, Department of Laboratory Medical Sciences, Gaza, Palestine ; [3]Saarland University, Department of Obstetrics and Gynecology- IVF and Andrology Laboratory, Homburg/Saar, Germany ; [4]Saarland Univsersity, Chair for Clinical Bioinformatics, Saarbrücken, Germany ; [5]University of Saarland, Institute of Human Genetics, Homburg/Saar, Germany

Study question: To investigate whether microRNA-23a/b-3p targets the genes *ODF2* and *UBQLN3* and whether this targeting impacts expression levels of *ODF2* and *UBQLN3* in patients with oligoasthenozoospermia.
Summary answer: The over-expression of microRNA-23a/b-3p and lower-expression of *ODF2* and *UBQLN3* genes are associated with male subfertility.
What is known already: Spermatogenesis is the process of male germ cell proliferation and differentiation within the testes. In this complex and highly regulated process, many genes are involved, the expression levels of which are strongly or partially coordinated by microRNAs (miRNAs). MiRNAs are small, non-coding RNAs that are involved in the post-transcriptional regulation of gene expression. Transcriptome analysis shows that hundreds of genes are expressed exclusively or predominantly in male germ cells including *ODF2* and *UBQLN3*, which play a crucial role during spermatogenesis and/or sperm function. However, the expression regulation of these two genes is still unclear.
Study design, size, duration: A total of 86 men were included in the study, including 43 oligoasthenozoospermic men who attended the IVF center for infertility treatment at Saarland University, Germany and 43 age-matched normozoospermic volunteers served as controls. Reverse transcription-quantitative PCR (RT-qPCR), Northern blot, and dual luciferase assay were used to validate the over-expression of microRNA-23a/b-3p and lower-expression of ODF2 and UBQLN3 genes. The study was conducted between 2019 – 2020, at the Institute of Human Genetics.
Participants/materials, setting, methods: Total RNA, including miRNA was isolated from sperm of oligoasthenozoospermic (n=43) and normozoospermic men (n=43). RT-qPCR was used to detect the expression levels of microRNA-23a/b-3p and *ODF2* and *UBQLN3* genes. In silico prediction and dual-luciferase assays were performed to confirm the potential links between the over-expression of microRNA-23a/b-3p and lower-expression of *ODF2* and *UBQLN3* genes. Correlation analyses of the miRNA and mRNA expression levels were done for clinical sperm parameters.
Main results and the role of chance: The expression levels of microRNA-23a/b-3p were significantly up-regulated and *ODF2* and *UBQLN3* genes were significantly down-regulated in oligoasthenozoospermic men compared with age-matched normozoospermic men as determined by RT-qPCR. Using dual-luciferase assays, *ODF2* and *UBQLN3* genes were identified as direct targets of microRNA-23a/b-3p. Mutations in the microRNA-23a/b-3p binding site within the 3′UTRs (3′untranslated regions) of *ODF2* and *UBQLN3* genes resulted in abrogated responsiveness to microRNA-23a/b-3p. Correlation analysis highlighted that sperm count, motility, and morphology was negatively correlated with microRNA-23a/b-3p and positively correlated with the lower expression level of *UBQLN3*, while *ODF* lower expression level was positively correlated with sperm motility.
Limitations, reasons for caution: Despite the negative correlation between the over-expression of microRNA-23a/b-3p and the lower-expression of *ODF2* and *UBQLN3* genes, further validation of these results is needed by an increased number of studied men and by a confirmation of the protein expression by Western blotting.
Wider implications of the findings: Findings suggest that the over-expression of microRNA-23a/b-3p or the lower-expression of *ODF2* and *UBQLN3* genes are associated with oligoasthenozoospermia and male infertility, probably through influencing sperm count, motility, and morphology. This study lay the groundwork for future studies focused on investigating therapies for male infertility.
Trial registration number: Ha195/11

O-246 Relevance of spermiogenic maturation of the male gamete through the epididymal journey

A. Melnick[1], A. Parrella[1], M.S. Wang[1], D. Tavares[1], M. Haddad[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Which area of the epididymis yields spermatozoa with the highest capacity for supporting embryonic development?
Summary answer: The cauda epididymis yields spermatozoa with optimal spermiogenic maturity, resulting in superior fertilization, embryo implantation, and delivery rates.
What is known already: Epididymal sampling is the preferred surgical treatment for men with obstructive azoospermia. The preferred site of retrieval is the caput, which is believed to yield the largest number of spermatozoa with superior kinetic characteristics. Only a few studies have described the fertilization competence of spermatozoa retrieved from the caput, corpus, and cauda regions of the epididymis.
Study design, size, duration: Between 2011 and 2019, 46 men diagnosed with obstructive azoospermia (OA) underwent surgical retrieval of spermatozoa from different areas of the epididymis. Spermatozoa were subsequently used for ICSI cycles with the patients' female partners (≤37 yrs old). Clinical outcome was compared among the different sources of spermatozoa.
Participants/materials, setting, methods: A total of 36 specimens from caput, 7 from corpus, and 3 from cauda were retrieved. Semen parameters were compared among the three sources, and spermatozoa were injected by ICSI in oocytes from the female partners. Fertilization, implantation, and delivery rates were assessed and compared for all the three epididymal locations. Unpaired t and Fisher's Exact tests were used to compare the outcomes. P values <0.05 were considered statistically significant.
Main results and the role of chance: A total of 46 men were divided in three groups according to the source of spermatozoa used: caput, corpus, and cauda. Maternal age was comparable among the three groups (32.0 ± 4, 32.1 ± 4, and 35.0 ± 1, respectively). Average and standard deviation of spermatozoa concentration was 35.1± 39 in the caput, 28.7±29 in the corpus, and 30.2± 59 x106/ml in the cauda.

The mean of motility was 15.8±15% in the caput, rising to 40.1±29.4% in the corpus (P<0.01) and decreasing to 7±11.8% in the cauda (P<0.05). The mean numbers of injected oocytes were 12.7, 11, and 12.5, respectively (P=NS). The fertilization rate was 65.8% with caput, 77.6% with corpus (P<0.05), and 88% (P<0.05) with cauda spermatozoa.

The implantation rate also progressively increased distally through the regions of the epididymis. In the caput, the implantation rate was 34.8%, rising to 44.4% and 57.1% in the corpus and cauda, respectively. The same trend was observed for delivery rates. In cycles using caput spermatozoa, the delivery rate was 48.4% with 5.8% pregnancy loss.

In cycles using corpus spermatozoa, the delivery rate was 75%, with no pregnancy loss. Ultimately, the cycles with cauda had the highest delivery rate, with 100%.
Limitations, reasons for caution: This novel study was performed on a small number of subjects. While we limited female age to ≤37 years, it is not possible to exclude all confounding factors with certainty. In men with OA, it is not always possible to choose the site of surgical sampling
Wider implications of the findings: We have found evidence that the epididymis retains an important role in spermiogenesis. This has been confirmed by the higher fertilization competence of spermatozoa retrieved from the cauda epididymis. Confirmation of these findings in a larger study population may serve as a guide for epididymal sperm retrieval.
Trial registration number: not applicable

O-247 Effect of malignancy on semen quality: An analysis of 3371 patients

E. Yasmin[1], T. Lukaszewski[1], E. Williamson[2]

[1]University College London Hospital, Obstetrics and Gynaecology, London, United Kingdom ;
[2]University College London Hospital, Reproductive Medicine, London, United Kingdom

Study question: How does malignancy and different diagnoses affect semen quality as compared with World Health Organisation (WHO) thresholds of semen analysis in fertile men?
Summary answer: A wide range of malignancies adversely affect semen quality led by testicular cancer and followed by bowel cancer, myeloma and leukaemia.
What is known already: The WHO (2010) published a set of reference values for semen analyses based on the assessment of fertile men with the threshold determined by fifth centiles. The WHO guideline is widely used to determine normality of semen analysis. Observational studies have shown the deleterious effect of malignancy on semen quality. Most studies have small cohorts and larger studies are limited to testicular cancer and haematological malignancies. One of the larger analysis of 4480 cases included both cancer and benign systemic diseases. This study demonstrated poorer sperm quality in different cancers but did not include lung, bowel, myeloma and prostate cancer.
Study design, size, duration: This is a retrospective observational study of single semen analysis prior to oncology treatment in 3371 patients. The data spans a 35 year period (1984-2019). All the samples were collected in a single centre. Only major groups of diagnoses were included in the analysis. Very small groups of heterogenous malignancies were excluded from the study.
Participants/materials, setting, methods: Semen analysis was performed in patients referred for fertility preservation and after they consented to sperm cryo-preservation. All patients were post pubertal. Semen analysis was based on the standardised protocol of the centre. The diagnoses, semen parameters and frozen samples were entered into a secure database. The groups were based on diagnosis. Distribution of the semen parameters at 5th, 10th, 25th, 50th, 75th and 95th was carried out and compared with the WHO references.
Main results and the role of chance: Of the 3371 patients, the majority (66%) were 20-39 yrs with 15.5% under 20yrs. Nearly a third of patients had testicular cancer (33%) and over a quarter had lymphoma (28%). Sarcoma was the third largest group (15%) followed by leukaemia (9%), prostate cancer (6.5%), brain tumour (4%), bowel cancer (3.5%), myeloma (1.5%), lung cancer (0.5%) and melanoma (0.5%). Oligozoospermia (<15mill/ml) was observed in nearly half (46.5%) of patients with testicular cancer followed by bowel cancer (43%), myeloma (41%) and leukaemia (40%). Azoospermia was noted in 4-12% of patients across all diagnoses bar melanoma. The centile distribution of sperm count, sperm concentration, motility and volume revealed normal parameters (as per WHO threshold at 5th centile) only at 50th centile in testicular, brain and bowel cancer, leukaemia and melanoma. Normal values were seen at 25th centile in lymphoma, lung cancer and sarcoma. The threshold of normal was noted at 10th centile in the melanoma group. The study highlights that semen quality is significantly diminished across all diagnoses. The centile distribution of the patients did not match the distribution in fertile men on which the WHO thresholds are based in any diagnosis. Semen quality was significantly affected in bowel, lung and prostate cancer.
Limitations, reasons for caution: A single sample of semen was used for analysis and therefore variation was not accounted for. Period of abstinence could not be standardised as the samples had to be collected at short notice in the context of fertility preservation.
Wider implications of the findings: The findings of the study can be used to inform clinicians and counsel patients presenting for fertility preservation. The study extends information about semen quality across wider diagnoses. The study also provided baseline information for comparison with semen analyses after treatment and in remission.
Trial registration number: Not applicable

O-248 Conditioned media of Sertoli cell cultures induced prepubertal mice spermatogonial cells differentiation in vitro, using methylcellulose system, to express high levels of acrosin and protamine.

M. Huleihel[1], S. Naor[2], E. Lunenfeld[3]

[1]Ben-Gurion University of the Negev, The Shraga Segal Dept. of Microbiology & Immunology, Beer - Sheva, Israel ;
[2]Ben-Gurion University of the Negev, The Shraga Segal Dep. of Microbiology-Immunology and Genetics- The Center of Advanced Research and Education in Reproduction CARER- Faculty of Health Sciences-, Beer-Sheva, Israel ;
[3]Soroka Medical Center and Faculty of Health Sciences- Ben-Gurion University of the Negev, Dep. OB/GYN and The Center of Advanced Research and Education in Reproduction CARER-, Beer-Sheva, Israel

Study question: Do Sertoli cells secrete factors that may induce proliferation and differentiation of mouse spermatogonial cells to meiotic and post-meiotic stages in vitro?
Summary answer: Addition of Sertoli cells conditioned media to spermatogonial cells in vitro, using methylcellulose culture system induced their development to cells that express acrosin and protamine.
What is known already: Sertoli cells (SCs) are active in the process of spermatogenesis and are in a direct contact with spermatogonial cells during their development from spermatogonial stem cells to sperm. Endocrine factors such as follicle stimulating hormone induce SCs to produce factors crucial for spermatogenesis. In addition, SPGCs are involved in the regulation of SC function. SCs produce different factors that affect the proliferation of the spermatogonial cells such as glial-derived nerve growth factor (GDNF), stem cell factor (SCF), leukemia inhibitory factor (LIF) and others. However, the factors that are involved in the differentiation of the spermatogonial cell are not yet clear.
Study design, size, duration: Seven-day-old mice were used to isolate cells from the seminiferous tubules by 2-step enzymatic digestion. Sertoli cell cultures were prepared by culturing the STCs for 3 days in 37 ^{0}C in 5% CO_2 incubator. Thereafter, the cells were treated with hypotonic shock to eliminate the residual germ cells, and re-culture in DMEM media containing 10% KSR. After over-night the media were replaced by fresh which was collected after 8 hours and stored at -80 ^{0}C.
Participants/materials, setting, methods: Isolate cells from the seminiferous tubules (STCs) which contain spermatogonial cells were cultured in vitro in methylcellulose culture system which contained GDNF, LIF, SCF with or without conditioned media (CM) which was collected from SC cultures. The effect of this CM on the development of spermatogenesis in vitro was evaluated by examining the presence/expression of markers of pre-meiotic (VASA, GFR-alpha, SALL4), meiotic (BOULE) and post-meiotic (ACROSIN, PROTAMINE) stages by immunostaining or by qPCR analysis.
Main results and the role of chance: Our results showed that isolated cells from seminiferous tubules of 7-day-old mice contained only pre-meiotic cells (VASA presence in around 8% of cells representing spermatogonial cells), but not meiotic or post-meiotic cells. These spermatogonial cells proliferated in vitro, in methylcellulose culture system, in the presence of GDNF, LIF and SCF to pre-meiotic (VASA presence in around 18% of cells), meiotic (BOULE in around 12% of cells) and post-meiotic cells (ACROSIN in around 8% of cells) after 4-5 weeks of culture (control system). Addition of 10% or 40% (v/v) of SC conditioned media to the spermatogonial cells in the culture did not significantly affect their proliferation of premeiotic cells compared to the control system. However, addition of these SC conditioned media to the spermatogonial cells in vitro significantly increased their development to the presence of acrosin in around 20% of the cells and around 1.5 fold of increase in the RNA expression. Furthermore, an increase in the RNA expression of protamine around 3 fold was found compared to the control system.
Limitations, reasons for caution: The study was performed in mice system and the relevant to human need to be confirmed.
Wider implications of the findings: This is the first demonstration that SCs produce factors that could induce development of spermatogonial cells to post-meiotic cells in vitro. These differentiating factors present in SC conditioned media need to be identified. Our results may assist in using the in vitro system for male fertility preservation in the future.
Trial registration number: Hub Reproduction, Faculty of Health Sciences, Ben-Gurion University

O-249 Appropriate Response of Fallopian Tube Cell Line to Sperms with DNA Fragmentation through Modulating Specific Cytokines

S.O. Mousavi[1], R. Mohammadi[2], F. Amjadi[3], S. Aghajanpour[2], M. Eslami[1], R. Aflatoonian[2]

[1]Faculty of Advanced Science and Technology- Tehran Medical Sciences- Islamic Azad University., Department of Genetics, Tehran, Iran ;
[2]Reproductive Biomedicine Research Center- Royan institute for Reproductive Biomedicine- Tehran- Iran., Department of Endocrinology and Female infertility-, tehran, Iran ;
[3]Iran University of Medical Science- Tehran- Iran., Department of Anatomical Science-, tehran, Iran ;
[4]Faculty of Advanced Science and Technology- Tehran Medical Sciences- Islamic Azad University- Tehran- Iran., Department of Genetics-, tehran, Iran

Study question: How sperms with DNA fragmentation can cause inflammation and influence the host defense?
Summary answer: Some investigations suggest that sperms with DNA fragmentation can change fallopian tube response with alteration in specific cytokines expression.
What is known already: Normal physiological homeostasis in the female reproductive tract needs appropriate regulation of inflammation through cytokines expression. Cytokines are fundamental compartments of immune system. Interaction of sperms with the fallopian tube in the female reproductive tract has an important role in different stages of pregnancy from fertilization to successful delivery. Investigations has shown that specific cytokines such as SPP1, MIF and C5 have relevance in host homeostasis and defense against pathogens.
Study design, size, duration: 30 patients who considered unexplained infertile were selected as donors of semen samples with normal features. After washing sperms, they were categorized to two groups of normal and abnormal DFI by TUNEL assay.

We also cultured fallopian tube epithelial cell into the culture flasks containing DMEM/F12 with 10% FBS medium up to 70% of confluence.
Participants/materials, setting, methods: Fallopian tube epithelial cells were co-incubated with sperms for 24h. after washing cells and extracting the RNA, we synthetized the cDNA. The control group was fallopian tube epithelial cells without sperm. Finally, the mRNA expression levels of the cytokines were evaluated by PCR Array and compared between 3 groups (control, normal DFI, abnormal DFI, n=3×10)**.**
Main results and the role of chance: Our data are agreeing with previous researches which show that cytokines play critical role in sperm interaction with female reproductive tract.

C5 expression in the abnormal DFI group was significantly higher than the control, however there was no significant difference between other groups.

Furthermore, SPP1 expression was higher in normal DFI group than the control, although it was significantly less than the abnormal DFI group. Finally, it is notable that MIF had no significant changes between groups (P<0.05).
Limitations, reasons for caution: Obtaining semen samples due to ethical and logistical issues was the major limitation of this study. Furthermore, *in vitro* co-incubation of fallopian tube epithelial cells with sperms may not directly mimic the *in vivo* interaction.
Wider implications of the findings: According to our data, DNA-fragmented sperms seem to be established as pathogens in female reproductive system and significantly change these cytokines in fallopian tube which prevent fertilization events in advance to other reproductive process.
Trial registration number: not applicable

O-250 A lack of DNA methylation covariation between human blood and sperm make it unlikely to mediate intergenerational inheritance of acquired traits

F. Asenius[1], S.J. Marzi[2], T.J. Gorrie-Stone[3], A. Brew[4], Y. Panchbaya[5], E. Williamson[6], L. Schalkwyk[3], V. Rakyan[4], D.J. Williams[1]

[1]University College London, UCL EGA Institute for Women's Health, London, United Kingdom ;
[2]Imperial College London, Department of Brain Sciences, London, United Kingdom ;
[3]University of Essex, School of Biological Sciences, Colchester, United Kingdom ;
[4]Queen Mary University of London, The Blizard Institute, London, United Kingdom ;
[5]University College London, UCL Genomics, London, United Kingdom ;
[6]University College London Hospital, Fertility & Reproductive Medicine Laboratory, London, United Kingdom

Study question: How does DNA methylation co-vary between matched samples of human whole blood and spermatozoa, and does obesity influence this DNA methylation covariation?
Summary answer: DNA methylation in blood and spermatozoa is clearly distinct, with little evidence of covariation between the tissues. We identified one cross-tissue obesity-associated DNA methylation site.
What is known already: Paternal obesity and T2DM have been associated with an increased risk of fathering low birth weight offspring. Human obesity and T2DM are associated with altered DNA methylation in blood. Animal studies suggest that obesity and insulin resistance are associated with DNA methylation changes in spermatozoa, and that these could mediate intergenerational effects. Such findings are lacking in humans. The largest previous study of DNA methylation in matched human sperm and blood had only 8 participants.
Study design, size, duration: Genomic DNA was extracted from matched samples of semen and blood from 68 lean and 22 obese males. DNA methylation at ~850,000 CpG sites across the genome was analysed using the Illumina MethylationEPIC array to test for 1) interindividual covariation in DNA methylation between blood and sperm, 2) consistent obesity-associated DNA methylation differences across both tissues, 3) obesity altered tissue-covariation, and 4) to compare spermatozoal DNA methylation to that of ~6,000 somatic tissue samples.
Participants/materials, setting, methods: Males of proven fertility were recruited from the University College London Hospital antenatal clinic. All participants provided informed consent and were phenotyped with regards to cardiovascular health.

DNA methylation was measured using the Illumina MethylationEPIC array at UCL Genomics and DNA methylation data was analysed using the wateRmelon package in R.

DNA methylation data from ~6,000 somatic tissue samples was obtained from the Gene Expression omnibus and analysed using the bigmelon package in R.
Main results and the role of chance: There were significant mean DNA methylation differences between blood and sperm at the majority (64%) of the interrogated 704,356 probes ($P < 9 \times 10^{-8}$). At 62% of these, sperm was relatively hypermethylated. Sperm displayed a more polarised DNA methylation distribution to blood; both low (<20%) and high (>80%) levels of methylation were more common.

In comparing the spermatozoal DNA methylome to those of ~6,000 somatic tissue samples, we identified 156,654 CpG sperm-specific hyper- and hypomethylated sites. Six gene ontology terms were enriched among sperm-specific sites, all of which related to transcriptional regulation.

When interrogating DNA methylation covariation between blood and sperm, analyses were restricted to sites meeting minimum variability criteria; range of middle 80% of samples ≥ 5% in blood and sperm. Out of 155,269 such sites, 1% showed a significant correlation of DNA methylation between blood and sperm ($P < 9 \times 10^{-8}$). Using the human dbSNP database, we identified SNPs in the probe sequences of most (>99%) of these correlated sites.

We found no evidence that obesity impacts on DNA methylation covariation between blood and sperm. However, DNA methylation at one site (cg19357369) was significantly associated with obesity status in blood and sperm ($P = 8.95 \times 10^{-8}$).
Limitations, reasons for caution: A small obesity cohort (n = 22) limited our ability to identify modest effects.

Lacking the genetic sequence of our subjects meant we could only speculate as to how SNPs influenced our results, not verify this directly.

The finding of an obesity-associated CpG site in blood and sperm requires replication.
Wider implications of the findings: The lack of DNA methylation covariation between blood and sperm means that blood should not be used as a surrogate tissue for spermatozoa.

Obesity has only a marginal influence on DNA methylation in human spermatozoa.

It is unlikely that DNA methylation is mechanistically involved in intergenerational inheritance of acquired traits.
Trial registration number: Not applicable

O-251 Fallopian tube response to DNA fragmented sperms: the role of Tumor necrosis factor receptors

R. Mohammadi[1], S.O. Mousavi[2], M. Sabbaghian[3], S. Aghajanpour[4], Z. Zandieh[5], T. Maadani[4], R. Aflatoonian[6]

[6]Reproductive Biomedicine Research Center- Royan institute for Reproductive Biomedicine, Department of Endocrinology and Female infertility-, Tehran, Iran

Study question: Can DNA fragmentation of sperm induce significant changes in immunological response of fallopian tube?

Summary answer: The results show that sperm DNA fragmentation may alter immunological response of fallopian tube.

What is known already: The interaction between the male and female gametes and embryos in the female reproductive system plays an important role in fertility, embryonic development, and implantation. Active immune systems throughout the female genitalia are against viral pathogens and bacterial agents which cause sexually transmitted diseases. TNF receptors super family members are one of the most important variables of immune cells that provide effective host protection. During fertilization sperms carry proteins which are allogenic to the female immune system. Therefore, TNF receptors play an important role in the fallopian tube specially in the presence of sperm.

Study design, size, duration: Fallopian tube epithelial cells were cultured into the tissue culture flasks containing DMEM/F12 with 10% FBS medium. Sperm samples from 20 donors with normal features were collected. The extent of sperm DNA fragmentation was measured by the TUNEL assay. Afterward, samples classified to two groups of normal and abnormal DFI. The third group was fallopian tube cells without sperm.

Participants/materials, setting, methods: Different sperms were co-incubated with fallopian tube cells for 24h. RNA extraction from cells was then fallowed by cDNA synthetized. Finally, PCR array was performed to evaluate TNF receptors genes expression profiling. In addition, this data was validated by q-PCR.

Main results and the role of chance: The results of the data analysis indicated that the expression of some TNF receptors in the vicinity of sperm significantly changes. Sperm DFI was assumed to be effective in different expression of TNF receptors. However, The results has shown that the expression of TNF receptors in cells exposed to abnormal-DFI sperms compared to the cells exposed to sperms with normal DFI had no significant changes. The present study on the effect of spermatozoa on TNF receptors production from the fallopian tube epithelial cells revealed that the expression of cytokines altered between different groups. In conclusion, TNF receptors super family members including TNF, TNFSF10, TNFSF11 and TNFSF11B had the highest expression in the group without spermatozoa.

Limitations, reasons for caution: The major limitation of this study was obtaining semen samples due to ethical and logistical issues. On the other hand, *in vitro* culture system may not directly mimic of *in vivo* environment.

Wider implications of the findings: This study indicate that abnormal DFI can change the expression of cytokines which have essential roles in sperm preservation and fertilization. Therefore, this promising novel outcome might be true that alteration in immunological responses of fallopian tube can disrupt fertilization events.

Trial registration number: not applicable

O-252 piR-32678 in the seminal plasma is a potential predictor for spermatogenic function in testis

T. Wu[1,2,3], L. Li[1,2,3], M. Song[1], C. Chen[1,3], Y. Chen[1,3], Y. Zeng[1,2,3]

[1]Shenzhen Zhongshan Urology Hospital, Fertility Center, Shenzhen, China ;
[2]Shenzhen Zhongshan Urology Hospital, Shenzhen Key Laboratory of Reproductive Immunology for Peri-implantation, Shenzhen, China ;
[3]Shenzhen Zhongshan Urology Hospital, Shenzhen Zhongshan Institute for Reproductive Medicine and Genetics, Shenzhen, China

Study question: Is there any seminal plasma piwi-interacting RNA (piRNA) to predict male fertility?

Summary answer: The expression of piR-32678 in seminal plasma was identified as a noninvasive evaluation of the spermatogenic function in testis.

What is known already: microRNAs (miRNAs) have been reported to be involved in spermatogenesis, and may serve as noninvasive biomarkers for evaluating male fertility. Unlike ubiquitous miRNAs which are secreted from a variety of tissues and organs, piRNAs are mainly expressed in germ cell. In this concern, piRNAs in seminal plasma seems to more reliable to develop as candidate predictor for male fertility.

Study design, size, duration: This retrospective cohort study was conducted from January to April 2018. A total of 31 fertile controls with normal semen parameters, 18 oligospermia, 12 non-obstructive azoospermia (NOA) and 11 obstructive azoospermia (OA) patients were enrolled in this study. Semen analysis was determined according to 2010 WHO reference criteria. Whilst, the seminal plasma was separated from the spermatozoa by high-speed centrifugation.

Participants/materials, setting, methods: Seminal plasma RNAs were extracted and quantified. Samples from 5 cases of NOA and 5 cases of controls were subjected to an Arraystar HG19 4×44K piRNA microarray. Among differential expressed piRNAs, piR-32678 was selected for verification on 26 controls, 18 oligospermia, 7 NOA and 11 OA patients using RT-qPCR. The diagnostic value of piR-32678 for the spermatogenic failure was evaluated by receiver operating characteristic (ROC) curve.

Main results and the role of chance: Firstly, there were totally 3652 piRNAs differentially exhibited in seminal plasma from patients with NOA compared with those from fertile controls (fold change > 2, $P < 0.05$), including 1532 up-regulated piRNAs and 2120 down-regulated piRNAs. Secondly, the qRT-PCR result showed that the relative expression of seminal plasma piR-32678 in oligospermia group [3.22 (2.55, 6.34), $U = 23.50$, $P < 0.001$] and in the NOA group [2.31 (1.65, 3.02), $U = 24.00$, $P = 0.003$] was significantly higher than that in the control group [1 (0.83. 1.42)]. However, no statistically difference was noticed between OA group and the controls [0.92 (0.54, 2.55), $U = 142.00$, $P = 0.973$]. Thirdly, ROC analysis demonstrated that the area under the curve (AUC) of piR-32678 was 0.891 (95% CI: 0.812 - 0.970, $P < 0.001$) for diagnosing spermatogenic failure. When the cut off value of the piR-32678 relative expression was set as 1.53, the sensitivity and specificity were 0.960 and 0.757, respectively.

Limitations, reasons for caution: Small sample size is the first limitation for this study. The findings require to be further validated in a large sample. The biological function of piR-32678 needs to be further investigated in the future study.

Wider implications of the findings: Seminal plasma piRNAs can be considered as new innovative noninvasive molecular makers for evaluating male fertility. Furthermore, piRNAs might provide a new clue for studying the etiology of spermatogenic disorders.

Trial registration number: Not applicable.

O-253 Endometrial gene expression profiling of recurrent implantation failure after in vitro fertilization

İ.G. Albayrak[1,2], F.A. Zarnagh[3], B. Karamustafaoğlu Balcı[4], E. Baştu[5], T. Günel[2]

[1]Uskudar University, Molecular Biology and Genetics, Istanbul, Turkey ;
[2]Istanbul University, Molecular Biology and Genetics, Istanbul, Turkey ;
[3]Istanbul Medical Faculty, Molecular Medicine, Istanbul, Turkey ;
[4]Istanbul Medical Faculty, Department of Obstetrics and Gynaecology, Istanbul, Turkey ;
[5]Acibadem Fulya Hospital, Department of Obstetrics and Gynaecology, Istanbul, Turkey

Study question: Has the expression of endometrial mRNAs in implantation phase of menstrual cycle significantly altered between RIF (Recurrent Implantation Failure) and the control group?

Summary answer: The study results showed that three selected mRNAs were significantly dysregulated in between RIF and control group samples.
What is known already: Successful embryo implantation depends on a well-functioning endometrium as well as a normal healthy embryo. This process might be blocked if either of these variables is defective. Recurrent implantation failure (RIF) is diagnosed when good-quality embryos repeatedly fail to implant after transfer in several in vitro fertilization (IVF) treatment cycles. Expression differences in maternal mRNAs could be reffering to so many diseases including recurrent implantation failure. A better understanding of the underlying mechanisms of RIF will give better treatment opportunities and better outcomes in IVF.
Study design, size, duration: In this study, there are two groups; RIF and normal fertility samples which are collected as endometrial biopsies in implantation phase of menstrual cycle. In the first step, total RNAs isolated from endometrium tissue. Then Droplet Digital PCR (ddPCR) performed for expression analysis of target mRNAs (mRNAs of TNC, WWC1, MME genes) in samples. And bioinformatic analysis of ddPCR results was performed. Study duration lasted from November 2018 until December 2019.
Participants/materials, setting, methods: Endometrial biopsy samples was collected from 35 RIF samples (age <40) and 35 fertile control samples (age <40). Samples were collected in the secretory phase of menstrual cylce (cycle day 20-24). In this study, mRNA expressions of three selected mRNAs were mesuared by ddPCR technique which is a highly sensitive method for measuring expression levels of targeting mRNAs in biological sample.
Main results and the role of chance: The significant feature of this study is the analysis of mRNA expression level in healthy and RIF endometrial biopsy samples which collected in implantation phase. Four target genes (MME, WWC1, TNC) were chosen by PANOGA database regarding to their possible relation with implantation process. Study results showed that, MME and WWC1 genes expression levels are significantly (P<0,05) up-regulated and TNC gene expression level is significantly (P<0,05) down-regulated in RIF samples comparing to the control group.
Limitations, reasons for caution: In this study, one of the challenges was endometrial biopsy step; sample obtaining from normal fertile women was difficult.
Wider implications of the findings: The importance of endometrial gene expression analysis studies lies in the impact of any identification of one or more markers specific for receptivity. In addition to identification of differentially expressed genes, identifying the related pathways is important for uncovering molecular processes in RIF and understanding the mechanisms underlying the disease.
Trial registration number: not applicable

O-254 Prediction of miscarriage in women presenting with threatened miscarriage in their first trimester of pregnancy using biomarkers, ultrasound markers and demographic variables

R. Pillai[1], D. Tincello[1], N. Potdar[1]

[1]University of Leicester, Department of health sciences, Leicester, United Kingdom

Study question: Can we predict miscarriage in women presenting with threatened miscarriage in the first trimester of pregnancy using biomarkers, ultrasound markers and demographic variables?
Summary answer: A log regression model using age, hCG, inhibin A and fetal heart rate can predict miscarriage with a sensitivity of 58% and specificity of 96%.
What is known already: A systematic review and meta-analysis on biomarkers to predict miscarriage has shown ca 125 as the best marker in predicting miscarriage (Pillai *et al*., 2016). Another systematic review conducted on ultrasound markers to predict miscarriage has demonstrated fetal heart rate (FHR) as the most predictive marker for miscarriage with a cut off value of 110 bpm (Pillai *et al.,* 2018). Maternal age is a well-established risk factor for miscarriage. Studies focussing on the combination of markers with FHR has shown promising results. However, existing evidence was limited by the quality of the studies and inconsistencies in the reporting formats.
Study design, size, duration: A prospective cohort study was conducted from December 2015 till September 2017, recruiting 278 women.
Participants/materials, setting, methods: The study included women presenting with bleeding +/- pain into the early pregnancy assessment unit and had a confirmed fetal heartbeat on the scan from 6+0 to 11+6 weeks of gestation. Women with uterine anomalies/ myomas, multiple pregnancies, extrauterine pregnancy and suspected trophoblastic disease were excluded from the study. The study also excluded women who had endometriosis, adnexal masses, exogenous hormones, diabetes, women less than 16 years of age and differently-abled women.
Main results and the role of chance: Out of 278 women recruited, 15 women miscarried (5.34%). Comparison of the miscarried women and those who continued pregnancy in women presenting with threatened miscarriage had shown that the two groups of women were different in the age (P value 0.05) and an objectively assessed bleeding score (P-value 0.03). The two groups were also different in the biomarkers hCG (P-value 0.04), progesterone (P-value 0.03), inhibin A (P value 0.02) and ultrasound markers MGSD (P-value 0.04), CRL (P-value 0.03) and FHR (P-value 0.01). On stepwise multivariate regression analysis, a regression model composed of the variables of age, hCG, inhibin and FHR gave the best sensitivity and specificity to predict miscarriage (P-value 0.0003). The ROC curve for the above regression model showed a sensitivity of 58% and specificity of 96%. The model gave a diagnostic odds ratio (95% CI) of 1.01 (1.01 – 1.02) to predict miscarriage.
Limitations, reasons for caution: Due to fewer numbers of miscarriages, the study was not able to establish a gestation age-specific cut off value for predictive markers. Failure to eliminate those miscarriages due to chromosomal problems might have negatively contributed to the results of the study.
Wider implications of the findings: The proposed prediction model needs to be tested and validated in a prospective research setting with a different study population. Contrary to the results of the previous systematic review, the current study established that ca 125 is not a useful marker to predict miscarriage in women presenting with threatened miscarriage.
Trial registration number: T 15-29

O-255 Does the outcome of fresh embryo transfer affect the outcome of the subsequent frozen-thawed embryo transfer originating from the same cohort of retrieved oocytes

G. Oron[1,2], M. Ronen[1,2], A. Wertheimer[1,2], E. Shlush[1,2], A. Hochberg[1,2], A. Ben-Haroush[1,2], O. Sapir[1,2], Y. Shufaro[1,2]

[1]Beilinson, Infertility and IVF Unit- Helen Schneider Hospital for Women- Rabin Medical Center- Beilinson Hospital, Petach - Tikva, Israel ;
[2]Tel-Aviv University, Sackler Faculty of Medicine-, Tel-Aviv, Israel

Study question: Does the outcome of the fresh transfer affect the subsequent frozen-thawed transfer originating from the same cohort of oocytes
Summary answer: The clinical pregnancy rate of the first frozen-thawed transfer is higher if a clinical pregnancy was attained in the fresh transfer regardless of live birth
What is known already: Numerous factors including maternal and treatment characteristics affect the outcome of an IVF treatment cycle. Current data is indecisive to whether the outcome of a fresh embryo transfer has an impact on the outcome of the subsequent frozen-thawed transfer of embryos originating from the same cohort of retrieved oocytes.
Study design, size, duration: The study included all oocyte collection cycles between January 2009 and September 2019 that had a fresh embryo transfer and at least one frozen-thawed embryo transfer cycle, in a tertiary medical center.
Participants/materials, setting, methods: Frozen-thawed cycles after a fresh cycle with a clinical pregnancy were compared to frozen-thawed cycles after a fresh cycle without a pregnancy. Logistic regression analysis was utilized to adjust for potential confounders including maternal age, treatment protocol, cause of infertility, treatment cycle number, number of oocytes retrieved, number of frozen embryos, day of fresh embryo transfer (cleavage vs. blastocyst) and outcome of the fresh embryo transfer
Main results and the role of chance: During the study period 1,758 oocyte retrieval cycles had a fresh embryo transfer and a subsequent frozen-thawed transfer of embryos originating from the same cohort of retrieved oocytes. The clinical pregnancy rate from the fresh embryo transfers in the study group was 28.9% (508/1758). The clinical pregnancy rate in the first frozen- thawed embryo transfer was 30.1% (153/508) among patients who achieved a pregnancy in the fresh transfer and 23.9% (299/1250) of those who did not (p=0.007). The clinical pregnancy rate from the subsequent frozen-thawed transfer was similar if a live birth was attained from the fresh embryo transfer 28.9% (69/239) or not 25.2% (383/1519); p=0.229. The live birth rate from the subsequent frozen-thawed

transfer was similar if a clinical pregnancy or live birth were attained from the fresh embryo transfer or not. On a multivariate regression analysis, pregnancy in the fresh transfer was a significant independent predictor for a pregnancy in the subsequent frozen-thawed embryo transfer p=0.043. Other significant predictors were maternal age and the treatment protocol.
Limitations, reasons for caution: The limitation of the study is in the retrospective nature of the study
Wider implications of the findings: Identifying predictive factors for the success of frozen-thawed embryo transfers is important to maintain acceptable pregnancy rates while reducing multifetal pregnancies. These can help physicians while counseling patients regarding the number of embryos to transfer taking into consideration the outcome of the previous fresh cycle.
Trial registration number: not applicable

O-256 Conception after early IVF pregnancy loss – Should we wait?

M. Sharon-Weiner[1], H. Gluska[1], S. Farladansky-Gershenabel[1], H. Schreiber[1], A. Wiser[1], A. Shulman[1], A. Hershko-Klement[1]
[1]Meir Medical Center, Obstetrics and Gynecology, Kfar Saba, Israel

Study question: Does the interval between early IVF pregnancy loss and the next IVF cycle predict the cycle's outcome?
Summary answer: Shorter intervals between early IVF pregnancy loss and reinitiating IVF treatment are related to the likelihood of live birth in the subsequent pregnancy.
What is known already: Approximately 5% of IVF cycles end in early pregnancy loss, representing 15% of pregnancies resulting from IVF. There is no consensus regarding the optimal interval between a miscarriage and the next attempt to conceive. Short inter-pregnancy intervals (IPIs) are associated with poor obstetric outcomes in the general population. Despite the abundance of studies examining IPI in the general obstetric population, there is a paucity of studies specifically evaluating IPI in the IVF population.
Study design, size, duration: This retrospective cohort study included 289 women who experienced first trimester IVF pregnancy loss, January 2014–January 2018 and reinitiation of IVF treatment.
Participants/materials, setting, methods: Women who experienced first-trimester pregnancy loss (including chemical pregnancy and miscarriage) following IVF were included. Treatments and follow-up occurred in a tertiary, university-affiliated, medical center. Miscarriages were classified as spontaneous/medical/surgical termination. We calculated intervals between miscarriage and the next cycle, interval to the subsequent pregnancy and number of cycles required**.** Primary outcome measure was the result of the IVF cycle following the miscarriage. Secondary measure was the interval between miscarriage and the next IVF pregnancy.
Main results and the role of chance: Among 289 women diagnosed with first trimester pregnancy loss following an IVF cycle, interval to the subsequent IVF treatment was not associated with the chance of achieving pregnancy. Patients after chemical pregnancy or spontaneous miscarriage experienced shorter intervals to next cycle, as compared with miscarriages managed medically or surgically (Kaplan-Meier survival curve, P=0.01) and higher pregnancy rates (P=0.009).

In a multivariable logistic model, type of miscarriage mattered: compared to chemical pregnancy, odds ratio (OR) for achieving pregnancy after a spontaneous miscarriage was 0.7 (P=0.5); OR=0.3 (P=0.002) for a pregnancy after a medical termination, and OR=0.3 (P=0.001) for a pregnancy following surgical termination. However, the time interval was not a significant factor (P=0.8).

When pregnancy was achieved in the first post-miscarriage cycle, the chance of a live birth was higher with shorter intervals (median 57.5 days), while another miscarriage was significantly related to a longer interval (median 82.5 days) between miscarriage and the next IVF cycle (P=0.03).
Limitations, reasons for caution: This was a non-randomized, retrospective study. Time intervals between cycles was not planned or randomized.
Wider implications of the findings: Following miscarriage, the subsequent IVF cycle should not be postponed, as shorter intervals are associated with greater likelihood of a live birth. We cautiously state that IVF cycles following chemical pregnancy or spontaneous miscarriage, rather than medically or surgically managed miscarriage result in higher pregnancy rates.
Trial registration number: Not applicable

O-257 The effect of vaginal microbiota on the outcome of assisted reproductive technologies

A. Karaer[1], B. Doğan[2], G. Tuncay[3], S. Gunal[4], A.N. Tecellioğlu[5]
[1]Inonu University School of Medicine, Obstetrics and Gynecology, Malatya, Turkey ; [2]School of Engineering- Inonu University-, Department of Biomedical Engineering, Malatya-, Turkey ; [3]Inonu University- School of Medicine, Department of Obstetrics and Gynecology-Division of Reproductive Endocrinology and Infertility-, Malatya, Turkey ; [4]School of Pharmacy- Inonu University, Medical Microbiology, Malatya, Turkey ; [5]Inonu University, Reproductive Sciences & Advanced Bioinformatics Application & Research Center, Malatya, Turkey

Study question: Is there any impact of the vaginal microbiota on the pregnancy rate in women undergoing assisted reproductive techniques (ART)?
Summary answer: Although the pregnancy rate is lower in women with community site type (CST)-IV and CST-V, there was no significant association between CSTs and pregnancy rate.
What is known already: Bacteria in the human body account for 2-3% of total body mass and urogenital tract accounts for around 9% of the total human microbiota. In literature, microbiome studies conducted on female reproductive tract usually investigate the obtained vaginal microbiota data under five different community state types (CSTs). Where, CST-I, II, III and V forms the groups in which *Lactobacillus crispatus*, *Lactobacillus gasseri*, *Lactobacillus iners,* and *Lactobacillus jensenii* are dominated (relative abundance > 50%), respectively. CST-IV forms the group in which none of the above Lactobacillus species are dominated. Growing evidence demonstrates the importance of vaginal microbiota in human reproductive functions.
Study design, size, duration: A cohort of 223 infertile patients undergoing ART in an university based ART center between May 2016 and May 2019 were enrolled in this study.
Participants/materials, setting, methods: The vaginal swab were collected from posterior vaginal fornix immediately before embryo transfer. Genomic DNA was extracted from vaginal samples and sequenced by the V3-V4 region of 16S ribosomal RNA (rRNA) gene. The vaginal microbiota profiles were assigned to one of the five CSTs based on the dominant bacterial species. The biochemical pregnancy rate (positive hCG test result day 14) was investigated.
Main results and the role of chance: In total the vaginal microbiota of 223 women who underwent a fresh embryo transfer were analyzed. The vaginal microbiata of 123 (55.2%) women dominated by Lactobacillus species, 100 (44.8%) women had bacteria related with bacterial vaginosis predominantly. The overall pregnancy rate was 48.4% (108/223). The pregnancy rate was 53.8% (21/39) in women with CST-I, 66.7% (10/15) in women with CST-II, 50% (32/64) in women with CST-III, 44% (44/100) in women with CST-IV, and 20% (1/5) in women with CST-V. There was no statistically significant difference between CSTs regarding to pregnancy rate. CST-IV was mostly dominated by *Gardnerella vaginalis*, *Streptococcus agalactiae* and *Streptococcus anginosus*. A linear discriminant analysis (LDA) of the vaginal microbiota data concluded that, the Streptococcaceae (family) has the highest contribution (|log10 LDA score| > 4) in the separation of women with positive and negative pregnancy test result.
Limitations, reasons for caution: The major limitation of sequencing are that it does not give information about the viability of the organism and it does not provide information about its biological function. These results are limited to the studied ART population and do not reflect the microbiota profile of a general population.
Wider implications of the findings: Our data demonstrated that the abnormal vaginal microbiota is not associated with poor pregnancy rate for ART treatment.
Trial registration number: Not applicable

O-258 First trimester pregnancy outcomes of subchorionic haematomas in a recurrent pregnancy loss population at a tertiary London teaching hospital.

C. Brooks[1], S. Webb[1], Y. Mulji[1], R. Rai[1]
[1]St Mary's Hospital Imperial College Healthcare NHS Trust, Obstetrics and Gynaecology, London, United Kingdom

Study question: Do subchorionic haematomas increase the likelihood of miscarriage in recurrent pregnancy loss population; are they related to use of aspirin and low molecular heparin?

Summary answer: Subchorionic haematomas do not increase the likelihood of miscarriage in the recurrent pregnancy loss population.
What is known already: There is conflicting evidence on the role of subchorionic haematomas (SCH) on pregnancy outcome and specifically in the recurrent pregnancy loss (RPL) population. Some studies report an association with miscarriage and increase of SCH incidence with the use of Aspirin. This is an important finding to confirm as aspirin and low molecular weight heparin (LMWH) are both established treatment regimens for conditions that can cause recurrent pregnancy loss.
Study design, size, duration: A retrospective observational cohort study on all new patients referred to the early pregnancy clinic at St Mary's Hospital, London, was conducted between January 2017 and June 2019.
Participants/materials, setting, methods: The patients seen in the early pregnancy unit have a history of RPL and are referred by their GP. They are seen in clinic at 6 weeks gestation and have a transvaginal ultrasound scan performed.

Patient data was collected from both Cerner © electronic records and carestream PACsweb imaging.
Main results and the role of chance: In this pilot study of 226 patients the median age of the RPL women were 36 (range 24-45) and had an median number of miscarriages per couple of 4 (range 1-15). There was a miscarriage rate of 28%.
There was a subchorionic haematoma incidence of 17%.
Comparing the RPL patients on medication with those on no medication, there was no increased likelihood of developing a SCH; aspirin alone (OR 1.6 CI 0.55-4.73 p=0.39); LMWH alone (OR 2.1CI 0.66-6.89 p= 0.2) or LMWH and aspirin combined (OR1.3 CI 0.5-3.37 p=0.5).
Women who were on medication for an identified cause of RPL were less likely to miscarry than those who were on no medication. (OR 0.38 CI0.19-0.76 p=0.006). Therefore the likelihood of having a miscarriage is higher in women on no medication where no cause was found for the RPL.
Having a SCH did not increase the likelihood of having a miscarriage in this population (OR 0.65 P 0.31)
Limitations, reasons for caution: It was a retrospective study and therefore relies on accurate record keeping. There will be inter-operator bias, as different sonographers scanned during the clinic.
Wider implications of the findings: In the RPL population we can reassure that having a SCH does not increase the risk of miscarriage in the first trimester. Aspirin and LMWH do not increase the risk of developing a SCH and therefore medication should not be stopped if they develop a SCH.
Trial registration number: Not Applicable

O-259 Low mannose binding lectin level in plasma is a risk factor for recurrent pregnancy loss

C. Nørgaard-Pedersen[1], R. Steffensen[2], O.B. Christiansen[1]

[1]Aalborg University hospital, Obstetrics and gynaecology, Aalborg, Denmark ;
[2]Aalborg University Hospital, Bioanalytic department, Aalborg, Denmark

Study question: Are low or high plasma mannose binding lectin (p-MBL) levels associated with recurrent pregnancy loss (RPL) and the perinatal outcome before and after RPL diagnosis?
Summary answer: While low p-MBL levels are significantly more frequent in RPL patients, high levels are significantly less frequent. No association with adverse perinatal outcomes was found.
What is known already: Low p-MBL levels have been associated with RPL, while relations to high levels have been poorly studied. Reports concerning association between RPL and perinatal outcomes including birth weight and gestational age are conflicting. Some but not all studies suggest an association between low maternal p-MBL levels and reduced birthweight and gestational age, which could be an important factor for the higher frequency of preterm birth and lower birth weight often reported in pregnancies after RPL.
Study design, size, duration: A combined case-control and cohort study in 248 RPL women admitted to the RPL Centre of Western Denmark from January 2016 to December 2019. At first consultation blood samples including p-MBL measurement and perinatal data from previous births were collected. Women were followed until birth or end of study. P-MBL levels were compared to those of 185 female blood donors, while perinatal outcomes were compared to all 3354 singleton births at our hospital in 2017.
Participants/materials, setting, methods: All women had ³3 consecutive pregnancy losses and a regular menstrual cycle, while none had significant chromosomal or uterine abnormalities. Frequencies of different subgroups of p-MBL levels in RPL patients were compared to MBL levels in the control group. Frequencies of adverse perinatal outcomes between subgroups defined by p-MBLlevels were compared. A multivariate analysis was performed identifying risk factors including low p-MBL level for adverse obstetrical outcomes in the patients.
Main results and the role of chance: Significantly more RPL patients had low p-MBL levels (<500 mg/l) (odds ratio [OR] = 2.45, 95% CI 1.61-3.71; p <0.001) and less had high MBL levels (>3000 mg/l) (OR = 0.51; 95% CI 0.33-0.80; p=0.003) compared to controls, while comparing the intermediate p-MBL levels showed no differences (OR = 0.73, 95% CI 0.49-1.07; p = 0.11). A previous moderate (>500 ml) or severe peripartum haemorrhage (>1000 ml) (p<0.001 for both) and previous birth of a boy (p<0.001) were associated with secondary RPL (sRPL). Smoking, increasing age, BMI and number of consecutive miscarriages but not low p-MBL levels were significantly associated with no pregnancy or pregnancy loss after admission. No clear association was observed between maternal p-MBL levels and birthweight or gestational age, neither before nor after RPL.
Limitations, reasons for caution: Only 93 (37.5 %) women gave birth after RPL in the follow-up period, which were too few to find any clear associations between p-MBL levels and adverse perinatal outcomes after RPL.
Wider implications of the findings: While low p-MBL levels are strongly associated with RPL, high levels may play a protective role. A previous large peripartum haemorrhage, previous delivery of a boy and low maternal p-MBL may predispose to a large feto-maternal transfer of fetal cells triggering an abnormal maternal immunization against fetal or trophoblast cells.

O-260 LH prevents follicular damage and preserves the meiotic potential of oocytes exposed to chemotherapy at the primordial stage

L.M. Castillo[1,2], M.J. Soriano[1], J. Martinez[1,2], A. Pellicer[1,3], S. Herraiz[1]

[1]IVI Foundation - IIS La Fe, Reproductive Medicine, Valencia, Spain ;
[2]University of Valencia, Department of Pediatrics- Obstetrics and Gynecology, Valencia, Spain ;
[3]IVI-RMA Rome, Reproductive Medicine, Rome, Italy

Study question: Does luteinizing hormone (LH) treatment protect follicle viability and meiotic potential of chemotherapy-exposed primordial follicles?
Summary answer: LH improves the meiotic potential of murine metaphase II oocytes (MII-oocytes), avoiding the alkylating agents´ gonadotoxic effects, by the promotion of follicular DNA repair mechanisms.
What is known already: High-dose chemotherapy with alkylating drugs induces detrimental changes on ovaries. Follicle viability is severely affected by DNA damage and apoptosis of oocytes and granulosa cells (GCs), leading to impaired follicular development and depletion. Early activation of DNA repair mechanisms, like homologous recombination through the ataxia-telangiectasia-mutated (ATM) pathway, is crucial for cell survival after cytotoxic events. Previous results suggested LH treatment as an alternative for fertility preservation based on its protective role on the ovarian reserve against chemotherapy. Therefore, we aimed to assess the follicular protective mechanisms of LH and the meiotic potential of chemotherapy-exposed MII-oocytes in a mouse model.
Study design, size, duration: Experimental study where twenty-four 7-week old CD-1 female mice were exposed to three experimental conditions (n=8/group): Control, chemotherapy (ChT) and ChT+LH. The ChT-treated groups were intraperitoneally injected with 12mg/Kg-busulfan and 120mg/kg-cyclophosphamide. The LH-treated animals received a pre-treatment dose with 1IU,

24 hours before ChT, followed by a second 1IU-dose administered with chemotherapy. Control-mice received saline. Ovaries from 6 animals/group were collected at 12 and 24 hours, while the remaining mice were maintained for 30 days.

Participants/materials, setting, methods: The ATM-pathway, by Rad51 gene expression, was evaluated by RT-qPCR, while apoptotic (cleaved caspase-3) and anti-apoptotic (Bcl2) proteins were quantified by western-blot, on ovarian samples at 12 and 24h. Additionally, the 12h samples were screened for follicle DNA damage and apoptosis by γH2AX-staining and TUNEL-assay, respectively. The remaining animals were superovulated (10IU-PMSG + 10IU-hCG, 18 hours later) for MII-oocyte collection. Thus, spindle formation and chromosome disposition, referred to equatorial plate, were analyzed by confocal microscopy.

Main results and the role of chance: LH treatment increased the expression of the DNA repair gene Rad51 at the 12h (Control: 1, ChT: 2.0±0.5; ChT+LH: 2.7±1.3; p=0.020 and p=0.019, respectively) and 24h timepoints (Control: 1, ChT: 0.5±0.5, ChT+LH: 1.4±0.3). The activation of the DNA repair signalling led to a rise of Bcl2/cleaved caspase-3 protein ratio, decreased by chemotherapy, enhancing cell survival on 24h-ovaries (Control: 2.5±0.9, ChT: 0.8±0.3, ChT+LH: 2.0±1.3).

Furthermore, LH treatment reduced the significant increase in the number of γH2AX-positive oocytes induced by chemotherapy (Control: 19.6±0.8%, ChT: 64.6±3.1%, ChT+LH: 42.6±4.1%; p=0.034 and p=0.021, respectively). Moreover, these positive effects were also observed in the GC integrity, by reducing the amount of follicles with >20% of TUNEL-positive GCs (Control: 1.6±0.8%, ChT: 8.5±0.8%, ChT+LH: 5.1±0.9%; p=0.034 and p=0.043), during the first 12 hours after treatment.

The meiotic potential, referring to MII-oocytes derived from follicles at the primordial stage during chemotherapy administration, was seriously affected in the ChT group, with a 34.5% decrease in spindle area (Control: 127.7±20.5μm^2, ChT: 83.7±7.7μm^2; p=0.019). Nevertheless, LH treatment was able to avoid this effect, preserving control-like values (ChT+LH: 119.7±2.7μm^2; p=0.034). Furthermore, LH diminished the number of MII-oocytes with at least one misaligned chromosome compared to ChT group (Control: 12.5%, ChT: 83.3%, ChT+LHx1: 58.3%).

Limitations, reasons for caution: Although these findings represent the first steps of a new strategy for fertility preservation in cancer patients, this is an animal model study developed in mouse ovarian samples. Therefore, these results should be validated in order to properly identify the repairing mechanisms in a preclinical approach with human samples.

Wider implications of the findings: LH treatment minimizes the deleterious effects induced by alkylating agents on follicular viability. The enhancement of DNA repair systems seems to be one of the main protective mechanisms promoted by LH. This improvement would contribute to produce MII-oocytes with increased potential to properly complete the meiosis II.

Trial registration number: not applicable

O-261 The developmental capacity of In Vitro Matured Oocytes originating from cumulus oocyte complexes (COCs) found during oVArian tissues (OT) preparation is compromised

K. Tilleman[1], S. Lierman[2], A. Tolpe[3], I. De Croo[4], S. De Gheselle[5], J. Defreyne[6], G. T'Sjoen[6], M. Baetens[7], A. Dheedene[7], B. Menten[7], P. De Sutter[8]

[7]Ghent University Hospital, Center for Medical Genetics, Ghent, Belgium ;
[8]Ghent University Hospital, Department for Reproductive Medicine- Ghent Fertility And Stem cell Team G-FAST, Ghent, Belgium

Study question: What is de fertilization capacity of **I**n **Vi**tro **M**atured **O**ocytes found during o**VA**rian tissues preparation(IViMOVA), subsequent embryo development and are these embryos euploid or do they harbor chromosomal abnormalities?

Summary answer: IViMOVA oocytes show lower fertilization rates, impaired embryo development characterized by irregular cleavage patterns and early embryo arrest apparently not related to chromosomal abnormalities.

What is known already: The collection of COCs during preparation of OT has been described as the maximization of fertility preservation. This technique is sometimes mistaken with IVM in Polycystic Ovary Syndrome(PCOS) patients where mild stimulation or primed ovarian punction show maturation rates of 70% and successful treatment outcomes. On the contrary, IViMOVA studies in literature show an average maturation rate of around 30% and the description of the developmental capacity of these oocytes is largely absent. IViMOVA reports in literature are mostly case reports and to our knowledge, so far 3 live births have been described (Segers I.,2015, Uzelac P.,2015, Prasath EB.,2014).

Study design, size, duration: During OT preparation, COCs were collected from surplus medulla, in vitro matured (MediCult IVM medium,Origio) for 44-48h and MII were vitrified(Irvine Scientific). Warmed intact MII were injected after 2h and cultured in sequential medium(Cook) in the Embryoscope®(Vitrolife). For genetic analysis, cells were lysed and DNA was amplified using the Sureplex Amplification system(Illumina), followed by shallow whole genome sequencing (sWGS) (average genome coverage of 0.1-1x), for the detection of aneuploidy or subchromosomal aberrations (resolution ~5Mb).

Participants/materials, setting, methods: From Nov.2015-Jan.2019, in total 93 persons (median age 20.7y) underwent hysterectomy with bilateral oophorectomy in the context of gender affirming surgery after a median duration of testosterone treatment of 75.3weeks. At the time of hysterectomy serum was analyzed for AMH-FSH-LH-E2-Progesterone-Testosterone-SHBG. A negative binomial regression model for counts was applied (SPSS) to find biochemical parameters associated with MII vitrified. Frozen thawed sperm form 1 donor (30y, proven fertile) was used for all ICSI procedures.

Main results and the role of chance: For the developmental capacity study, 1765 COCs of 80 patients were in vitro matured in 5%CO_2, 6%O_2 at 37°C which resulted in 390MII oocytes (22%maturation rate) being vitrified. After correction of demographic variables (duration of testosterone treatment, age and BMI), AMH was significantly (P=0.0058) associated with the number of MII vitrified. 238MII oocytes were donated for this study of which 208 were warmed and 151 (72.6%) intact. ICSI was performed in 92%(139/151) of the intact warmed oocytes. After ICSI, 35% of the oocytes showed normal fertilisation (48/139); 12%(17/139) were 1pn, 19%(27/139) were 0pn and 15%(21/139) were 3pn or more. After ICSI, 19%(26/139) were degenerated. Only 2pn were further cultured and embryo development was monitored. On day 3, 52% of the 2pn (25/48) developed up the cleavage stage of which 44%(11/25) were 6 cell or more. Out of 139 injected oocytes and 48 normally fertilized, only 1 (2%) blastocyst (4BB) was obtained on day 5. Timelapse imaging showed direct or reversed cleavage, no extrusion of the 2nd polar body and arrest in the cleavage stage. For genetic analysis, 32 embryos were available and was successful in 30/32 embryos. Interpretable results showed normal chromosomal patterns in 43% (13/30) of the embryos.

Limitations, reasons for caution: This descriptive cohort study used tissue from transgender patients undergoing men with testosterone treatment, hence it is possible that this could affect the developmental capacity of the oocytes although previous work from our group has shown that the oocytes look morphologically normal and display normal spindles (Lierman S., 2017).

Wider implications of the findings: IViMOVA should be considered an innovative technique (Provoost V. 2014). As this technique is often described as a maximization of fertility preservation for oncology patients, information should be given on the uncertainty concerning the developmental capacities of these oocytes and the lack of data in scientific literature.

Trial registration number: This study was funded by FWO TBM T001016N and was approved by the Ghent University Hospital Ethical Committee (UZ Ghent Reference: 2015/0124, Belgian registration number B670201523543) and the injection of the in vitro matured oocytes and creation of embryos for this study was approved by the Belgian Federal Ethics Committee (reference Adv_056).

O-262 Effects of cancer on biology of granulosa cells, follicular fluid and quality of oocytes

G. Younes[1], W. Buckett[1], Q. Yang[2], W.Y. Son[1], A. Volodarsky-perel[1], T. Tulandi[1], H.J. Clarke[2]

[1]Mcgill University Health Centre, reproduction centre, montreal, Canada ; [2]Mcgill University Health Centre, research institute, montreal, Canada

Study question: Do factors associated with cancer damage the granulosa cells of the ovarian follicle or alter the follicular fluid, leading to abnormal development of the egg?

Summary answer: Inhibitors of Wnt signaling pathway and regulators of cell growth and differentiation, cell-cell interactions and adhesion are downregulated in cancer patients.

What is known already: The adverse effects of chemotherapy and radiotherapy on fertility are well known. Cryopreservation of oocytes and embryos are considered the standard of care for preserving fertility in reproductive-age cancer patients before starting treatments.

Whether the malignancy itself has a negative effect on the reproductive system remains unclear. Some clinical studies have shown apparent adverse effects of malignant disease on the response to ovarian stimulation and on the quality and performance of oocytes, whereas others have shown no difference when compared to healthy controls.

Study design, size, duration: This prospective pilot study included 20 patients treated at our academic reproductive centre. Patients could be divided into two groups: a study group that consisted of 10 cancer patients treated for fertility preservation before chemotherapy or radiotherapy and a control group of age-matched 10 healthy fertile patients treated with IVF due to male factor or social fertility preservation. Research and Ethics Board of McGill University Health Centre approved the study.

Participants/materials, setting, methods: Cumulus cells and follicular fluid were collected from all patients. Total RNA of ten samples was extracted from the cumulus cells. We evaluated mRNA expression profiles of cumulus cells using next generation sequencing by Illumina Novaseq 6000. The follicular fluid of all twenty samples was tested by automatic immunoassay for C -reactive protein (CRP) as an inflammatory marker, cortisol as a stress marker, and insulin like growth factor.

Main results and the role of chance: All patients were treated with the antagonist protocol. The number of total oocytes retrieved, and the number of mature or immature oocytes in the 2 groups were comparable. Three samples from the study group and three others from the control group were further analyzed by mRNA sequencing. Compared with controls, 85 known mRNAs were differentially expressed in cancer patients' cumulus cells, including 45 mRNAs upregulated and 40 mRNAs downregulated. The potential regulating roles of mRNA and gene annotation showed downregulation of genes that act as regulators of cell growth and differentiation, cell-cell interaction and adhesion (*GPC4, ID3, CGC20, IGSF-9, CPXM1*). We also found that two strongly downregulated genes are inhibitors of the canonical Wnt signaling pathway (*SFRP4*, *WIF1*). The concentrations of CRP, cortisol, or insulin like growth factor in the two groups were comparable.

Limitations, reasons for caution: This pilot study has a small sample size. Two patients were treated with letrozole which may have an effect on the results.

Wider implications of the findings: Our data suggest that cellular regulators and inhibitors of the Wnt signaling pathway may be downregulated in cancer.

These changes may have negative effects on cumulus oocyte expansion, ovulation, and luteinization.

Our results provide novel candidates for molecular targets in the research of the effect of cancer on female fertility.

Trial registration number: none

O-263 Pre-treatment with Granulocyte-Colony Stimulating Factor does not protect germ cell populations in the immature human testis from Cisplatin-induced germ cell loss

G. Matilionyte[1], R.A. Anderson[1], R.T. Mitchell[1]

[1]The University of Edinburgh, Centre for Reproductive Health, Edinburgh, United Kingdom

Study question: Does Cisplatin affect germ cell populations in the immature testis and can this effect be rescued by treatment with Granulocyte-Colony Stimulating Factor (GCSF)?

Summary answer: Cisplatin exposure causes acute loss of germ cells in the immature human testis and this effect was not rescued by short-term exposure to GCSF.

What is known already: Long-term survival rates for children with cancer are more than 80%. However, childhood cancer treatment may result in subsequent infertility. Cisplatin is one of the most commonly used drugs for childhood cancers. Knowledge of the effects of Cisplatin exposure in childhood is still limited. Moreover, there are currently no clinical agents to protect spermatogonial stem cells from chemotherapy-induced damage. Animal studies suggest that GCSF may protect germ cells in males and females, however, there is no information whether GCSF could prevent loss of germ cells in human testes.

Study design, size, duration: *In-vitro* culture of human fetal testis tissues was utilised as an established model for pre-pubertal testis development. Tissues were exposed to: 1) 0.5 µg/ml Cisplatin or vehicle control on day 4 for 24hrs and kept in culture until 72 and 240 hours post-exposure; 2) combined treatment of Cisplatin with GCSF (5 or 20 ng/ml) for first 7 days (3 days prior, during and 3 days after Cisplatin exposure).

Participants/materials, setting, methods: Second trimester human fetal testis tissue fragments (14-22 gestational weeks; n=3-14) were cultured in a 'hanging drop' system. Tissue was cultured for 7 and 14 days in total which reflected 72 and 240 hours post-exposure to Cisplatin.

Quantification of germ cell populations (cells per tubular area (mm^2)) was performed on sections stained for AP2γ (gonocytes) and MAGE-A4 (pre-spermatogonia). Statistical analysis was performed using two-way ANOVA to account for inter-individual variation between fetuses.

Main results and the role of chance: Cisplatin exposure significantly reduced the number of gonocytes (478.7±85.30 vs 379.7±92.29 cells/mm^2; $p<0.01$) at 72 hours post-exposure compared with vehicle-exposed controls, whereas the number of pre-spermatogonia was unchanged. After 240 hours, exposure to Cisplatin resulted in significant reduction in both gonocyte (327.1±45.13 vs 193.5±37.94 cells/mm^2; <0.0001) and pre-spermatogonial (393.0±36.73 vs 324.0±60.45 cells/mm^2; $p<0.01$) numbers.

In combined treatment experiments, addition of GCSF from 3 days prior to 3 days after Cisplatin exposure did not protect against the reduction of germ cell numbers 72 or 240 hours post-Cisplatin exposure.

Limitations, reasons for caution: Human pre-pubertal testis tissue is of limited availability, thus, a validated *in-vitro* system using human fetal testis was utilised. These tissues contain similar germ cell sub-populations, which includes gonocytes (present in infancy) and pre-spermatogonia (present throughout pre-puberty). 'Hanging drop' culture might not recapitulate all *in-vivo* aspects of immature testis microenvironment.

Wider implications of the findings: This study shows that Cisplatin exposure causes early loss of gonocytes in the immature human testis, whereas the effect on (pre)spermatogonial number is delayed. This germ cell reduction could not be protected by concurrent GCSF treatment. Alternative regimens of GCSF supplementation are currently under investigation and will be discussed.

Trial registration number: Not applicable

O-264 In vitro fragmentation of ovarian tissue activates primordial follicles through the Hippo pathway

C. De Roo[1], S. Lierman[1], K. Tilleman[1], P. De Sutter[1]

[1]University Hospital Ghent UZ, Reproductive Medicine- Department of Gynaecology, Ghent, Belgium

Study question: What is the role of the Hippo and PI3K/Akt pathway in follicles during ovarian tissue culture in tissue derived from oncological patients and transgender men?

Summary answer: Results highlight a Hippo pathway driven primordial follicle activation *in vitro*, predominantly from day 0 to day 4

What is known already: *In vitro* OT culture aims at activating and maturing primordial follicles for fertility restoration in patients with a threatened ovarian reserve. Not all patients are eligible for ovarian cortex transplantation and therefore several groups attempt to culture ovarian tissue in vitro.

Cortex fragmentation disrupts the Hippo pathway, leading to increased expression of downstream growth factors and follicle growth. The PI3K/Akt pathway is considered the intracellular pathway to where different extracellular factors involved in primordial follicle activation *in vivo* converge to. In order to optimize current ovarian tissue culture models, information on progression of these pathways during tissue culture is mandatory.

Study design, size, duration: The first step of a multistep cortex culture system was performed using 144 ovarian cortex pieces of in total 6 patients. Per patient, 24 cortical strips were cultured for 6 days and 6 pieces per patient were collected for downstream analysis of follicle development and Hippo and PI3K/Akt pathway targets every second day.

Participants/materials, setting, methods: OT was obtained from oncological (N=3; 28.67+/-4.51years) and transgender (N=3; 23.33+/-1.53 ears) patients. Follicles were analysed using hematoxylin-eosin staining and pathways were studied using immunohistochemistry and precise follicle excision by laser capture microdissection for RT-qPCR analysis. MIQE guidelines for RT-qPCR were pursued. Reference gene selection (GAPDH, RPL3A, 18s rRNA) was performed using GeNorm Reference Gene Selection Kit. Statistical analysis was conducted with IBM SPSS Statistics 23 (Poisson regression, negative binomial regression, ANOVA and paired t-test).

Main results and the role of chance: Immunohistochemical analysis confirmed a Hippo pathway driven primordial follicle activation by mechanical manipulation of the cortical strips. Ovarian tissue preparation and culture induced the inhibitory pYAP to disappear in granulosa cells of primordial follicles on day 2. The stimulatory YAP on the contrary appeared in primordial granulosa cells over increasing culture days. Looking at the YAP target CTGF, a significantly up regulated CTGF was noted in primordial follicles when comparing day 2 and day 4 (ratio day 2/4 = 0.082; $p<0.05$), clearly showing an effect on the Hippo pathway in primordial follicles during tissue culture.

Follicle classification objectified a significant drop in estimated primordial follicle counts in the oncological cohort (-78%; p=0.021) on day 2 and in transgender cohort on day 4 (-634%; p=0.008). Intermediate follicle counts showed a non-significant trend to increase during culture and this follicle recruitment and growth resulted in a significant raise in estimated primary follicle counts on day 6 in oncological patients (170%; p=0.025) and although limited in absolute numbers, a significant increase in secondary follicles on day 4 (367%; p=0.021) in the transgender cohort. Subsequent antral follicle development could not be observed.

Limitations, reasons for caution: A limitation is the small sample size, inherent to this study subject, especially as a large amount of tissue was needed per patient to reduce inter patient variation in different downstream analysis techniques. A particular and specific weakness of this study is the inability to include an age-matched control group.

Wider implications of the findings: These findings support an adapted tissue preparation for Hippo pathway disruption and a shorter first phase of tissue culture. This work may also have a reflection on transplantation of cryopreserved tissue as larger strips (and thus slower burnout because of less Hippo pathway disruption) could be a benefit.

Trial registration number: This research was financially supported by the Foundation Against Cancer (Stichting tegen Kanker) and Flemish Foundation of Scientific Research (FWO Vlaanderen), Belgium

O-265 Purging human ovarian cortex of contaminating leukaemic cells by targeting the Mitotic Catastrophe Signalling Pathway

L. Eijkenboom[1], C.L. Mulder[2], B.A. Van der Reijden[3], N.M. Van Mello[4], J. Van Leersum[1], D.D.M. Braat[1], C.C.M. Beerendonk[1], R. Peek[1]

[1]Radboudumc, Obstetrics and Gynaecology, Nijmegen, The Netherlands ; [2]Amsterdam UMC, Reproductive Biology, Amsterdam, The Netherlands ; [3]Radboudumc, Laboratory Medicine, Nijmegen, The Netherlands ; [4]Amsterdam UMC, Obstetrics and Gynaecology, Amsterdam, The Netherlands

Study question: Is it possible to eliminate metastasized chronic myeloid leukaemia (CML) and acute myeloid leukaemia (AML) from ovarian cortex by inhibition of Aurora B/C kinases (AURKB/C)?

Summary answer: Inhibition of AURKB/C *ex vivo* effectively eradicated experimentally induced CML and AML tumour foci and viability of ovarian tissue was not compromised by this treatment.

What is known already: Despite the success of ovarian tissue cryopreservation, autotransplantation is not without risk since malignant cells may be present in the graft. Safety procedures to detect minimal disseminated disease render the fragment useless for autotransplantation and remaining fragments could still harbour malignant cells. Strategies to separate follicles from possibly contaminated stromal cell compartment followed by *in vitro* maturation or grafting to an artificial ovary are actively pursued, but are experimental. We have recently shown complete elimination of rhabdomyosarcoma cells by efficient *ex vivo* purging of ovarian cortex fragments is possible, allowing treatment of all cortex fragments without compromising ovarian tissue integrity.

Study design, size, duration: Human ovarian cortex tissue with experimentally induced tumour foci of CML and AML were exposed to a 24 h treatment with an AURKB/C inhibitor to eliminate malignant cells by invoking mitotic catastrophe. After treatment the inhibitor was removed followed by an additional culture period of 6 days to allow any remaining tumour cells to form new foci. Ovarian tissue integrity was analysed by 4 different assays. Appropriate controls were included in all experiments.

Participants/materials, setting, methods: Tumour foci of CML and AML cell lines were induced in ovarian cortex from transgender men undergoing oophorectomy. Presence of any remaining cancer cells after *ex vivo* treatment was analysed by (immuno)histochemistry of serial sections from entire tissue fragments. Effect of the AURKB/C inhibitor exposure on the viability of ovarian cortex tissue and follicles was determined by histology, glucose uptake assay, follicular viability assay and an assay for the *in vitro* growth of small follicles.

Main results and the role of chance: Foci of metastasized CML and AML cells in ovarian cortex tissue were severely affected by a 24 h *ex vivo* treatment with an AURKB/C inhibitor, leading to the formation of multi-nuclear syncytia and large scale apoptosis. Only the megakaryocytic CML cell line MEG-01, known for its aberrant AURKB expression, was not affected. Ovarian tissue morphology and viability was not compromised by the treatment, as no significant difference was observed regarding the percentage of morphologically normal follicles, follicular viability, glucose uptake or *in vitro* growth of small follicles between the ovarian cortex treated with the AURKB/C inhibitor and the control.

Limitations, reasons for caution: The persistence of CML and AML metabolically-active multinuclear syncytia after treatment precludes the use of molecular techniques to verify the complete absence of viable tumour cells. The functional integrity of the ovarian cortex tissue after *ex vivo* treatment requires further investigation *in vivo*.

Wider implications of the findings: Purging of CML/AML metastases in ovarian cortex is possible by targeting the Mitotic Catastrophe Signalling Pathway using an AURKB/C inhibitor without harming ovarian tissue. This provides a therapeutic strategy to prevent reintroduction of leukaemia and enhances safety of autotransplantation in leukaemia patients currently considered at high risk for ovarian involvement.

Trial registration number: not applicable

O-266 The role of F-actin and MYO10 distribution in quality assessment of fresh and frozen-thawed human growing follicles

S. Granados Aparici[1], T. Tulandi[1], W. Buckett[1], W.Y. Son[1], G. Younes[1], J.T. Chung[1], S. Jin[1], H. Clarke[1], A. Volodarsky-Perel[1]

[1]McGill University Health Centre, Obstetrics and Gynecology, Montreal, Canada

Study question: Does the distribution of F-actin and MYO10 protein differ in human preantral follicles from fresh and frozen human ovarian tissue?

Summary answer: Cryopreservation and the freezing method have an impact on the distribution pattern of F-actin and MYO10 protein in granulosa cells and oocytes.

What is known already: Cryopreservation of ovarian tissue has emerged as an option for fertility preservation for oncological patients. Slow freezing and vitrification, the two major methods of ovarian tissue cryopreservation, may disturb essential communication between oocyte and granulosa cells. Granulosa cells communicate with the oocyte via specialized actin-rich filopodia termed transzonal projections (TZPs) that enable the oocyte to be supplied with key nutrients and regulatory signals. MYO10 protein regulates filopodial growth and/or function and may work similarly in TZPs. However, the effects of freeze-thawing on the expression and distribution of MYO10 and F-actin in TZPs remain unclear.

Study design, size, duration: Frozen ovarian tissue was donated by patients who underwent ovarian tissue cryopreservation due to malignant disease. Fresh ovarian tissue was prospectively collected from patients who underwent ovarian surgery during the period from 2017 to 2019. Only patients with normal ovaries were included in this analysis. Ovarian follicles at primordial to secondary stages were retrieved from patients who donated fresh ovarian tissue (n=4), underwent vitrification (n=3), and slow freezing (n=5) of ovarian tissue.

Participants/materials, setting, methods: Fresh and thawed samples were immediately delivered for follicle harvesting. Follicles comprising a morphologically normal oocyte and non-pyknotic granulosa cells were stained using phalloidin and anti-MYO10. Confocal microscopy was used to image equatorial optical sections of each follicle. Parameters measured were the number of MYO10 foci and intensity of F-actin in the granulosa cells and oocytes. The correlation between the oocyte diameter and the structures associated with TZP development (MYO10 foci and F-actin) was evaluated.
Main results and the role of chance: A total of 180 good-quality follicles with a mean oocyte diameter of 36.6±9.1 µm from women of 22-37 years of age were included in the analysis. A positive correlation between oocyte diameter and MYO10 distribution in granulosa cells (correlation estimate (CE) 0.63; 95% confidence interval (95%CI) 0.43-0.77; P=0.001) and in oocytes (CE 0.43; 95%CI 0.19-0.63; P=0.001) was demonstrated in fresh follicles. In frozen-thawed follicles, a correlation was observed for MYO10 distribution in granulosa cells (CE 0.22; 95%CI 0.04-0.38; P=0.02) but not in oocytes. When vitrified follicles were compared to those subjected to slow freezing, the correlation between oocyte diameter and MYO10 distribution in granulosa cells was revealed only in the slow freezing group (CE 0.38; 95%CI 0.17-0.55; P=0.0005). Strikingly, large MYO10 aggregates within the oocyte were significantly more common after slow freezing compared to vitrification [25(30.5%) vs. 4(9.1%); P=0.007]. Correlation between oocyte diameter and F-actin intensity was observed in the slow freezing group (CE 0.31; 95%CI 0.09-0.49; P=0.006) but not in the vitrified follicles. The different patterns of MYO10 and F-actin distribution in growing fresh and thawed follicles suggests a significant impact of cryopreservation and method of freezing on the structures mediating physical communication between oocyte and granulosa cells.
Limitations, reasons for caution: Only follicles from patients without ovarian pathology were included. The effect of ovarian pathology on the structures associated with TZP development in fresh and frozen-thawed ovarian tissue is a matter for further studies.
Wider implications of the findings: Our study suggests that MYO10 distribution and F-actin intensity in granulosa cells as well as the presence of MYO10 aggregates in oocytes can be used for quality assessment of growing follicles in fresh and frozen-thawed ovarian tissue.
Trial registration number: Not applicable

O-267 Protection of the mouse testis tissue and sperm production from X-ray induced damages by pharmaceutical compounds that increase telomerase

H. Elul[1], **E. Priel**[1]

[1]*Ben-Gurion University of the Negev, The Shraga Segal Dept. Immunology-Microbiology & Genetics, Beer-Sheva, Israel*

Study question: Do pharmaceutical compounds (AGS) that increase telomerase protect the mouse testes from damages induced by X-ray?
Summary answer: A single AGS treatment increased telomerase in the mouse testes and protected the testis and sperm production from the damages induced by X-ray radiation.
What is known already: The telomerase reverse transcriptase (TERT) is expressed and active in the testes and is important for the spermatogenesis process. Short telomeres were identified in men with oligozoospermia and idiopathic infertility. Shortened telomeres in spermatozoa are markers for abnormal spermatogenesis. In addition to its role in the re-elongation of telomeres, TERT possesses non-canonical functions: protects cells from apoptosis, participates in the repair of DNA strand breaks and regulates the expression of genes. We synthesized novel compounds that transiently increased TERT expression and activity in various human and mouse cells and tissues. The compounds protected cells from damages induced by oxidative stress.
Study design, size, duration: Adult mice were divided to various treatment groups (>10 mice per group): with/ without exposure to X-ray radiation and with/without AGS treatment or vehicle treatment. At various intervals, post irradiation and treatment, the mice were sacrificed and their testes including the epididymis were removed and subjected to further analysis.
Participants/materials, setting, methods: Testis slices were stained with hematoxylin- eosin for tissue morphology. To identify the various cell types in the seminiferous tubules we used specific markers (VASA, CREM, acrosin) applying the immunohistochemistry procedures. The expression of TERT and specific spermatogenesis genes was measured by qRT-PCR. The presence of DNA strand breaks was detected by gamma-H2AX and cell proliferation by PCNA. Sperm cells were isolated from the epididymis, counted and analyzed for motility and morphology.
Main results and the role of chance: TERT expression and activity in the mouse testis increased following a single AGS dose. The expression of spermatogenesis markers (VASA and CREM) increased followed by a significant enhancement in the sperm count. Exposure of mice to X-ray radiation (2.5 Gy) damaged the testis tissue and decreased sperm count and sperm parameters (motility, normal morphology). Treatment of the X-ray irradiated mice with a single dose of AGS, significantly restored testis tissue morphology, the expression of spermatogenesis markers and decreased the number of seminiferous tubules that exhibited DNA strand breaks. AGS treatment of irradiated mice restored the sperm count and sperm motility and reduced the percentage of sperm cells with altered morphology. A higher sperm count and an increase in testis tissue regeneration, following X- ray radiation, was also detected in AGS treated mice 21 and 30 days after irradiation and treatment.
Limitations, reasons for caution: We could not use an X- ray dose that completely abolished sperm production. Therefore, under these conditions no significant differences in the ability to produce offspring, between X-ray irradiated and X- ray irradiated + AGS treated mice, were observed
Wider implications of the findings: This study suggests the ability of telomerase increasing compounds to restore the normal tissue morphology, the spermatogenesis process and the sperm count in damaged testes. Therefore, these compounds may be used as possible therapy in conditions that reduced male fertility.

SESSION 64: PROSPECTIVE CARRIER SCREENING OF ART COUPLES

08 July 2020 Parallel 6 10:00 - 11:45

O-268 Insights from the largest study on the genetics of sporadic and recurrent miscarriage

T. Laisk[1]

[1]*Institute of Genomics- University of Tartu, Estonian Genome Center, Tartu, Estonia*

Study question: Can we discover and map the maternal genetic susceptibility and underlying biology of sporadic and recurrent miscarriage using large-scale biobank data?
Summary answer: Our results confirm miscarriage as a complex partly heritable phenotype and implicate novel biology through regulation of genes involved in placental biology.
What is known already: Miscarriage is a common complex trait that affects 10-25% of all clinically confirmed pregnancies. Miscarriage is associated with excessive bleeding, infection, depression, infertility and an increased lifetime risk of cardiovascular disease. A variety of predisposing factors have been associated with increased miscarriage risk, and it has a genetic component that thus far has remained poorly characterized.
Study design, size, duration: Genome wide association study (GWAS) meta-analysis of up to 69,118 sporadic miscarriage cases from seven different ancestries, 750 recurrent miscarriage cases of European ancestry, and up to 359,469 female controls from biobanks all over the world.
Participants/materials, setting, methods: We investigated the genetic architecture of miscarriage with biobank-scale GWAS, Mendelian randomization, heritability, genetic correlation and functional annotation analyses.
Main results and the role of chance: We identify one genome-wide significant association (rs146350366, minor allele frequency (MAF) 1.2%, P=3.2×10-8, odds ratio (OR)=1.4) for sporadic miscarriage in our European ancestry meta-analysis and three genome-wide significant associations for recurrent miscarriage (rs7859844, MAF=6.4%, P=1.3×10-8, OR=1.7; rs143445068, MAF=0.8%, P=5.2×10-9, OR=3.4; rs183453668, MAF=0.5%, P=2.8×10-8, OR=3.8). Following functional annotation linked these associations with genes

related to placental biology. We found a heritability of 29% (95%CI 20%-38%) for miscarriage. Consistent with observational associations, we found significant genetic correlations between sporadic miscarriage and number of children ($p=7.210^{-9}$). The Mendelian randomization analyses suggest that smoking may causally increase the risk of sporadic miscarriage. Finally, our analysis of health outcomes associated with miscarriage confirms previously observed observations and identifies several novel ones.

Limitations, reasons for caution: Only maternal genetic data was analysed. Further studies are needed to assess the functional impact of the associated variants.

Wider implications of the findings: Our study shows the potential involvement of genes regulating placental function in the etiopathogenesis of miscarriage and highlights the utility of large population-based biobank data for understanding these understudied pregnancy complications. This research is presented on behalf of the International Miscarriage Genetics Consortium.

O-269 High detection rates in both IVF and general population confirm the clinical utility of Expanded Carrier Screening for the management of reproductive genetic risk

M. Fabiani[1], S. Caroselli[1], L. Girardi[1], C. Patassini[1], M. Poli[1], C. Simon[1,2,3,4], A. Capalbo[1,2]

[1]Igenomix Italia, Reproductive Genetics, Marostica VI, Italy ;
[2]Igenomix Foundation, Reproductive Genetics, Valencia, Spain ;
[3]Harvard School of Medicine- Harvard University-, Department of Obstetrics and Gynecology, Boston MA, U.S.A. ;
[4]Valencia University- and INCLIVA, Department of Obstetrics and Gynecology, Valencia, Spain

Study question: What is the Detection Rate (DR) and the clinical utility of Expanded Carrier Screening (ECS) application on the management of patients trying to conceive?

Summary answer: The high DR of At-Risk Couples (ARCs) and the remarkable proportion opting for IVF/Preimplantation Genetic Testing (PGT) treatment demonstrate ECS clinical utility in reproductive contexts.

What is known already: Around 1-2% of couples are at risk of conceiving a child with an autosomal recessive or X-linked disorder. Carrier screening (CS) identifies ARCs improving their reproductive autonomy. Previously, CS was employed to test single diseases (e.g., Cystic Fibrosis). Current genetic technologies allow simultaneous/parallel testing of multiple disorders. However, the previous low cost-effectiveness, suboptimal construction of test panels and inexperience with such genetic analysis across medical professionals are still undermining mainstream application of ECS. Here, a minimal ECS gene-panel was routinely applied on a large population of reproductive patients providing evidence of its DR, clinical utility and cascade testing opportunity

Study design, size, duration: A total of 2,013 individuals without family history of genetic disorders were enrolled at affiliated clinics in different Italian regions between March 2017 and December 2019. Of these, 1,172 individuals were from couples trying to conceive (902 through In Vitro Fertilization (IVF) and 270 by natural conception). Additionally, 181 individuals undergoing homologous IVF, 636 heterologous IVF and 24 natural conception were enrolled through *One-Member Screening Strategy*. Data were collected and elaborated anonymously following IRB approval.

Participants/materials, setting, methods: Monogenic disorders included in our panel (n=10) were selected based on ACMG-recommended criteria (prevalence, carrier rate, severity) and unequivocally associated with highly penetrant childhood conditions. Analytical methods employed include qPCR/Taqman assays for SNPs/indel variants, triplet-primed PCR and melting curve analysis for expansions and qPCR-based CNV analysis for exons/introns deletions. Couples were defined at-risk when both partners carried an autosomal recessive pathogenic variants on the same gene or when woman was a carrier of X-Linked disorder.

Main results and the role of chance: A total of 174 patients (8.6%) were identified as carriers of one of tested pathogenic variants: CFTR (n=59, 2.9%); SMN1 (n=46, 2.3%); DHCR7 (n=23, 1.1%); PMM2 (22, 1.1%); ACADM (n=15, 0.7%); HADHA (n=4, 0.2%); FMR1 (n=3, 0.4%); ARSA (n=1, 0.05%) and DMD (n=1, 0.1%). Remarkably, across the 586 couples tested, 13 (2.2%) were found to be at increased risk of having an affected child (ARCs). In particular, the identified ARCs were carriers of Cystic Fibrosis (n=5, 0.8%), Spinal Muscular Atrophy (SMA) (n=3, 0.5%), Fragile-X Syndrome (n=3, 0.5%), Smith-Lemli-Opitz Syndrome (n=1, 0.2%) and Duchenne/Becker Dystrophy (n=1, 0.2%). Notably, 3 of these ARCs were identified among couples trying to conceive by natural conception. Moreover, the identification of a patient carrying a pathogenic variant on the SMN1 gene led to cascade testing of his relatives, revealing another ARC for SMA in the family. At present, among ARCs that were followed up, all of them (N=10) pursued actions to reduce their reproductive risk by undergoing IVF with PGT for monogenic conditions (PGT-M). To date, 4/10 (40.0%) couples completed their PGT-M cycle with euploid/healthy embryos. Two of these couples have already achieved a healthy pregnancy after embryo transfer.

Limitations, reasons for caution: The main limitation of this study involves the lack of ethnic diversity in our cohort (mainly Caucasians). Also, the use of a limited panel of core gene-disease pairs can underestimate the rate of carriers and ARCs detectable in this cohort of individuals.

Wider implications of the findings: Extensive application of ECS detects a remarkable proportion of ARCs, improving couples' reproductive autonomy and providing opportunities for cascade genetic analysis. Continuous reduction in sequencing costs and improvement in variant interpretation and genotype-phenotype association are predicted to widen the diagnostic scope of ECS, leading to increasingly higher detection rates.

Trial registration number: not applicable

O-270 A novel long-range DNA sequencing approach improves the design of new protocols for preimplantation genetic testing of monogenic disease (PGT-M).

M. Leaver[1], N. Kubikova[1], X. Tao[2], C. Jalas[2], D. Wells[3]

[1]University of Oxford, Nuffield Department of Women's and Reproductive Health, Oxford, United Kingdom ;
[2]The Foundation for Embryonic Competence, New Jersey, New Jersey, U.S.A. ;
[3]Juno Genetics, Oxford, Oxford, United Kingdom

Study question: Can long-range next-generation sequencing assist in the work-up of PGT-M cases, with potential to increase patient access, improve accuracy and reduce costs?

Summary answer: Long-range DNA sequencing provides a powerful, low-cost method that reveals the informative SNPs closest to gene mutations and eliminates the need for additional family samples.

What is known already: To avoid misdiagnoses caused by allele dropout (failure to amplify one of the two alleles in an heterozygous cell), PGT-M strategies usually involve parallel analysis of several diagnostically relevant sites (e.g. mutations+linked polymorphisms). Polymorphisms need to be as close as possible to mutation sites because of the possibility of recombination. To determine which polymorphic alleles are associated with the disease, DNA from additional family members is usually analysed. However, relatives are not always available, as patients may carry *de novo*mutations, relatives may be untested or deceased, or patients may not wish to disclose their PGT-M treatment to others.

Study design, size, duration: A novel work-up method for PGT-M was evaluated. DNA was obtained from 13 couples undergoing PGT for different monogenic disorders. For each mutation, two primer sets (A and B) were designed, allowing amplification of the mutation plus an additional ~10kb upstream (A) or downstream (B). Amplicons were sequenced as single contiguous reads using the MinION (Oxford Nanopore). This identified informative single nucleotide polymorphisms (SNPs) and revealed which alleles exist on the same chromosome as mutations.

Participants/materials, setting, methods: 10kb regions flanking (and encompassing) mutation sites were sequenced from the 26 patients. Traditionally, candidate linked polymorphisms are identified from databases, but many turn out to be uninformative. Alternatively, parental samples can be analysed by microarray, simultaneously assessing many SNPs, but only evaluating a fraction of the variations in the genome. The SNPs found to be informative are sometimes relatively distant from the affected gene, increasing the chances of recombination between the SNP and mutation.

Main results and the role of chance: All 18 mutations in the 13 couples were successfully detected using long-range sequencing. Additionally, between 2 and 83 (average 18) informative SNPs were found in the 10kb flanking regions. The average distance from mutation sites to the nearest informative SNPs was 2529bp.This compares to an average distance of 32,179bp when microarrays were used to identify suitable SNPs. The extremely close proximity of

polymorphisms identified by long-range sequencing means that diagnostic challenges due to separation of SNPs from the disease-causing mutation by meiotic recombination can be virtually ruled out. In 28% of patients the closest informative polymorphism had a minor allele frequency <0.1. Such SNPs are rarely heterozygous and are therefore unlikely to be included in SNP-microarrays and are also unlikely to be chosen from databases as a candidate marker for PGT-M work-up.Additionally, novel informative intragenic SNPs, not present in any database, were identified in three couples. Because mutations and SNP alleles were contained within the same sequencing 'read', phasing was successfully accomplished in all cases, without any need for samples from additional family members. This will be of great value for couples who have no relatives suitable for phasing of polymorphisms (approximately one quarter of all PGT-M couples).
Limitations, reasons for caution: Unlike generic PGT-M methods (e.g. haplarithmisis/karyomapping), this strategy requires a customised protocol for each couple. The use of direct mutation testing combined with analysis of the closest possible SNPs flanking the mutation site is an approach that is unsurpassed in accuracy, but requires primer design and therefore slightly more work-up.
Wider implications of the findings: By providing a simple, inexpensive, rapid method of identifying the closest informative polymorphisms to parental mutations, long-range sequencing potentially improves PGT-M accuracy, reduces costs of customised protocols and accelerates test development. Furthermore, this approach removes the need to obtain DNA from any family members other than the couple undergoing PGT.
Trial registration number: N/A

O-271 KDM1A mediates transgenerational metabolic disturbances in a sex-specific manner and is linked to diet-induced altered sperm chromatin signatures

A.S. Pepin[1], C. Lafleur[2], V. Dumeaux[3], D. Sloboda[4], S. Kimmins[2]

[1]McGill University, Department of Pharmacology and Therapeutics, Montreal, Canada ;
[2]McGill University, Department of Animal Science, Montreal, Canada ;
[3]Concordia University, PERFORM Centre, Montreal, Canada ;
[4]McMaster University, Department of Biochemistry and Biomedical Sciences, Hamilton, Canada

Study question: Our objectives were to investigate whether epigenome-environment interactions can lead to enhanced metabolic phenotypes transgenerationally, and whether transmission of phenotypes are linked to sperm chromatin signatures.
Summary answer: Combining a genetic model of epigenetic inheritance with a diet-induced obesity model led to sex-specific transgenerational metabolic disturbances and aberrant sperm chromatin profiles.
What is known already: Obesity occurs in 650 million people worldwide (World Health Organization, 2016). Known factors contributing to obesity risks include genetics, lifestyle and maternal factors. Epidemiological studies and animal model data indicate that paternal diet also affects offspring risks to develop adult-onset metabolic disorders. However, the mechanisms underlying this non-genetic inheritance of complex metabolic disease remain elusive. Sperm histone methylation has been implicated in transgenerational epigenetic inheritance and offspring health (Siklenka et al. 2015). This was previously demonstrated using a transgenic mouse model that overexpresses the histone demethylase KDM1A specifically in the germline, giving rise to males with an abnormal sperm epigenome.
Study design, size, duration: KDM1A transgenic males with a pre-existing compromised sperm epigenome and C57BL6NCrl wildtype sires, were exposed to either a low- or high-fat diet (10% or 60% kcal fat, respectively) for two spermatogenic cycles (10-12 weeks). The next generations were generated by mating males with chow-fed C57BL6NCrl females. All animals were subjected to a series of metabolic tests at 4 months of age (F0: n=15-25 animals per group, F1: n=28-49, F2: n=8-21) and sacrificed at 5 months.
Participants/materials, setting, methods: Metabolic assessment was performed using glucose and insulin tolerance tests and baseline blood glucose levels. At necropsy, mesenteric adipose depots were weighted to assess adiposity. Liver RNA was extracted (n=4-6 per sex per group per generation) for differential gene expression. Sperm of F0 sires (n=5 per group) was subjected to chromatin immunoprecipitation sequencing targeting histone H3 methylation and analyzed to identify diet-modulated changes in enrichment which could be implicated in offspring phenotypes.
Main results and the role of chance: Sires (F0) fed a high-fat diet became obese, glucose intolerant and insulin insensitive, with increased adiposity, irrespective of their genotype. Intergenerational effects of paternal diet were observed in male offspring only, while metabolic functions in female descendants were not impacted by paternal high-fat diet. Males sired by obese transgenics had enhanced metabolic phenotypes compared to wildtype obese descendants. Interestingly, transgenerational effects of high-fat diet were only observed in transgenic descendants, suggesting that paternal exposure to a multitude of environmental stressors may exacerbate descendants' risk for obesity and metabolic syndrome. Sex-specific effects were further observed in the F2 generation, suggesting males may be more susceptible to paternal and grand-paternal diets. Sperm chromatin profiling revealed diet-induced alterations in enrichment. Differentially enriched regions occurred at genes with functions corresponding to the observed offspring phenotypes, including genes involved in placenta development, as well as glucose and lipid metabolism.
Limitations, reasons for caution: Further studies are required to better understand the molecular mechanisms underlying the links between diet-induced obesity, an aberrant sperm epigenome and offspring metabolic functions.
Wider implications of the findings: This is the first report linking high-fat feeding and alterations in the sperm epigenome at the level of a histone modification. These findings shed light on the potential contribution of chromatin in sperm in paternal transmission of complex diseases.
Trial registration number: not applicable

O-272 Germline Characterization of Genes Associated with Spermatogenesis and Embryonic Developmental Competence in Azoospermic Men

S. Cheung[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can DNA sequencing of spermatozoa from azoospermic men identify germline mutations related to the etiology of their infertility and ability to support a pregnancy?
Summary answer: Men with secretory azoospermia have mutated key genes that impair sperm production and affect the ability of their spermatozoa to support embryonic development.
What is known already: Azoospermia accounts for about 15% of male factor infertility cases. Although it can be caused by pre-testicular factors, the most recognized forms are testicular and post-testicular. Post-testicular azoospermia, the most severe form, is characterized by scattered functional germinal epithelia that strive to support the meiotic process during gamete development. To shed light on the etiology of this condition, genetic studies have been performed, exclusively on peripheral blood. We performed a genetic assessment of the spermatozoa to preferentially detect germline mutations that may be passed onto offspring.
Study design, size, duration: During the last 18 months, we performed DNAseq on epididymal and testicular spermatozoa from men with acquired azoospermia (OA) (n=17) and nonobstructive azoospermia (NOA) (n=10), respectively, as well as on the ejaculated gametes from 3 fertile donor controls. Gene mutations related to azoospermia origin were categorized and compared. Gene mutation profiles of the OA and NOA men were then assessed in relation to their ability to generate a pregnancy (fertile) or not (infertile).
Participants/materials, setting, methods: DNA was extracted and amplified from at least 500 spermatozoa (DNA concentration, 705±562 ng/ul; quality, 1.7±0.1 nm). Following NGS, gene mutations, duplications, and deletions were detected using the CLC Genomic Server 9.0. Genes were considered duplicated or deleted when the read depth was >1.5 or <0.5 times the median read depth in the control. Common gene mutations from the OA and NOA cohorts were assessed according to the couples' clinical outcome.
Main results and the role of chance: Of the 27 couples (paternal age, 41.3±5yrs) included in this study, 17 OA men underwent surgical sperm retrieval, with an average concentration of 1.3±3x10^6/ml and 7±14% motility. Ten NOA men yielded spermatozoa with a concentration of 0.03±0.2x10^6/ml and 0.5±1% motility. NGS assessment did not show a significant difference in overall sperm aneuploidy between the two groups (OA, 1.7%; NOA, 1.9%).

In the OA group overall, only 3 housekeeping genes were mutated (ATP4A, SLC17A7, and OR1D4). In the NOA patients, however, 5 genes involved in RNA transcription (POLR2L), apoptosis (AP5M1), and basic spermiogenic function (AP1S2, AP1G2, and APOE) were deleted.

The OA patients were treated in 17 ICSI cycles (maternal age, 34.8±3yrs), resulting in a pregnancy and delivery rate of 47.1% (8/17). The fertile and infertile OA cohorts had only 1 mutated gene, ZNF749 and PRB1, respectively. Both were unrelated to spermatogenesis or embryo developmental competence.

When NOA men were treated in 10 ICSI cycles (maternal age, 38.2±2yrs), the pregnancy rate was 70% (7/10). While the fertile cohort displayed 1 mutated gene (MPIG6B) related to stem cell lineage differentiation, the infertile NOA cohort had deleted genes involved in spermatogenesis (n=6), apoptosis (n=4), acrosomal function (n=2), and early embryonic development (n=8).

Limitations, reasons for caution: This is a novel study with a limited number of observations, and it cannot demonstrate genetic association with obstructive azoospermia independently of reproductive performance. In addition, although female partner age was controlled for, confounding factors cannot be excluded with certainty.

Wider implications of the findings: This novel DNAseq study aims to identify germline mutations. The reproductive performance of OA men was not associated with any genetic mutations. In the NOA cohort, fertile men had only one deleted gene involved in sperm production, while infertile men had several deleted genes involved in spermatogenesis and embryonic development.

Trial registration number: not applicable

O-273 Knowledge, attitudes and preferences regarding expanded carrier screening among reproductive-aged men and women in Belgium

E. Van Steijvoort[1], I. Geysen[1], S. Van Epperzeel[1], H. Devolder[1], H. Peeters[2], K. Peeraer[3], G. Matthijs[2], P. Borry[1]

[1]KU Leuven, Department of Public Health and Primary Care, Leuven, Belgium ;
[2]KU Leuven, Department of Human Genetics, Leuven, Belgium ;
[3]KU Leuven, Department of Development and Regeneration, Leuven, Belgium

Study question: What is the knowledge, attitudes and preferences regarding expanded carrier screening among reproductive-aged men and women in Belgium?

Summary answer: Health care providers and policy makers should take the current knowledge level, attitudes and preferences of potential users in account when implementing ECS.

What is known already: Through carrier screening couples at-risk of conceiving a child with an autosomal recessive or X-linked condition can be identified prior to conception, allowing prospective parents to make informed reproductive decisions when planning for a family. In the last decade, expanded carrier screening has become available to (prospective) parents. Following recommendations made by the Superior Health Council (SHC) of Belgium, a Belgian Genetic Carrier Screening test (BeGECS) was launched in October 2019. However, little is known about the interest, knowledge level, attitudes and preferences of potentials users. More insights are need to ensure responsible implementation of the BeGECS offer.

Study design, size, duration: A cross-sectional survey was conducted using convenience sampling. Individuals of reproductive age visiting their public pharmacist were invited to answer a self-administered questionnaire assessing knowledge, attitudes and preferences regarding expanded carrier screening (ECS). Prior to filling in the questionnaire, participants were asked to read an information letter explaining some key concepts. Based on our sample size calculation we aimed to collect 385 completed questionnaires. Data collection was carried out between September 2019 and December 2019.

Participants/materials, setting, methods: The study population consisted of reproductive aged (18-49 years) men and women. Participants were recruited through five public pharmacies in Flanders (Belgium). Potential participants were approached about the study by researchers present in the pharmacies and were asked to fill in the anonymous questionnaire on the spot after reading an information sheet explaining some key concepts. The questionnaire contained questions on socio-demographic characteristics, risk perception, intention to have ECS, knowledge, attitudes, preferences, etc.

Main results and the role of chance: Our sample (n=387) consists of 265 females (68.5%) and 122 males (31.5%). Most of the participants were below 34 years old (72.9%), didn't have children (68.6%) and were currently in a relationship (69.1%). Of those who were in a relationship, 52.1% had a future child wish. More than half of the participants (53.6%) estimated their chance of being a carrier for a recessive disorder (very) low. Likewise 64.8% of participants estimated their chance of conceiving a child with a recessive disorder (very) low. Offering ECS to couples with a child wish was found acceptable by 86% of participants. However, fewer participants would consider ECS for themselves in the future (61%). Only 19 (4.9%) participants answered all knowledge questions correctly. Half of the participants (50.9%) preferred the disclosure of individual results, while 35.2% preferred couple-based results. Most participants indicated that ECS should be offered through the gynecologist (81.1%), followed by the GP (71.5%) and the Center for Human Genetics (64.8%). About 68.9% of participants were willing to pay out-of-pocket for an ECS test. If participants were willing to pay themselves, they indicated that the test should have a maximum cost of 150 euros (45.3%) or between 150 – 300 euros (40%).

Limitations, reasons for caution: Our study employed convenience sampling to recruit participants, therefore our reported results should be interpreted with caution. Another limitation of our study is that we didn't offer an actual ECS-test to participants so some results are only hypothetical. Actual participation might differ from the intention to do a behavior.

Wider implications of the findings: Our study reports on the views of the potential users of ECS. These results can guide health care providers and policy makers when implementing ECS in the future to ensure that couples makes informed reproductive decisions based on accurate knowledge and consistent with the values of the couple.

Trial registration number: Not applicable

O-274 Single nucleotide polymorphisms (SNPs) in FSHR/FSHβ genes do not modify ovarian response to stimulation with rFSH. A prospective multicentre study in Europe and Asia

N.P. Polyzos[1], C. Blockeel[2], C. Spits[3], B. Alvaro Mercadal[1], S. Garcia[4], P. Ma[5], L. Le[5], M. Ho[5], G. Duqué[3], J. Mertens[3], D. Stoop[6], P. Drakopoulos[2], H. Tournaye[2], F. Martinez[1], N. Vuong[7]

[1]Dexeus University Hospital, Reproductive Medicine Department, Barcelona, Spain ;
[2]Universitair Ziekenhuis Brussel-Vrije Universiteit Brussel, Centre for Reproductive Medicine, Brussels, Belgium ;
[3]Vrije Universiteit Brussel, Research Group Reproduction and Genetics, Brussels, Belgium ;
[4]Dexeus University Hospital, Statistics Department, Barcelona, Spain ;
[5]My Duc Hospital, IvfMD, Ho Chi Minh City, Vietnam ;
[6]Ghent University Hospital, Centre for Reproductive Medicine, Ghent, Belgium ;
[7]University of Medicine and Pharmacy, Medical Statistics Department, Ho Chi Minh City, Vietnam

Study question: Does the presence of SNPs in FSHR/FSHβ influence oocyte yield and Follicular output rate (FORT) in predicted normal responders treated with rFSH?

Summary answer: The presence of SNPs in FSHR/FSHβ (rs6165, rs6166, rs1394205, rs10835638) does not influence ovarian response in predicted normal-responders treated with a fixed-dose of 150IU rFSH

What is known already: Ovarian reserve markers have been a breakthrough in response prediction following ovarian stimulation. However, a significant percentage of patients show a disproportionate lower ovarian response, as compared with their actual ovarian reserve. Studies on pharmacogenetics demonstrated a relationship between FSHR/FSHβ genotyping and drug response, suggesting a potential effect of individual genetic variability on ovarian stimulation. However, evidence from these studies is inconsistent, due to inclusion patients with variable ovarian reserve, use of different starting gonadotropin doses and allowance for dose adjustments during treatment. This highlights the necessity of a well-controlled prospective study, in homogenous population treated with an identical protocol.

Study design, size, duration: We conducted a multicenter multinational prospective study, including 368 patients from Vietnam, Belgium and Spain (168 from Europe and 200 from Vietnam), from November 2016 till June 2019. All patients underwent ovarian stimulation followed by oocyte retrieval in an antagonist protocol with fixed daily dose of 150IU of rFSH until triggering. Blood

sampling and DNA extraction was performed prior to oocyte retrieval, followed by genotyping of 4 SNPs from FSHR/FSHβ (rs6165, rs6166, rs1394205, rs10835638).

Participants/materials, setting, methods: Eligible were predicted normal responder women <38 years old undergoing their 1st/2nd ovarian stimulation cycle. Laboratory staff and clinicians were blinded to the clinical results and genotyping respectively. The number of oocytes and the FORT (number of follicles on trigger day/AFCx100) were compared between different FSHR/FSHβ genotypes. Results were analysed with x^2 or oneway ANOVA and were corrected for multiple comparisons as appropriate.

Main results and the role of chance: The prevalence of homozygous SNPs in the FSHR was: rs6166(c.2039 A>G) 15.8%, rs6165(c.919 A>G) 34.8% and rs1394205(c.-29G>A) 14.1% with significant differences between European and Asian women. FSHβ rs10835638(c.-211 G>T) was very rare: 0.5%.

Comparison between different SNPs and genotypes, wild-type (WT), heterozygous(HT) or homozygous(HZ), did not reveal significant differences in terms of ovarian response.

The number of oocytes was comparable between the 3 genotypes (WT vs.HT vs.HZ) for all 3 variants in FSHR :

1. a. rs6166 (mean(SD)): 14.81(7.07) vs. 13.49(7.30) vs. 13.69(5.82), p=0.066
2. b. rs6165: 14.39(7.08), 13.59(7.54), 14.25(6.30), p=0.095
3. c. rs1394205: 15.06(8.10), 13.24(5.89), 13.61 (6.95), (p=0.088)

Similarly, no differences were observed on the FORT for rs6166 (p=0.814), rs6165 (p=0.974) and rs1394205 (p=0.081). Linear regression analysis to predict the number of oocytes in relation to genetic variants (rs6166, rs1394205, rs6165) adjusted for age, AMH, continent and duration of stimulation, did not show differences between WT, HT, HZ for rs6166 and rs6165. Although rs1394205 HZ had statistically significant lower oocyte yield compared with WT, this was of minimal clinical significance, 0.84 95%CI [0.71;0.98] oocytes less.

Finally, the proportion of women with optimal response (>10 oocytes) was also comparable between the 3 groups (WT vs. HT vs. HZ) for rs6165, rs6166 and rs1394205

Limitations, reasons for caution: The study was performed in relatively young women with normal ovarian reserve to eliminate biases related to age-related fertility decline; thus, caution is needed when extrapolating results to other populations. In addition, no analysis was performed for FSHβ rs10835638 due to the very low prevalence of homozygotes (n=2).

Wider implications of the findings: Based on our results, genotyping SNPs rs6165, rs 6166, rs1394205, rs10835638 prior to initiating an ovarian stimulation with rFSH in predicted normal responders should not be recommended since their presence does not modify ovarian response in these women. Future research may focus on other genes related to folliculogenesis or steroidogenesis

Trial registration number: NCT03007043

INVITED SESSION

SESSION 65: BIOMARKERS OF FAILED PREGNANCY

08 July 2020 Parallel 1 12:00 - 13:00

O-275 Biomarkers of failed pregnancy (miscarriage ectopic). The clinician's perspective

A. Daponte[1], O. Koukoura[2]

[1]*University of Thessaly- School of Health Sciences- Faculty of Medicine, Obstetrics and Gynaecology, Larissa, Greece*

[2]*University Hospital of Larissa, Obstetrics and Gynaecology, Larissa, Greece*

Abstract text

Ectopic pregnancy (EP) occurs when a blastocyst abnormally implants outside the endometrium The fallopian tube is the commonest location in more than 95% of cases The prevalence of EP has doubled since 1960 and accounts for about 2% of the pregnancies in the first trimester. In recent years, its incidence has increased due to the increase in incidence of pelvic inflammatory diseases, use of fertility drugs, and pelvic surgery. Transvaginal ultrasound and serial measurement of serum beta-hCG levels are the most common diagnostic methods for EP. Despite the use of transvaginal ultrasound and measurement of beta-hCG levels, about 40% to 50% of the initial cases of the disease are not diagnosed. Therefore, the need for new diagnostic tools, preferably serum biomarkers, is essential.

Several diagnostic biomarkers for EP have been proposed over the past decades. Progesterone along with beta-hCG are the first and widely used biomarkers. Progesterone however, although represents a good indicator of early pregnancy viability, is a poor predictor of pregnancy location. To produce the optimal biomarker for early EP detection, several obstacles must be overcome. Firstly the behaviour of an EP and the substances produced during the first few days following implantation, might vary considerably in cases where the pregnancy is a result of assisted reproduction technology, the site of implantation and whether the EP is intact ruptured or aborted. Investigators studied several biomarkers produced by the fallopian tube, the early embryo, the endometrium, the ovary, or peritoneal inflammatory factors. So far none of these substances have been widely used in clinical practice.

Cancer antigen 125 has been reported as a marker for pregnancies "likely to continue". Inhibin A, activin A, and high sensitivity C-reactive protein (hsCRP) were not significantly different in women with successful and failed expectant management. On the other hand, inhibin A may be useful for predicting spontaneous resolution of pregnancy of unknown location (PUL) but is not as good as progesterone. Recent attention has focused on metalloprotease 12 (ADAM 12) and fibronectin as potentially promising candidate markers in PUL pregnancies. Serum Interleukin-15 (IL-15) and anti-C1q antibodies although showed promising results in differentiating between an abortion and EP, they had no further clinical application. Similar results presented when placental growth factor (PlGF) and the soluble Flt-1 (sFlt-1) receptor of vascular endothelial growth where investigated.

Several studies outline the utility of creatine phosphokinase (CPK), which is an intracellular enzyme found in the fallopian tube, as a marker for early diagnosis of EP. The theory behind the idea is that since CPK is an intracellular enzyme, lysis of trophoblast cells leads to an increase in plasma CPK levels. Therefore, the level of this enzyme can be used for evaluation of tubal ectopic pregnancy because increased CPK can be associated with trophoblastic invasion and trophoblast mass. However different studies produced conflicting results.

Metabolomics and epigenomics represent two rather new fields of research in medicine. Metabolomic markers have been produced promising results in recent studies. Epigenetic studies are mainly focused on detecting micro-RNAs that regulate expression of EP-associated genes such as VEGFA, EGFR, ESR1 and immune response-related genes. Most of these studies have a limited number of subjects, therefore, their results need to be confirmed by future studies.

The ideal diagnostic tool for an EP would be a single serum marker to replace ultrasound and serial biochemistry. This implies earlies management and the opportunity for conservative management in most cases. To date this ideal serum biomarker is under investigation.

O-276 Developing biomarkers for non-viable pregnancies: the laboratory expert perspective

A. Horne[1]

[1]*University of Edinburgh, MRC Centre for Reproductive Health, Edinburgh, United Kingdom*

Abstract text

The development of biomarkers for prompt diagnosis, and safe timely treatment, of non-viable pregnancies is essential. A blood-based biomarker that accurately identifies an ectopic pregnancy could be used to offer early diagnostic certainty in cases where ultrasound cannot determine the location of the embryo ('a pregnancy of unknown location'). Here, I review the literature on the development of molecularly targeted diagnostics for ectopic pregnancy, miscarriage and viable pregnancies. Molecules examined so far can be broadly grouped into biological themes of relevance to reproduction: (i) Fallopian tube (dys)function,

(ii) embryo/trophoblast growth, (iii) corpus luteum function, (iv) inflammation, (v) uterine function and (vi) angiogenesis. While a sensitive and specific biomarker for ectopic pregnancy has yet to be identified, it is possible that improvements in platform technologies or a multi-modal biomarker approach may yield an accurate diagnostic biomarker test. Furthermore, with the advent of better imaging technology, the need for a blood-based biomarker test may be superseded by improvements in ultrasound or magnetic resonance imaging technology.

SESSION 66: SYNTHETIC EMBRYOLOGY: MYTH OR REALITY?

08 July 2020 Parallel 2 12:00 - 13:00

O-277 Modelling blastocyst formation and in utero implantation solely from stem cells

N. Rivron[1]

[1]*IMBA- Austrian academy of science, Laboratory for synthetic development, Vienna, Austria*

Abstract text

The pre-implantation conceptus (blastocyst) forms all embryonic and extra-embryonic tissues. It consists of a spherical thin-walled layer, the trophectoderm, that surrounds a fluid-filled cavity sheltering the embryonic and primitive endoderm cells. From mouse blastocysts, both trophoblast and embryonic stem cell lines can be derived, which are in vitro analogues of the trophectoderm and embryonic compartments, respectively. Our lab showed that trophoblast and embryonic stem cells self-organize in vitro to form structures that morphologically and transcriptionally resemble blastocysts (blastoids). Blastoids form primitive endoderm-like cells, the second extra-embryonic lineage, and implant upon in utero transfer. Like blastocysts, blastoids form via inductive signals originating from the inner embryonic cells and driving outer trophectoderm development. However, the nature and function of these molecular signals are largely unexplored. Genetically and physically uncoupling the embryonic and trophectoderm compartments, along with single cell transcriptomics, revealed an extensive list of inductive signals. We show that the embryonic cells maintain trophoblast proliferation and self-renewal, while fine-tuning trophoblast epithelial morphogenesis. Altogether, these embryonic inductions are paramount to form a trophectoderm state that robustly implants and triggers a genuine decidualization in utero. Thus, at this stage, the nascent embryo fuels the development and implantation of the future placenta. Altogether, the blastoid is a powerful embryo model that can be reproducibly generated in large numbers, finely tuned, contains all the cell types to form the conceptus, and implants in utero.

INVITED SESSION

SESSION 67: COVID-19 - PSYCHOSOCIAL IMPACT OF DELAYED TREATMENT

08 July 2020 Parallel 3 12:00 - 13:00

O-279 Impact of COVID-19 pandemic on the psychological status of infertile patients who had in vitro fertilization treatment interrupted or postponed

S. Ferrero[1], **C. Scala**[2], **M. Altieri**[1], **F. Barra**[1]

[1]*IRCCS Ospedale Policlinico San Martino- University of Genoa, Academic Unit of Obstetrics and Gynecology, Genoa, Italy*

[2]*Gaslini Hospital, Unit of Obstetrics, Genoa, Italy*

Study question: To understand the changes in the psychological status of infertile patients who had in vitro fertilization (IVF) treatment interrupted or postponed because of the COVID-19 pandemic.

Summary answer: Infertile women who had IVF treatment postponed because of COVID-19 pandemic have psychological symptoms. IVF centers must strengthen psychological counseling to improve patients' mental health.

What is known already: Infertility is a severely distressing experience for many couples. Depression and anxiety are psychological disorders associated with infertility, and they may worsen during infertility treatments.

Study design, size, duration: This study was conducted in April 2020. A survey's link was e-mailed to the partecipants. A reminder e-mail was sent every week for one month.

Participants/materials, setting, methods: This study included all the patients attending our institution who had IVF treatment interrupted or delayed because of the COVID-19 pandemic. The severity of anxiety and depression was assessed using the Generalized Anxiety Disorder-7 (GAD-7) and the Patient Health Questionnaire-9 (PHQ-9). Subjects with pre-existing psychiatric disorders were excluded.

Main results and the role of chance: 503 patients (294 women and 209 men) completed the questionnaire (response rate: 80.9%; n = 622). The mean (± SD) age of the women included in the study was 37.3 (± 4.6) years; the mean age of men was 38.4 (±6.2). The median number of previous failed IVF cycles was 2 (range, 0-8). The prevalence of anxiety or depression, or both was 37.0% (186 of 503). The prevalence of anxiety or depression or both was significantly higher in women (41.5%; 95% C.I. 35.8%-47.4%) than in men (30.6%; 95% C.I., 24.4%-37.4%; p = 0.012). The median total score on GAD-7 was 11 (interquartile range, IQR: 9-14). The median total score on PHQ-9 was 10 (IQR: 9-14). The occurrence of anxiety and/or depression was significantly associated with a diagnosis of poor ovarian reserve (odds ratio, OR=2.13), diagnosis of endometriosis (OR=1.54), diagnosis of uterine fibroids (OR=1.34) and time spent on COVID-19 related news per day (> 1 hour per day, OR=1.47). Notably, 187 patients (37.2%; 32.9%-41.6%) declared that they would like to undergo the IVF treatment despite the COVID-19 pandemic. 384 patients (76.3%; 72.4%-80.0%) declared that they would be reassured if they knew when they could restart the IVF treatment.

Limitations, reasons for caution: A longitudinal follow-up would be helpful in tracking the changes in anxiety and depression levels at different stages of the epidemic.

Wider implications of the findings: This study reveals that the COVID-19 epidemic caused a sharp increase in the prevalence of anxiety and depression among infertile patients undergoing IVF. IVF center must strengthen the psychological counseling for these patients to improve their sleep quality and mental health.

O-280 Patient experiences of fertility clinic closure during the COVID-19 pandemic: Appraisals, coping and emotions

J. Boivin[1], **C. Harrison**[1], **R. Mathur**[2], **G. Burns**[3], **A. Pericleous-Smith**[4], **S. Gameiro**[1]

[2]*Manchester University NHS Foundation Trust and Manchester Academic Health Sciences Centr, OB-Gyn, Manchester, United Kingdom*

[3]*Fertility Network UK, Director, London, United Kingdom*

[4]*British Infertility Counselling Association, Chair, York, United Kingdom*

Study question: What are appraisals, coping strategies and emotional reactions to COVID-19 fertility clinic closure?

Summary answer: Clinic closure was appraised as stressful due to uncertainty and threat to attainability of parenthood goal but patients were able to cope using accommodative strategies.

What is known already: According to stress and coping theory, imbalance between threat and coping resources leads to stress reactions. People facing disasters generally experience more stress than usual, but remarkably most are able to cope and recover, with some eventually seeing benefits from the situation. Research to date on experiences of COVID-19 in the general population indicates more anxiety and depression among respondents than historical norms, worry about becoming mentally unwell due to uncertainty and loss of control but nevertheless ability to cope. Reports of reactions to COVID-19 in infertility patients shows these are moderately to extremely upset about COVID-19 treatment cancellation.

Study design, size, duration: Cross-sectional design. Mixed-methods, English, anonymous, online survey posted from April 09 to April 21 to social media. Eligibility criteria was being affected by COVID-19 fertility clinic closures, 18 years of age or older and able to complete survey in English. In total 946 people clicked on the survey link, 76 did not consent, 420 started the survey but did not complete it, and 450 completed the survey (48% completion, 446 women, 4 men).

Participants/materials, setting, methods: On average participants were 33.6 years (SD=4.4) and had been trying to achieve pregnancy for 3.5 years (SD=2.22). The survey comprised quantitative questions about intensity of threat, emotions, and ability to cope with clinic closure. Open-text questions covered understanding of COVID-19, fears, concerns and perceived benefits of clinic closure, and desired information about closure and future re-opening. Inferential statistics were used on quantitative data and thematic qualitative analysis (inductive coding) performed on open text data.

Main results and the role of chance: Overall 82.2% (n=367) had tests/treatments postponed. Patients appraised fertility clinic closure as significantly more negative than positive [$t(447)=45.2$, $p < .001$], and to be very or extremely uncontrollable [$t(445)=38.99$, $p < .001$] and stressful [$t(445)=27.44$, $p < .001$]. Most reported below average ability to cope with the closure (11.9% not at all able) [$t(445)=5.57$, $p < .001$]. Question by question textual analysis revealed 33 broad themes, grouped into four meta-themes across questions. First, COVID-19 effects were unknown and clinic closure perceived as precautionary or as unfair relative to advice about getting pregnant given to the public. Second, closure was appraised as a threat to attainability of the parenthood goal largely based on uncertainty of effects of delay and intensification of pre-existing hardships of fertility problems. Third, threat emotions and uncertainty taxed personal coping resources but most managed the situation using diverse strategies (e.g., thought-management, getting mentally and physically fit for next treatments, strengthening their social network, and keeping up-to-date with clinics. Finally, almost all participants reported significant stress, worry and frustration at the situation with a minority reporting intense feelings of hopelessness. More information about effects of delay and eventual wait-list prioritisation at re-opening was desired.

Limitations, reasons for caution: The survey captured reactions at a specific point in time (during lockdown before clinics announced re-opening) but results offered future directions for handling of information in COVID-19 conditions. Participants were self-selected, 25% non-UK countries and only 4 men all of which may affect generalisability.

Wider implications of the findings: Fertility stakeholders (e.g., clinics, patient groups, regulators, professional societies) need to work together proactively to address the continuing impact of COVID-19 on patients. Transparent processes for COVID-19 and sign-posting to information and coping support resources will bolster patients existing coping resources and support staff deliver the new normal for clinics.

O-317 A study to explore participants experiences of fertility services during the Covid-19 lockdown; a biphasic mixed methods study

B. Karavadra[1], **A. Balen**[2], **E. Morris**[1]

[1]*Norfolk & Norwich University Hospital, Obstetrics & Gynaecology, Norwich, United Kingdom*

[2]*Leeds Teaching Hospital, Obstetrics and Gynaecology, Leeds, United Kingdom*

Study question: What is the impact of Covid-19 on individuals using fertility services in the United Kingdom?

Summary answer: The implications of COVID-19 on individuals has been drastic and include uncertainty, delay in care and anxiety about pregnancy outcomes during the pandemic.

What is known already: COVID-19 has been declared a pandemic during which fertility services in the United Kingdom were temporarily suspended. Recently, services have started the process of resumption, but there remains significant uncertainty in the way fertility care will be delivered in the United Kingdom.

Study design, size, duration: The study involved two phases; an online questionnaire designed to obtain an overview of participants perceptions of Covid-19, impact on fertility care and perceived barriers to care from 422 participants. In phase two, pertinent themes from the questionnaire findings were explored further in greater depth and detail in 15 individual semi-structured interviews through purposive sampling in May 2020. The study was designed with patient and public engagement, as well as a clinicians and academics.

Participants/materials, setting, methods: The study was advertised via online platforms throughout the UK. Eligible participants included anyone who has experience of fertility services within the past one year. The 'open-ended' questionnaire results and transcribed semi-structured interview findings were analysed through thematic analysis (familiarisation with the data, creating initial codes, generating and reviewing subsequent themes, as well as refining themes in the context of the research question). Percentages were also used to compliment the qualitative findings.

Main results and the role of chance: 718 participants replied to the questionnaire with the majority identifying as White British (82%) and 5% as male. Over 60% had used fertility services within the last one year. 92% of individuals explained that COVID-19 had a 'negative impact' on their fertility treatment, namely 'delay in care'. 62% of participants discussed concerns about the 'uncertainty' they felt about fertility services; these included the 'unknown impact of COVID-19 on pregnancy outcomes', the 'unknown impact on general gynaecology services' and the 'unknown impact of COVID-19' on 'fertility success'. The influence of the media and its focus on COVID-19 at present was a perceived barrier to care as participants felt fertility care was 'less prioritised by the government'.

Through semi-structured interviews with fifteen participants, we learned about the concerns they had about the extension of the 10-year storage limit, particularly in relation to embryos. Interestingly, participants from a Black and Minority Ethnic (BAME) background discussed the 'cultural pressures' they faced during COVID-19 and the implications on their wider social circumstances. Participants were mindful about the 'pressures on the service' when re-opening, and therefore 'advancing maternal age', 'socio-economic background' and 'previous unsuccessful fertility treatment' were the main factors individuals considered important when 'prioritising' fertility care.

Limitations, reasons for caution: The questionnaire findings are representative mainly from individuals in the UK and from those identifying mainly as White British; subsequently, cultural influences that may affect participants views may not be representative. Those individuals without online connectivity may have had valuable insight but we were not able to capture this.

Wider implications of the findings: This study has truly enabled participants voices to be heard. The findings from this study can be used by fertility service providers to appreciate the patient perspective when considering the re-opening of fertility services nationally and internationally and be mindful of patient concerns.

O-318 Covid-19 does not stop fertility preservation: The Italian situation during the pandemic emergency.

A. Anastasi[1,8], **L. Sosa Fernandez**[2,8], **D. Cimadomo**[3,8], **F.G. Klinger**[4,8], **E. Licata**[5,8], **C. Scarica**[6,8], **L. De Santis**[7,8]

[6]Casa di Cura Villa Salaria in partnership with Institut Marques, Reproductive Medicine, Rome, Italy
[7]San Raffaele Scientific Institute- University Vita-Salute San Raffaele, Department of Obstetrics & Gynecology- IVF Unit, Milan, Italy
[8]On behalf of the Italian Society of Embryology, Reproduction and Research (SIERR)

Study question: How Coronavirus disease (Covid-19) influenced fertility preservation cycles in Italy? A SIERR (Italian Society of Embryology, Reproduction and Research) survey.
Summary answer: The survey carried out by SIERR shows how in Italy the pandemic influenced in a limited fashion fertility preservation treatments.
What is known already: At the beginning of March 2020 Italy was severely hit by SARS-CoV-2, whose rapid spreading has forced the government to impose the total lockdown of the country. Therefore, all ART centres in Italy decided to postpone their activities and reorganize their schedule to assure the safety for both patients and staff members. However, given the known reproductive risks of cancer therapies, there has been a special attention to fertility preservation. In fact, during the pandemic, most Italian ART centres guaranteed the execution of fertility preservation treatments. Currently, ART treatments are gradually restarting for any clinical indication.
Study design, size, duration: The aim of this longitudinal survey is to verify whether the pandemic has reduced the number of male and female fertility preservation procedures. The survey questionnaire consisting of fifteen questions (six multiple choice/nine brief answers), has been sent to all SIERR members on May 12th. On May 17th we no longer accepted responses for the first call. We will send a recall on May 22nd trying to collect a greater amount of data.
Participants/materials, setting, methods: In this highly stressful and demanding period, 46 SIERR members responded to the survey trough GoogleForm. Data obtained were analysed in order to receive one answer from each centre. Therefore, we collected answers from 42 centres. We asked our members how many fertility preservation cycles they have performed from 1st-January-2019 to 30th-April-2019 and how many in the same period of this year. The remaining questions regarded the management of these cycles during the pandemic.
Main results and the role of chance: Albeit a general reduction of the number of procedures in many medical fields, our data show that fertility preservation was not hampered by lockdown. Comparing the number of procedures during the same period in 2019 and 2020, results show a reduction of 19.6% in 2020. Interestingly, this reduction refers to the period previous Covid-19 emergency. In fact, from 1st-January-2019 to 30th-April-2019 Italian centres performed 626 fertility preservation cycles. Conversely, during the same period in 2020, 503 cycles were performed, of which 43% (74 female and 145 male preservation procedures) during the lockdown.

All patients have been screened with different methods: Triage (61%), RT-PCR (33%) or both screening methods (6%). Eleven centres performed female preservation cycles using open cryopreservation devices (91%) or closed system (9%). These samples have been stored in non-infected patients' tanks (81%) or in quarantine tanks (19%).

In 5 centres some members of the staff resulted positive to the virus; not surprisingly 3 out the 5 interested centres are located in Lombardia, the most affected region by SarsCoV-2 in Italy.
Limitations, reasons for caution: Unfortunately, due to the abstract deadline, the survey remained opened only for six days. ART Societies recommendation helped to ensure safety in the execution of fertility preservation cycles. However, in the short-term we recommend to keep the guard up in order to avoid the possibility of a return to phase1.
Wider implications of the findings: Many reasons may have caused the decrease in the number of cases comparing 2019 to 2020: some not urgent oncological surgeries have been probably postponed and consequently their fertility preservation procedures. Moreover, because during the lockdown it was strictly recommended to stay at home, many diagnoses might have been missed.

SELECTED ORAL COMMUNICATIONS
SESSION 68: GENETIC DETERMINANTS OF EMBRYO QUALITY
08 July 2020 Parallel 4 12:00 - 13:00

O-281 Complex mosaic embryos after preimplantation genetic testing: go for a second biopsy?

Z. Shuang[1], X. Pingyuan[2], H. Liang[3], T. Yueqiu[3], L. Ge[4]
[1]Hunan Guangxiu Hospital, Laboratory, Changsha- Hunan, China ;
[2]Hunan Normal University, School of Basic Medicine, Changsha- Hunan, China ;
[3]Central South University, Basic Medical College, Changsha- Hunan, China ;
[4]Reproductive and Genetic Hospital of Citic-Xiangya, Research Department, Changsha- Hunan, China

Study question: What is the incidence of complex mosaic in pre-implantation genetic testing (PGT) embryos and how to manage these embryos in clinical practice?
Summary answer: The incidence of complex mosaic blastocysts in PGT was 1.9%(253/13451) and it can be safe re-biopsy, implant and result in live births
What is known already: Some studies have reported that the births of babies after mosaic embryo transfer though the pregnancy rates were lower and the miscarriage rates were higher. The PGDIS and COGEN were given the practice recommendations on chromosome mosaicism, they were suggested if non-mosaic euploid embryos are not available, a non-complex, low-level mosaic embryo may be considered for transfer. But the complex mosaicism (mosaicism observed three or more chromosomes) were not recommended to transfer. The incidence of complex mosaicism appears to be lower, however, for the poor prognosis patients with only complex mosaic embryo, the clinical management becomes very complicated.
Study design, size, duration: Trophectoderm (TE) biopsy and NGS for genetic testing was performed on blastocysts generated from 13451 embryos between 2018 to 2019 in the IVF centre of the Reproductive and Genetic Hospital of CITIC-Xiangya. All biopsy samples were subjected whole genome amplification(WGA). The validated NGS platform were used to detect the copy number and the mosaic were defined 30-70%. The complex mosaicism were defined as three or more chromosomes with the copy number between 30% to 70%.
Participants/materials, setting, methods: Eighty-five patients opted to undergo warming, re-biopsy and re-vitrification in an effort to obtain a chance to transfer these embryos. Blastocysts resulting in a euploid diagnosis following the re-biopsy procedure were transferred with appropriate genetics counseling in subsequent frozen embryo transfer (FET) cycles. The main outcome measures were euploid, implantation and live birth rates. The study was approved by the ethics committee of the Reproductive and Genetic Hospital of CITIC-XIANGYA.
Main results and the role of chance: Overall, 13451 blastocysts were analyzed from 4359 PGT cycles, 253(1.9%) blastocysts from 243 cycles were complex mosaic. Of these 243 cycles with complex mosaic embryos, 85 patients opted to re-biopsy these embryos. The warmed rate were 96.7% (88 /91) and all the re-biopsied embryos were assigned a genetic diagnosis. Fifty-five re-biopsied blastocysts from a total 53 individual patients were diagnosed as euploid (55/88) and were suitable for subsequent FET. Of the 33 embryos that were abnormal, the most common diagnosis was mosaic, other abnormalities included 7 aneuploidy, 7 segmental aneuploidy, 2 complex mosaic. Sixteen patients have already undergone a subsequent FET of a re-biopsied single euploid blastocyst. The survival rate for blastocysts undergoing second warming was 100% (16/16) resulting in an ongoing pregnancy rate of 31.3% (5/16) and birth of two normal healthy babies to date.
Limitations, reasons for caution: But it should be noted that all the complex mosaic embryos re-biopsied in this study were with lower levels(30-50%) and the NGS platform for mosaic detection has been validated by known samples. At the time of writing the sample size is relatively modest.
Wider implications of the findings: The damage from laser, the quality of the TE cells, the bias in the WGA and NGS may be the reason for the complex mosaic in first biopsy samples. Finally, we all endeavor to maximize the most efficient route to a healthy birth for our patients in a single attempt.

O-282 Developmental potential and pregnancy outcomes of 210 mosaic embryo transfers - a single center experience

S. Madjunkova[1], M. Madjunkov[1], R. Antes[1], R. Abramov[1], S. Chen[1], H. Belakier[1], V. Kuznyetsov[1], C. Librach[1]
[1]Create Fertility Centre, Reproductive Genetics, Toronto, Canada

Study question: What is the developmental potential and pregnancy outcomes of mosaic embryos diagnosed by NGS based PGT-A and are there determinants that predict outcome?
Summary answer: Mosaic embryos have considerable implantation and developmental potential. Type and level of chromosomal aberrations did not impact implantation and ongoing pregnancy rates for mosaic embryos.
What is known already: Preimplantation genetic testing for aneuploidies(PGT-A) using NGS in IVF has increased rates of implantation per transfer, but at the same time has increased mosaic embryo detection to ~20%. Current recommendation is to consider mosaic embryos for transfer if there are no euploid embryos left. The evidence is limited on the developmental potential, implantation and birth outcomes of mosaic embryos. Some studies have suggested that level and type of chromosome aberrations may determine the implantation potential of mosaic embryos. This study aims to evaluate the implantation and pregnancy outcomes after mosaic embryo transfer detected at NGS resolution.
Study design, size, duration: This is a single centre retrospective cohort study where we analysed the clinical from 210 single mosaic embryo transfers from Jan. 2015-Dec. 2019.
Participants/materials, setting, methods: Clinical outcomes (implantation rate, ongoing pregnancy rate, miscarriage rate and birth outcomes) from 210 single mosaic embryo transfers from Jan. 2015-Dec. 2019 were available for analysis. NGS PGT-A analysis was performed using VeriSeq PGS (Illumina) kits. CNV analysis was done using BlueFuse software. The sensitivity for mosaicism detection was established at 20%, and aberrations considered clinically relevant were ≥10Mb in size and with ≥25% mosaicism.
Main results and the role of chance: Overall implantation rate for mosaic embryos was 53.3%. Of the 210 transferred mosaic embryos 80.9% had mosaic levels ≥25%-50% (Group 1) (58.6% with segmental mosaic (SM) gain or loss, 41.4% with whole chromosome mosaic (WCM) gain/loss) and 19.1% had mosaic levels of 50-70% (Group 2) (72.5% with SM and 27.5% with WCM). There was no statistical difference between Group 1 and Group 2 embryos in implantation rates (IR) 55.3% vs 45%, ongoing pregnancy rates (OPR) 46.5% vs 30%, and miscarriage rates (MR) 11.8% vs 10% respectively. Two pregnancies 2(1.2%) from Group 1 were ectopic. 70.9% of the ongoing pregnancies were from embryos diagnosed with SM (47.7% segmental losses, 28.4% segmental gains, 23.9% complex segmental gains/losses), while the rest 29.1% had whole chromosome aberrations-WCA (24% trisomies, 48% monosomies and 28% complex trisomy/monosomy). Similar distribution of SM and WCM were observed among miscarried embryos. There was no predictive outcome based on the chromosome involved in the SA mainly because of the small sample size. Birth outcome is available for 72 ET and healthy babies were delivered in all cases.
Limitations, reasons for caution: This is one of the largest studies presenting pregnancy outcomes after mosaic embryo transfer, however the sample size is still limiting the ability to correlate specific chromosomal aberrations with pregnancy outcomes. The sensitivity and specificity to detect mosaicism in our study applies to the assay used to diagnose mosaicism (NGS,VeriSeq-PGS-Kit).
Wider implications of the findings: Our findings provide evidence that mosaic embryos develop in healthy babies and support the hypothesis that low level mosaicism in early embryonic development may be a physiological phenomena. Our results will aid to better genetic counseling on the risks of mosaic embryo transfer, supporting their consideration for transfer.

O-283 Cumulus cells secrete microvesicles carrying miRNAs that might contribute to the acquisition of oocyte developmental competence

M. Zuccotti[1], D. Cimadomo[2], F. Cavalera[1], L. Dusi[3], S. Bertelle[3], B. Iussig[3], F. Ubaldi, Maria[2], L. Rienzi[2], S. Garagna[1]

[1]University of Pavia, Dipartimento di Biologia e Biotecnologie 'Lazzaro Spallanzani', Pavia, Italy ;
[2]Clinica Valle Giulia, Genera centers for reproductive medicine, Rome, Italy ;
[3]Genera Veneto, Genera centers for reproductive medicine, Marostica, Italy

Study question: What do the cumulus cells (CCs) secrete during the germinal-vesicle to metaphase II (GV-to-MII) transition that might mediate the acquisition of oocytes' developmental competence?
Summary answer: CCs release microvesicles which are internalised from the oocytes and contain miRNAs possibly involved in the acquisition of oocytes' developmental competence.
What is known already: During folliculogenesis oocytes grow and acquire developmental competence inside the cumulus-oocyte-complex (COC) thanks to a bidirectional communication with companion CCs. The nature of the CC-determinants contributing to oocytes' developmental competence remains poorly understood. We recently showed that when mouse CCs-free antral oocytes are cultured to MII with a feeder layer (FL) of CCs isolated from developmentally competent *surrounded-nucleolus* (FL-SN-CCs) or incompetent *not-surrounded-nucleolus* (FL-NSN-CCs) oocytes, the former acquire developmental competence to blastocyst, whereas the latter undergo developmental arrest. The hunt for FL-SN-CCs determinants points to the exocytosis of microvesicles containing functional molecules and to their fusion with or endocytosis by oocytes.
Study design, size, duration: Between March-2019 and December-2019, SN-FL-CCs and NSN-FL-CCs were prepared from CD1 mouse SN-COCs and NSN-COCs, respectively, to investigate the release of microvesicles into the culture medium and their internalisation into CCs-free mouse oocytes. The FL-CCs-derived microvesicles-specific miRNA content was screened from three cohorts of SN-FL-CCs and three of NSN-FL-CCs by RNA-sequencing. Sequencing was performed also on human FL-CCs produced between November-2018 and May-2019 from 6 IVF patients.
Participants/materials, setting, methods: Secreted-microvesicles were isolated by ultracentrifugation, sized and quantified with Nanosight. FL-SN-CCs were labelled with PKH67, co-cultured with CCs-free mouse antral oocytes and microvescicles internalization was assessed by confocal-microscopy. Next Generation RNA-sequencing, followed by bioinformatics analysis, was conducted to screen FL-CCs-derived microvesicles-specific miRNAs in i) mouse FL-SN-CCs versus FL-NSN-CCs cohorts, and ii) human FL-CCs obtained from 6 maternal age-matched cohorts of developmentally-competent (blastulation-rate per COC>30%, n=3) versus less-competent (blastulation-rate per COC<30%, n=3) oocytes.
Main results and the role of chance: After 15hr of maturation of mouse CCs-free antral oocytes upon FL-SN-CCs, a large number of microvesicles ($9.65x10^{10}$/ml) was detected in the media, 77% were potentially exosomes (129.7nm mean diameter and positive to Alix-targeted labelling).
Confocal-microscope analysis on three separate experiments showed that a massive number of CCs-derived microvesicles passed through the zona pellucida, while only a few could penetrate the ooplasm.

The comparison between the sequencing of miRNAs isolated from microvesicles released by mouse FL-SN-CCs versus FL-NSN-CCs highlighted 325 differentially expressed miRNAs, 21 of which up-regulated (top-5: mmu-miR-5112, mmu-let-7a-1-3p, mmu-let-7c-2-3p, mmu-miR-28c, mmu-miR-28a-5p) and 23 down-regulated (top-5: mmu-miR-712-5p, mmu-miR-1195, mmu-miR-410-3p, mmu-miR-122-5p, mmu-miR-342-5p). Pathway analysis (conducted with the DIANA miRpath v3 software using the micro-T-CDS database of predicted targets and the "genes union" merging algorithm) showed 27 and 42 pathways potentially controlled from the up-regulated and down-regulated miRNAs, respectively.

The comparison between miRNA sequencing data produced from microvesicles secreted by human CCs of developmentally-competent or less-competent cohorts of oocytes highlighted 370 miRNAs, 25 of which differentially expressed, 6 up-regulated (hsa-miR-3675-3p, hsa-miR-4741, hsa-miR-640, hsa-miR-133a-5p, hsa-miR-1909-3p, hsa-miR-6852-3p) and 19 down-regulated (top-5: hsa-miR-6866-5p, hsa-miR-1303, hsa-miR-7110-5p, hsa-miR-2278 and hsa-miR-4639-5p). The pathway analysis showed 12 and 8 pathways potentially controlled from the up-regulated and down-regulated miRNAs, respectively.
Limitations, reasons for caution: CCs-derived microvesicles internalization should be confirmed also in human oocytes. The sequencing data should be validated via more specific techniques, like qPCR and immunofluorescence, and with a larger samples size of CCs. Possibly, CCs should be isolated from single oocytes, rather than cohorts.
Wider implications of the findings: The identification of CCs-secreted microvesicles carrying miRNAs that are internalized by developing oocytes and might govern the acquisition of developmental competence will have numerous implications to improve: i) in-vitro-maturation, ii) treatment of patients suffering from reduced maturation rates (cancer, polycystic-ovarian-syndrome,

poor-ovarian-reserve and/or oocyte-maturation-arrest) iii) supplementation of culture media.
Trial registration number: not applicable

O-284 Abnormal fertilization in ICSI and association with abnormal semen parameters: A retrospective observational study on 1855 cases

A. Pappas[1], K. Pantos[1], K. Sfakianoudis[1], E. Maziotis[2], A. Rapani[2], E. Karantzali[2], S. Grigoriadis[2], P. Tsioulou[2], P. Giannelou[2], T. Vaxevanoglou[1], M. Chronopoulou[1], M. Koutsilieris[2], M. Simopoulou[2]

[1]Center for Human Reproduction, Genesis Athens Clinic, Athens, Greece ; [2]National and Kapodistrian University of Athens, Department of Physiology-Medical School, Athens, Greece

Study question: Is abnormal fertilization following ICSI related to abnormal semen analysis (SA) parameters?
Summary answer: A SA entailing more than two abnormal parameters-particularly for oligozoospermia-may compromise normal fertilization, cleavage and blastocyst formation rates, along with clinical pregnancy rates.
What is known already: Intracytoplasmic sperm injection (ICSI) efficiently addresses male factor infertility. However, even when ICSI is employed, a positive fertilization outcome may not be guaranteed. Undoubtedly, occurrence of abnormal fertilization patterns, mainly referring to abnormal pronuclei (PN) patterns of extra or missing pronuclei, merits further investigation. This may be heightened especially with regards to management of couples presenting with a trend for abnormal fertilization patterns. Identifying potential causative associations between specific abnormal SA parameters, their respective combination, and fertilization outcome following ICSI may be of added value for the IVF laboratory.
Study design, size, duration: This retrospective observational study included 1855 ICSI cycles performed between 2014 and 2018. Medical records from couples submitted to a first fresh autologous ICSI cycle between 2014 and 2019 were retrieved and included in the study. The principal inclusion criteria were male age of 18-50 years old, female age of the partner 18-40 years old, and employment of the gonadotropin-releasing hormone (GnRH) long agonist stimulation protocol.
Participants/materials, setting, methods: The participants were divided into groups, according to pathologies identified following SA, and the respective combinations of individual abnormal parameters, based on WHO criteria. Cases of normal SA served as the control group. Presence of two PN and extrusion of the second polar body indicated normal fertilization. Embryo transfer was performed on day three or five, based on the number and quality of cleavage stage embryos. R programming language was used for the statistical analysis.
Main results and the role of chance: From the total of 1855 men, 162 presented without any abnormal observations in the SA, serving as the control group. Two-hundred and ninety-five were diagnosed with asthenozoospermia, 229 with oligozoospermia, 83 with teratozoospermia, 232 with oligoasthenozoospermia, 213 with oligoteratozoospermia, 284 with asthenoteratozoospermia and 356 with oligoasthenoteratozoospermia (OAT). The results demonstrated that SA pathologies affect 2PN formation rate ($p<0.0001$), fertilization failure ($p=0.0001$), cleavage rate ($p=0.0001$) and blastocyst formation rate ($p<0.0001$). No correlation was established between abnormalities and 1PN or 3PN formation rates. Regarding 2PN rate, the control group presented with the highest (0.82±0.05) and the OAT group presented with the lowest (0.60±0.08). The highest fertilization failure rates were reported in the oligoasthenoteratozoospermic (0.246±0.0749) and the lowest in the normal group (0.155±0.0511). The lowest cleavage rates were identified for oligoasthenozoospermic and oligoasthenoteratozoospermic patients (0.814±0.508 and 0.78±0.0999). The aforementioned groups along with oligoteratozoospermic patients presented with the lowest blastocyst formation rate (0.457±0.043, 0.453±0.068 and 0.459±0.035). Regarding clinical pregnancy data, only oligoasthenozoospermic and oligoasthenoteratozoospermic patients were associated with lower rates compared to the normal group (OR:0.538, 99.3225%CI:0.302-0.956; p-value=0.004 and OR:0.582, 99.3225%CI: 0.344-0.985; p-value=0.005, respectively). Following adjustment for number of blastocysts no statistically significant difference was observed regarding the clinical pregnancy rate.
Limitations, reasons for caution: The retrospective nature of this observational study may be correlated with bias, along with the fact that the study was conducted in a single center. Finally, DNA fragmentation index assessment is not included herein, albeit representing a valuable complimentary tool to evaluate sperm quality.
Wider implications of the findings: Different abnormal SA parameters may lead to different IVF cycle outcomes. Oligozoospermic semen samples featuring at least one more abnormal parameter are associated with compromised blastocyst formation rates. Oligoasthenozoospermic and OAT patients present with lower clinical pregnancy rates. Depending on SA parameters a different IVF treatment strategy may be required.

08 July 2020 Parallel 1 14:00 - 15:15

O-285 An oocyte assessment tool using machine learning; Predicting blastocyst development based on a single image of an oocyte

D. Nayot[1], J. Meriano[2], R. Casper[1], K. Alex[3]

[1]TRIO Fertility, Reproductive Endocrinology and Infertility, Toronto, Canada ; [2]TRIO Fertility, Embryology, Toronto, Canada ; [3]FutureFertility, Embryology, Toronto, Canada

Study question: Can an Artificial Intelligence (AI) based image analysis tool predict the blastocyst development potential of oocytes better than the current standard?
Summary answer: Our AI image analysis tool outperformed all 17 embryologists by an average of 21.2% in predicting blastocyst development and, unlike the embryologists, was 100% reproducible.
What is known already: There are no morphological features of oocytes that have been validated to have prognostic value for further developmental competence (Rienzi 2011). Currently there is no standardized or accepted visual oocyte scoring system (Alpha 2011), and therefore limited feedback about oocyte quality is available to patients and clinicians.

Deep learning offers promise for the automation and standardization of embryo quality assessment. There are several studies using machine learning in an attempt to automate embryo grading and improve embryo selection, but this is the first clinical application focusing on oocytes.
Study design, size, duration: The Violet (an AI image analysis tool) was created with convoluted neural networks based on a retrospective dataset (n=17,659 oocyte images). It's able to predict fertilization and blastocyst development with 91.2% and 63% accuracy respectively in an unbalanced dataset.

In a balanced test set of 300 oocytes, the Violet outperformed all 17 embryologists, from 8 IVF clinics, in accurately predicting fertilization (71.7% vs 58.9±4.3%; 21.8% increase) and blastocyst development (62.8% vs 52.2±3.7%; 20.2% increase).
Participants/materials, setting, methods: N/A
Main results and the role of chance: In an unbalanced data set, the Violet was able to predict fertilization and blastocyst development with 91.2% and 63% accuracy respectively. It was especially effective at identifying negative cases with 99% accuracy when the confidence was > 70%

Two validation studies were performed to compare the Violet to embryologists. A balanced data set of 300 oocyte images was randomly selected from the test subset: 100 failed fertilization, 100 fertilized but did not reach blastocyst stage, and 100 reached blastocyst stage.

The Violet outperformed all 17 embryologists, from 8 IVF clinics, in accurately predicting fertilization (71.7% vs 58.9% ± 4.3%; 21.8% increase) and blastocyst development (62.8% vs 52.2% ± 3.7%; 20.2% increase).

In a reproducibility study, 7 of these embryologists underwent the same task 2-3 months later. The average accuracy remained close to chance, 53% ± 3.3% with an intra-observer reproducibility of 81.4% for blastocyst formation, while the Violet was 100% reproducible.

Limitations, reasons for caution: As with all AI image analysis tools, a larger and more diverse data set is necessary to extrapolate findings. A prospective multi-centre validation study is currently underway to validate the Violet technology
Wider implications of the findings: The lack of a visual oocyte assessment criteria is congruent with our findings that 17 senior embryologists were essentially unable to predict blastocyst development (average 52.2%). Machine learning image analysis improves our ability to assess oocyte quality in an instantaneous, non-invasive, reproducible and more accurate method than the current standard.
Trial registration number: 16325-16:10:0722

O-286 Fresh or vitrified oocytes from the same donor cohort: do they differentially affect clinical outcomes?

J. Maidana[1], E. De Martino[1], M. Papayannis[1], P. Filardi[1], C. Bisioli[1], G. Terrado[2], I. De Zúñiga[2], M. Horton[2], M. Bianchi[2], H. Pettorossi[2], N. Passi[2], M. Marcelli[2], F. Sobral[2], M. Gómez Peña[1]

[1]Pregna Reproductive Medicine, Embryology Laboratory, Buenos Aires, Argentina ; [2]Pregna Reproductive Medicine, Reproductive Medicine, Buenos Aires, Argentina

Study question: Do clinical outcomes differ when using fresh or vitrified oocytes from the same donor cohort?
Summary answer: Fresh or vitrified oocytes lead to similar clinical outcomes in an egg donation program.
What is known already: The extended use of frozen oocytes in egg donation programs rest on the success of oocyte vitrification and the need to optimise synchronisation between donors and recipients. Oocyte vitrification has proven its efficacy, however the impact of thermal and osmotic stress on embryo development and clinical results still remains controversial.
Study design, size, duration: We retrospectively compared embryo development (fertilisation, embryo quality and blastocyst formation) and clinical outcomes (implantation, pregnancy and miscarriage rates) of fresh and vitrified oocytes cycles from the same cohort of 34 donors in 117 recipients between January 2017 and December 2018.
Participants/materials, setting, methods: Recipient cycles were divided into two groups: those who received fresh (n= 75) or vitrified oocytes (n= 42). All oocytes (n= 679) were fertilised by ICSI and transfers were performed at the blastocyst stage. Cycles with frozen embryo transfers or severe male factor were excluded from this study. The mean number of embryos transferred was similar in both groups (1.01 vs 1.0). Chi-Square test was used as statistical data analysis.
Main results and the role of chance: Each recipient received 5.4 and 6.5 MII oocytes on average in the synchronous (406 fresh) and the asynchronous group (273 vitrified) respectively (p=NS). A total of 323 oocytes were warmed and 273 (84.5%) survived. Although blastocysts formation rate (58.1 vs 48.4%, p<0.05) and the rate of usable blastocysts (45.5 vs 35.6%, p<0.05) were higher in the fresh oocyte group, no differences were observed between fresh and vitrified oocytes regarding fertilisation rate (80.5 vs 80.2%; p=NS), percentage of good quality embryos (80.0 vs 86.0%; p=NS), clinical pregnancy (55.0 vs 45.0%; p=NS), miscarriage (2.0 vs 10.0%; p=NS) or implantation rates (55.0 vs 50.0%;p=NS).
Limitations, reasons for caution: Our study is limited by its sample size and retrospective design. Oocytes were donated by healthy, young women so these results should not be generalised to other populations.
Wider implications of the findings: Although blastocyst formation was significantly lower in the group of vitrified oocytes, we didn't observe differences in clinical outcomes. This could mean a possible stress effect or cell pre-conditioning for better stress tolerance. Our study suggests that the reproductive results should not be affected by donor oocyte vitrification.
Trial registration number: Not applicable

O-287 F-actin and MYO10 protein distribution: a novel tool in assessing the quality of human growing follicles

A. Volodarsky-Perel[1], S. Granados Aparici[2], T. Tulandi[1], W. Buckett[1], S. Krishnamurthy[1], F. Williamson Mansour[1], J. Papillon Smith[1], H. Clarke[1]

[1]McGill University, Obstetrics and Gynecology, Montreal, Canada ; [2]McGill University, Research Institute, Montreal, Canada

Study question: Does the distribution of F-actin and MYO10 protein differ in human preantral follicles from patients of different age and ovarian pathology?
Summary answer: Advanced age and endometriosis have an impact on the distribution pattern of F-actin in granulosa cells and MYO10 protein in granulosa cells and oocytes.
What is known already: Direct markers of oocyte quality described so far include spindle dysfunction and chromosomal misalignment during meiotic maturation, whereas markers of the surrounding granulosa cells usually focus on cell proliferation and death. Granulosa cells communicate with the oocyte via actin-rich cytoplasmic extensions termed transzonal projections (TZPs) which penetrate the zona pellucida and enable the oocyte to be supplied with essential nutrients and regulatory signals necessary for its growth. MYO10 protein likely regulates filamentous (F-) actin assembly or function in TZPs. However, the expression and distribution pattern of MYO10 protein and F-actin in women of different ages and clinical conditions remains unclear.
Study design, size, duration: A prospective study was conducted among 21 women who underwent ovarian surgery and consented to fresh ovarian tissue donation in the period from 2017 to 2019. Ovarian follicles of primordial to secondary stages were retrieved from 9 women aged 22 to 40 years. Four had no ovarian pathology; the other five were diagnosed with endometriosis confirmed by histological analysis.
Participants/materials, setting, methods: Fresh tissue samples were immediately delivered for follicle harvesting. Follicles with a morphologically normal oocyte and non-pyknotic granulosa cells were fixed and stained using phalloidin and anti-MYO10. Confocal microscopy was used to image equatorial optical sections of each follicle. Parameters measured were the number of MYO10 foci and intensity of F-actin in the granulosa cells and oocytes. Correlation between the oocyte diameter and the structures associated with TZP development (MYO10 foci and F-actin) was evaluated.
Main results and the role of chance: A total of 93 good-quality follicles were included in the analysis. Mean oocyte diameter was 32.6 ± 6.8 µm. A correlation between oocyte diameter and MYO10 distribution (correlation estimate (CE) 0.37; 95% confidence interval (95% CI) 0.08-0.61; P = 0.01) as well as between oocyte diameter and F-actin intensity (CE 0.36; 95% CI 0.07-0.59; P = 0.008) in granulosa cells was demonstrated in patients of 22-30 years of age. These correlations for both MYO10 distribution and F-actin intensity with oocyte diameter were not observed in the group of 35-40 years (P = 0.15, P = 0.16, respectively). The intensity of F-actin in granulosa cells was also correlated with oocyte diameter in patients with normal ovaries (CE 0.31; 95%CI 0.02-0.55; P = 0.02). This correlation was not observed in patients with endometriosis (P = 0.83). Strikingly large MYO10 aggregates within the oocyte were significantly more common in cases with endometriosis compared to those with normal ovaries (14 (41.2%) versus 8 (17.8%); P = 0.02). The absence of correlation of MYO10 and F-actin distribution with oocyte diameter suggests a disorganization of TZPs development in small growing follicles, which may contribute to poorer follicle quality in older women and patients with endometriosis.
Limitations, reasons for caution: Only fresh ovarian samples were included in the study. The effect of age and ovarian pathology on the structures associated with TZP development in frozen ovarian tissue is a matter for further studies.
Wider implications of the findings: We suggest that MYO10 distribution and F-actin intensity in granulosa cells as well as the presence of MYO10 aggregates in oocytes can be used for quality assessment of ovarian follicles in women of different ages and ovarian pathology.
Trial registration number: not applicable

O-288 Dynamic oxygen level (5%-2%) during human in vitro embryo culture significantly improves usable blastulation and cumulative live birth rates in in vitro fertilization (IVF)

S. Brouillet[1], A. Andreeva[1], A. Gala[1], A. Ferrieres[1], M. Anav[1], A. Fournier[1], V. Loup[2], N. Ranisavljevic[2], S. Hamamah[1]

[1]University of Montpellier - University hospital of Montpellier - INSERM U1203, preimplantation genetic testing- assisted reproductive techniques- CECOS, Montpellier, France ; [2]University hospital of Montpellier, preimplantation genetic testing- assisted reproductive techniques- CECOS, Montpellier, France

Study question: Does dynamic oxygen level (5-2%) during *in vitro* embryo culture improve IVF outcomes compared to continuous oxygen level (5%)?

Summary answer: Dynamic oxygen level significantly increases total and usable blastocyst formation rates as well as cumulative implantation, clinical pregnancy and live birth rates in IVF.

What is known already: In IVF, human embryos are usually cultured under 20% or 5% of oxygen. A dynamic oxygen exposure during *in vitro* culture may represent the most physiologic system as *in vivo* oxygen tension is ≈5% for early cleaved embryos in the oviduct and ≈2% for morulas/blastocysts in the uterus. Moreover, ultra-low oxygen tension (2%) increases the expression of antioxidant enzymes in mouse embryos and enhances the proliferation rate of human trophoblast, protecting the blastocyst against an excess in oxidative stress during its high metabolic activity and providing a favorable environment for blastocyst viability and implantation potential.

Study design, size, duration: A monocentric retrospective cohort study was performed from June 2014 to March 2019. A total of 120 couples were enrolled. The study was approved by local institutional review board (2019_IRB-MTP_05-12). All couples underwent one IVF cycle associated with continuous oxygen exposure (5% from Days 0-6) and the subsequent IVF cycle associated with dynamic oxygen exposure (5% from Days 0-3 and 2% from Days 3-6) for *in vitro* embryo culture.

Participants/materials, setting, methods: The first objective was to evaluate total and usable blastocyst formation rates in both "continuous 5% oxygen exposure" and "dynamic 5-2% oxygen exposure" groups. Blastocysts were scored using the Gardner grading system. The secondary objective was to evaluate cumulative implantation, clinical pregnancy and live birth rates obtained after fresh and frozen-thawed morula/blastocyst transfers in both "continuous 5% oxygen exposure" and "dynamic 5-2% oxygen exposure" groups.

Main results and the role of chance: The maternal age (35.3 ± 4.4 vs. 33.5 ± 4.6, p=0.003) and the total number of IVF cycles (2.7 ± 1.0 vs. 1.6 ± 0.9, p< 0.0001) were significantly higher in the "dynamic 5-2% oxygen exposure" group. All other clinical and biological parameters were similar in both groups. The blastocyst formation rate (54.8% vs. 44.4%, p=0.0007) and usable blastocyst formation rate (32.8% vs. 21.8%, p<0.0001) were both significantly higher in the "dynamic 5-2% oxygen exposure" group than in "continuous 5% oxygen exposure" group. Implantation, clinical pregnancy and live birth rates seem increased in the "dynamic 5-2% oxygen exposure" group compared to the "continuous 5% oxygen exposure" group after fresh morula/blastocyst transfers, but the differences didn't reach significance. The cumulative implantation (33.1% vs. 16.8%, p=0.016), clinical pregnancy (36.8% vs. 15.2%, p=0.006), and live birth (23.2% vs. 8.4%, p=0.004) rates were significantly higher in the "dynamic 5-2% oxygen exposure" group than in "continuous 5% oxygen exposure" group, respectively.

Limitations, reasons for caution: This is a retrospective study. The selection of embryos to be transferred and cryopreserved was based on embryo morphology criteria that might be different in other clinics.

Wider implications of the findings: Improved IVF outcomes were obtained in the same couples when dynamic oxygen exposure (5-2%) was used compared to continuous oxygen exposure (5%), in spite of the negative impact of increased maternal age. Dynamic oxygen exposure (5-2%) may improve blastocyst formation and implantation potential by preventing oxidative stress during IVF.

Trial registration number: 2019_IRB-MTP_05-12

O-289 Detection of Cannabis in Follicular Fluid and its impact on Oocyte Quality, Endocannabinoid Signaling, and Epigenetics

N. Fuchs Weizman[1], B. Wyse[2], P. Szaraz[3], M. Defer[2], S. Jahangiri[4], C. Librach[5]

[1]University of Toronto, Department of Obstetrics, Toronto, Canada ; [2]CReATe Fertility Centre, Research - Ovarian Biology Group, Toronto, Canada ; [3]CReATe Fertility Centre, Research - Cardiac Stem Cell Group, Toronto, Canada ; [4]CReATe Fertility Centre, CReATe BioBank, Toronto, Canada ; [5]CReATe Fertility Centre, Medical Director, Toronto, Canada

Study question: How do phytocannabinoids (PC) in follicular fluid (FF) affect the dynamics of endocannabinoid receptors (endoCB-Rs) and of methyl-transferase expression in the surrounding granulosa cells?

Summary answer: Marijuana exposure does appear not alter the dynamics of the endocannabinoid system; however, it changes the epigenetic machinery in the follicular niche.

What is known already: THC, a cannabis plant derivative, is used for medicinal and recreational purposes. It is the third most commonly used substance by women of childbearing age, hence knowledge of the effect it has on reproduction is of utmost importance. THC exerts its effects via receptors of the endocannabinoid system and can interfere with its regular functions which are required for successful reproduction. Moreover, previous studies have shown THC alters methylation and histone modifications in sperm, brain, and blood cells. The levels of endocannabinoids have been measured in follicular fluid obtained during oocyte retrieval and are implicated in controlling folliculogenesis.

Study design, size, duration: Samples were previously biobanked from consenting patients during IVF oocyte retrieval. Their follicular fluid was analyzed for patient exposure to phytocannabinoids, and to measure endoCBs. The corresponding granulosa cells (hGC) were utilized to explore the dynamics of endoCB-Rs and a methylating enzyme in the follicular niche. Cases were patients with at least one PC detected in their follicular fluid, and matched controls were negative for all three tested PCs (delta9-THC, 11-OH-delta9-THC, 11-COOH-delta9-THC).

Participants/materials, setting, methods: We performed liquid chromatography-mass-spectrometry (LC-MS/MS) at the Analytical Facility for Bioactive Molecules (SickKids Hospital, Toronto, CA) on FF obtained from dominant follicles between Jan 2018-July 2019. Cases were matched with controls by age, BMI, AMH and trigger day E2 levels. Levels of endoCB-Rs (CB1R-APC, CB2R-Alexa488; R&D Systems) and of the methylating enzyme DNMT3b (DNMT3b-APC, Miltenyi Biotec), in corresponding hGC were assessed by flow cytometry (MACSQuant 10). Median fluorescence intensities were calculated (FlowJo10).

Main results and the role of chance: Out of 244 samples analyzed, 17 tested positive for PCs (6.5%) and these were matched with 15 samples that were negative for all PCs tested (controls). The percentage of positive samples among our population increased from 3.8% to 13.3% after legalization of cannabis in Canada in October 2018 (chi^2; p=0.02). The concentrations of PCs did not change following legalization. There was no significant effect of PCs on maturation rate (mean case maturation rate 75.9% vs. control maturation rate 74.4%). In addition, the levels of endocannabinoids (including AEA, 2-AG, among others (10 in total)) did not differ significantly between cases and controls. Next, the cell surface protein expression levels of endoCB-Rs in corresponding hGC was examined. Overall CB2R expression was higher than CB1R, however, exposure to PCs did not significantly alter this expression. Taken together, this indicates that PC exposure might not alter endocannabinoid signaling significantly. DNMT3b, a DNA methylation enzyme, is involved in de-novo methylation and is crucial for epigenetic integrity. Interestingly, exposure of hGC to PC decreased DNMT3b positive events, indicating that cannabis exposure appears to affect epigenetic machinery at the protein level.

Limitations, reasons for caution: Our study is limited by lack of details regarding mode, frequency, and timing of PC consumption. A further limitation is the small sample size, which warrants larger-scale studies to validate our findings. Finally, future studies should also focus on the effects of PC exposure on developing oocytes.

Wider implications of the findings: To our knowledge, this is the first study measuring cannabis derivatives in FF by LC-MS/MS. We show that consuming cannabis does not appear to affect the endocannabinoid system in the developing follicle. Lastly, we have implicated cannabis in disrupting epigenetic mechanisms in hGCs.

SESSION 70: OVARIAN STIMULATION STRATEGIES IN IVF AND IUI

08 July 2020 Parallel 2 14:00 - 15:15

O-290 Impact of controlled ovarian stimulation on vaginal and endometrial microbiota in IVF cycles: a pilot study

A.R. Carosso[1], A. Revelli[1], G. Gennarelli[1], S. Canosa[1], S. Cesarano[1], N. Brunod[1], C. Scarafia[1], S. Leoncini[1], L. Boatti[2], E. Zanotto[3], F. Sidoti[3], R. Cavallo[3], C. Benedetto[1]

[1]Obstetrics and Gynecology 1U- Physiopathology of Reproduction and IVF Unit, Department of Surgical Sciences- Sant'Anna Hospital- University of Torino, torino, Italy ;

[2]University of Piemonte Orientale, SmartSeq s.r.l.-, Novara, Italy ;
[3]Division of Virology- University of Turin- Città della Salute e della Scienza di Torino, Public Health and Pediatrics Department, Turin, Italy

Study question: Does controlled ovarian stimulation (COS) modify the vaginal and endometrial microbiota of women undergoing in vitro fertilization (IVF)?
Summary answer: COS modifies vaginal and endometrial microbiota inducing a reduction of Lactobacillus abundance and an increased heterogeneity, leading to the potential growth of pathogenic bacteria.
What is known already: COS is associated with raising estrogen levels and several studies report improved pregnancy rate when frozen embryos transfers are performed, probably due to a better endometrial receptivity. Although changes of the vaginal microbiota depending on hormone levels during a menstrual cycle have been demonstrated, the impact of raising estrogens levels associated with COS on the female microbiota is unknown. Furthermore, the effects of the presence of an active vaginal and endometrial microbiota on the outcomes of IVF treatments are still controversial.
Study design, size, duration: In this pilot study, 15 women (age, 29-42 years) undergoing IVF or ICSI treatment attending the Reproductive Physiopathology Center of the S. Anna Hospital in Turin (Italy) were included between July 2018 and October 2019.
Participants/materials, setting, methods: Patients underwent vaginal and endometrial microbiota analysis in two moments:

- PRE-COS ANALYSIS: simulation of embryo transfer plus a vaginal swab were performed in the luteal phase of the cycle preceding COS.
- POST-COS ANALYSIS: at the time of fresh embryo(s) transfer.

The distal extremity of the catheter tip and the vaginal swab were analyzed by 16S rRNA gene sequencing. To characterize the samples, the Shannon diversity index (SDI) was used.
Main results and the role of chance: The genus most present in the PRE-COS vaginal samples was that of Lactobacillus, as in POST-COS analysis, although with lower abundance (71.5 ± 40.6% and 61.1 ± 44.2 %, respectively). At the same time, an increase of pathogenic species, such as Prevotella (3.5 ± 8.9% Vs 12 ± 19.4%) and Atopobium (5.7 ± 10.6% Vs 5.6 ± 9.4%), was observed. In the endometrium, the genus most represented was that of Lactobacillus, although the concentrations decreased between the two analyses (27.4 ± 34.5 % and 25 ± 29.9 %, PRE-COS and POST-COS respectively), with a simultaneous increase of Prevotella and Atopobium (3.4 ± 9.5% Vs 4.7 ± 7.4 % and 0.7 ± 1.5 Vs 5.8 ± 12 %). The Shannon indices evaluated at the PRE-COS and POST-COS analysis were significantly different, indicating an effect of COS on vaginal and endometrial microbiota diversity ($p< 0.001$ for both sites). Furthermore, the presence of a Lactobacillus dominated microbiota at POST-COS analysis in the endometrium was associated with a greater thickness at ultrasound monitoring on the day of ovulation trigger (12 ± 0.8 mm Vs 8.8 ± 0.9 mm, $p<0.005$). However, an impact on pregnancy rates of vaginal and endometrial microbiota was not observed.
Limitations, reasons for caution: Our research is a pilot study and it is limited by the restricted number of patients included. Furthermore, the presence of bacteria in the endometrium forming an active microbiota is still discussed.
Wider implications of the findings: Our results indicate that vaginal and endometrial microbiota undergo relevant modification after COS. COS induces higher instability at both levels that could justify the negative reproductive and obstetric outcomes of a proportion of IVF treatments supporting the diffusion of the "freeze all strategy".

Study question: Does ovarian stimulation with gonadotrophin or letrozole increase live birth rate compared to clomiphene citrate (CC) in couples with unexplained or mild male factor infertility undergoing intrauterine insemination (IUI)?
Summary answer: Ovarian stimulation with gonadotropins results in higher live birth rate compared to CC in couples undergoing IUI while evidence on letrozole versus CC is insufficient.
What is known already: Ovarian stimulation in IUI aims to increase pregnancy rates by increasing the number of dominant follicles. Ovarian stimulation can be achieved with CC, letrozole and gonadotropins. Today IUI with ovarian stimulation is the main source of multiple pregnancies. Multiple pregnancies carry the risk of higher morbidity to mother and child. Individual participant data meta-analysis (IPD-MA) is considered as the gold standard for evidence synthesis which provides accurate assessments of outcomes from primary randomised controlled trials (RCTs) and allows additional analyses for time-to-event outcomes.
Study design, size, duration: We performed an IPD-MA of relevant RCTs. We searched PubMed, MEDLINE, EMBASE, CENTRAL and the Clinical Trial Registration Database indexed up to 16 August 2018. No language restrictions were applied.
Participants/materials, setting, methods: We included RCTs that compared ovarian stimulation with CC, letrozole or gonadotrophins to each other in IUI among couples with unexplained infertility or mild male factor infertility. We contacted the authors of the identified trials to join and share their IPD. The primary effectiveness outcome was live birth and the primary safety outcome was multiple pregnancy. The secondary outcomes included clinical pregnancy and time to ongoing pregnancy leading to live birth.
Main results and the role of chance: We identified 22 eligible RCTs (4624 couples). Authors from 6 RCTs provided IPD. After further excluding 411 couples with infertility due to anovulation or other factors, we included 2,299 couples in this IPD-MA.

Compared to IUI with CC, IUI with gonadotrophins increased live birth rate (RR 1.28, 95%CI 1.06-1.55, 5 RCTs) and clinical pregnancy rate (RR 1.22, 95%CI 1.06-1.40, 6 RCTs), while it reduced time to ongoing pregnancy leading to live birth (HR 1.38, 95%CI 1.15-1.66, 5 RCTs). Data between the two groups on multiple pregnancy were inconclusive (RR 1.55. 95%CI 0.57-4.22, 5 RCTs). RCTs with IPD and RCTs without IPD showed similar results in this comparison. One RCT compared letrozole versus CC in IUI. The evidence on IUI with letrozole versus CC was inconclusive on live birth (RR 0.80, 95%CI 0.59-1.10), clinical pregnancy (RR 0.79, 95%CI 0.60-1.04), multiple pregnancy (RR 1.13, 95%CI 0.44-2.89) and time to ongoing pregnancy leading to live birth (HR 0.78, 95%CI 0.55-1.11). RCTs with IPD and RCTs without IPD showed inconsistent results on clinical pregnancy (group difference p=0.01) and none of the RCTs without IPD reported live birth in this comparison.
Limitations, reasons for caution: The evidence between letrozole and CC are based on one RCT sharing the IPD. The difference between RCTs with and without IPD may be due to the differences in study population or study quality.
Wider implications of the findings: Ovarian stimulation with gonadotrophins should be considered as the first-line treatment in couples with unexplained or mild male infertility undergoing IUI, if intracycle monitor is available and extra costs are acceptable. There is an urgent need for further RCTs to compare letrozole and CC in IUI to confirm existing evidence.

O-292 In vitro maturation versus in vitro fertilization in women with high antral follicle count: a cost-effectiveness analysis alongside a randomised clinical trial

H. Vu Ngoc Anh[1,2], N. Loc Minh Tai[1,2], H. Tuong Manh[1,2], D. Vinh Quang[1,2], W. Rui[3], N. Robert J[4], M. Ben[3], V. Lan Ngoc[1,2,5]

[1]IVFMD, My Duc Hospital, Ho Chi Minh City, Vietnam ;
[2]HOPE Research Center, My Duc Hospital, Ho Chi Minh, Vietnam ;
[3]Monash University, Department of OB/GYN, Melbourne, Australia ;
[4]Robinson Research Institute, University of Adelaide, Adelaide, Australia ;
[5]University of Medicine and Pharmacy at HCM City, Department of OB/GYN, Ho Chi Minh, Vietnam

Study question: Is in vitro maturation (IVM) more cost-effective than in vitro fertilization (IVF) in women with high antral follicle count (AFC)?
Summary answer: IVM should be considered as cost-effective if society is willing to accept €8,847 for foregoing an additional live birth.
What is known already: Both IVF and IVM are treatment options in women with high AFC undergoing ART, mainly anovulatory women not responding to ovulation induction. IVM has no risk of ovarian hyperstimulation syndrome (OHSS) and is potentially more patient friendly. However, the cost-effectiveness of IVM versus IVF has not been assessed.
Study design, size, duration: This cost-effectiveness analysis was based on data from a randomised clinical trial at IVFMD, My Duc Hospital, HCMC, Vietnam (NCT03405701). Between December 2017 to April 2019, women were randomly assigned to one cycle of IVM or one cycle of IVF at IVFMD. The effectiveness measure for the CEA was the cumulative live birth rate after one completed cycle including subsequent cryo-cycles within 12 months following randomisation.
Participants/materials, setting, methods: We collected data on resource use related to treatment, medication, pregnancy from case report forms. The primary economic analysis was performed from a health care perspective. We measured costs relating to treatment (medication, complications, pregnancy, delivery). We additionally did the analysis from a societal perspective including non-medical costs. We calculated mean costs, effects, averaged differences in costs and incremental cost-effectiveness ratios (ICER) using nonparametric bootstrap resampling to assess the effect of uncertainty in our estimates.
Main results and the role of chance: A total number of 546 women were randomized to the IVM group (n = 273) or the IVF group (n = 273). Cumulative live birth rates after one completed cycle were 112/273 (41.0%) in the IVM group vs. 160/273 (58.6%) in the IVF group (RR 0.70, 95%CI 0.59-0.83). OHSS did not occur in the IVM group versus 2/273 (0.7%) in the IVF group. The mean total costs per couple were €5,684 for IVM and €7,240 for IVF (Absolute difference €-1,556, 95%CI €-1,837 to €-1,274). The ICER for IVM compared with IVF per additional live birth was €8,847 (95%CI €8,634 - €9,083).
Limitations, reasons for caution: We only compared one cycle of IVM versus one cycle of IVF. As data were collected from a single centre, unit costs obtained might be less representative in other settings.
Wider implications of the findings: IVM is less effective, but less expensive than IVF, therefore, the use of IVM in women with high AFC depends on society's willingness to accept foregoing an additional live birth.
Trial registration number: NCT03405701

O-293 Evaluation of Time Interval Between Ovulation Trigger With Triptorelin Acetate and Oocyte Retrieval in IVF Cycles. A Randomized Controlled Trial

C. Díaz-García[1], N. Garcia Camuñas[2], A. Marzal[3], M.J. Soriano[4], J. Subira[4], A. Garcia belda[4], A. Pellicer[5]

[1]IVI London, Reproductive Medicine, London, United Kingdom ;
[2]Hospital Universitario La Fe, IVF Unit, Valencia, Spain ;
[3]IVI Valencia, Reproductive medicine, Valencia, Spain ;
[4]IIS La Fe, Reproductive Medicine Research Group, Valencia, Spain ;
[5]IVI Roma, Reproductive Medicine, Rome, Italy

Study question: What is the optimal time interval between GnRH agonist trigger and follicular aspiration to maximise the number of mature oocytes collected?
Summary answer: The egg collection performed after 36 hours of triptorelin acetate administration allows obtaining a higher number of metaphase II (MII) oocytes
What is known already: Both GnRH agonists (GnRHa) and hCG have proven to be effective in achieving ultimate oocyte maturation. Nevertheless, their mechanism of action is different, and the hormonal dynamics of the ovulatory peak and the molecular profiles differ between them. GnRHa faithfully reproduces the physiological characteristics of natural cycles. Therefore, the accurate time to achieve oocyte maturation could be different between the two drugs. Consequently, the optimum moment to perform the follicular puncture after the GnRHa administration could be different from the 36 hours described for hCG. A study of the optimum time interval between ovulation triggering and follicular puncture is crucial
Study design, size, duration: Randomised, controlled, single-blind clinical trial carried out in a university-based IVF unit between September 2014 and December 2017. Patients undergoing ovarian stimulation with FSH in a short antagonist protocol were randomized to undergo egg collection after 30, 36 or 40 hours after ovulation trigger with 0.2 mg of triptorelin acetate. In patients undergoing fresh embryo transfer, luteal phase support was achieved by administering 1500 IU of hCG and 400 mg of vaginal micronized progesterone
Participants/materials, setting, methods: Women aged 18-37 years with a baseline FSH <10mIU/ml, AMH 5-45pmol/l, AFC 6-24 were included in the study. Patients with at least 5 follicles ≥16mm were randomized. Egg collections were done separating follicles measuring more and less than 16mm. Embryo transfer was performed according to usual clinical practice. The main outcome variable was the number of MII oocytes retrieved and the number of MII oocytes retrieved per follicle measuring > 16mm the day of trigger
Main results and the role of chance: A total of 121 patients were randomized to undergo ovulation triggering and egg collection after 30h (n=41), 36h (n= 42) or 40 hours (n=38). The proportion of MII retrieved was significantly lower after 30h of Decapeptyl administration in comparison with 36h and 40h follicular aspiration times (30h: 6.63±4.14, 36h: 9.10±4.75 and 40h: 7.26±4.49; p=0.03698). In addition to that, the ratio MII/follicles >16mm was higher 36h after trigger, compared to the 30h group (0.98±0.56 vs 0.73±0.39; p=0.05277). MII rates were concordant with molecular analysis results: a significantly down-regulation of genes related to oocyte maturation (AREG, BTC, CYP19A1, EFNB2, EREG, PHLDA1, RGS2 and UGP2) were found in GCs of punctured follicles at 30h. No significant differences regarding pregnancy rates or live birth rates were found between groups
Limitations, reasons for caution: The external validity of this study could be limited to patients undergoing the same type of ovarian stimulation. The present study was not designed to detect differences in pregnancy or live birth rates. Larger studies need to be performed in order to confirm the findings of the present study
Wider implications of the findings: The results of this study contribute to improving IVF protocols in order to recover the maximum number of MII oocytes and therefore, enhancing pregnancy rates. In addition, the use of GnRHa for ovulation induction would decrease the risk of OHSS associated with hCG stimulation protocols
Trial registration number: NCT02244151

O-294 Duration of infertility and IVF outcomes: analysis of 252 359 IVF cycles

Y. Beebeejaun[1], T. Copeland[2], I. Sarris[1], M. Kamath[3], S. Sunkara[4]

[1]King's Fertility, Women's Health, London, United Kingdom ;
[2]University of California Los Angeles, Department of Health Policy &-Management-, Los Angeles, U.S.A. ;
[3]Christian Medical College-, Department of Reproductive Medicine, Vellore, India ;
[4]King's College London, Women's Health, London, United Kingdom

Study question: Does infertility duration affect clinical and perinatal outcomes following IVF treatment?
Summary answer: The present study demonstrated an increased risk of low birth weight when the duration of infertility exceeds 48 months. Further research validation is warranted.
What is known already: Infertility is associated with adverse reproductive outcomes and women with infertility have a higher risk of adverse perinatal

outcomes. Furthermore, risk of adverse perinatal outcomes is also higher following assisted reproductive treatments (ART) compared to spontaneous conceptions. Globally, when IVF is indicated for infertility, the duration of infertility varies when women undergo treatment. There are several factors that influence when women have IVF. These factors could be other failed treatments before resorting to IVF, logistical or funding issues. With scant literature on whether infertility length could affect IVF outcomes, it is a matter of interest to explore this.

Study design, size, duration: Anonymous data were obtained from the Human Fertilization and Embryology Authority (HFEA), the statutory regulator of ART in the UK.

Data from 1991 to 2016 comprising a total of 252 493 first fresh IVF ± ICSI cycles were analysed based on the length of infertility (< 24 months vs 24 to 48 months vs > 48 months). Multiple births were excluded for analysis of perinatal outcomes.

Participants/materials, setting, methods: Perinatal outcomes of pre-term birth (PTB), early PTB (ePTB) and low birth weight (LBW) and very LBW (vLBW) as well as clinical outcomes of live birth rate, miscarriage and stillbirth were analysed in singleton live births. Occurrence of a live birth at < 37 weeks gestation is defined as a PTB and at < 32 weeks gestation as ePTB. Birth weight < 2500 grams is defined as LBW and < 1500 grams as vLBW.

Main results and the role of chance: Logistic regression analysis was performed adjusting for female age category, previous pregnancy, period of treatment, cause of infertility (male factor, tubal disease, ovulatory disorder, endometriosis, unexplained) and number of oocytes retrieved. Our control group was those suffering from infertility for <24 months.

Clinical outcomes: The live birth rate following single embryo transfer was 25.8% (95% CI 25.6%- 26.2%) for those suffering from infertility for less than 24 months, 24.6% (95% CI 24.3%-25.0%) for those suffering from infertility between 24 and 48 months and 21.9% (95% 21.6%-22.2%CI) when the duration of infertility is over 48 months. The relative risk ratio (RRR) of miscarriage was 0.94 (p-value=0.09) and 1.03 (p-value=0.35) when the duration of infertility was between 24-48 months and >48 months respectively The RRR of stillbirth was 0.87 (p-value=0.44) and 0.88 (p-value=0.11) for the 24-48 months and > 48 months period respectively.

Perinatal outcomes: The relative risk of ePTB and vLBW was not seen to be associated with increased duration of infertility. However, the RRR of PTB was 1.01 (p-value=0.84) and 1.11 (p-value=0.04) for the 24-48 months and >48 months respectively. , For LBW, the RRR was 0.99 (p-value=0.78 in the 24-48 months and 1.13 (p-value= 0.01) in the >48 months cohort respectively.

Limitations, reasons for caution: Limitations with observational data would apply to this study including residual confounding. This is the first study to address this study question.

Wider implications of the findings: The perinatal outcomes of offsprings born following ART techniques is of clinical relevance for patients and clinicians.

Trial registration number: Not applicable

[7]IVI-RMA Global, IVI Valencia, Valencia, Spain

Study question: Is male factor infertility associated with an altered incidence of chromosomal abnormalities of potential relevance to subsequent preimplantation development?

Summary answer: Male factor infertility is associated with increased mosaic chromosome abnormalities, a potential consequence of the sperm's role in formation of the first mitotic spindle.

What is known already: Infertility affects one in six couples worldwide with male factors contributing in ~50% of cases. Currently, the relative insensitivity of methods used to assess the competence of male gametes represents a significant limitation in evaluating the likelihood that a sperm sample will produce viable embryos if used for oocyte fertilisation. The close relationship between advancing female age and increasing oocyte aneuploidy rates has been well described. However, the extent to which the male gamete influences the genetics of the early embryo and its subsequent development is less clear.

Study design, size, duration: 331 embryos produced by couples with male factor (MF) infertility (semen sample concentration <5million/ml with/without testicular biopsy or epididymal aspiration) were evaluated, and their cytogenetic status retrospectively compared to that of 1245 embryos derived from infertile couples without MF evidence. Examination involved trophectoderm (TE) biopsy followed by next generation sequencing (NGS) for preimplantation genetic testing for aneuploidy (PGT-A). NGS enabled the accurate identification of mosaic and non-mosaic aneuploidies in blastocysts generated by both patient groups.

Participants/materials, setting, methods: 517 couples having IVF with PGT-A in 12 clinics participated. 69 patients (average female age 38.2 years) underwent PGT-A due to MF infertility. The remaining 448 (average female age 40.2 years) underwent PGT-A due to other indications. Patients were divided into "younger" (MF- 32.8 years, others-33.7 years average female age) and "older" (MF- 39.7 years, others- 40.6 years average female age) for data comparison. A highly validated targeted NGS approach was employed for chromosomal analysis.

Main results and the role of chance: More MF generated blastocysts were euploid compared with those generated by patients undergoing PGT-A for other indications (49% versus 32%, P<0.001). This is presumably a consequence of lower meiotic error rates in the oocytes of MF couples, due to their lower average female age. Conversely, MF patients generated significantly (P<0.001) more mosaic blastocysts (38%) compared with the remaining patients [17% 95%CI (2.906)], a difference that was detectable in both age groups. This increased mosaicism incidence suggests that the MF generated embryos experience more mitotic errors post-fertilisation. No significant difference (P=0.118) in the incidence of segmental aneuploidies was observed between the two patient groups. Of the 339 abnormalities scored in MF generated blastocysts, 286 (84%) affected whole chromosomes and 53 (16%) affected segments. A total of 1853 aneuploidies were identified in the blastocysts generated by the patients undergoing PGT-A for other indications, and 1624 (88%) affected whole chromosomes, with the remaining 229 (12%) being partial. This finding argues against sperm DNA fragmentation having a possibly detrimental effect after fertilisation. MF infertility patients had a significantly lower no-transfer rate, compared to all remaining patients (16% vs. 39% respectively, P<0.001), presumably a consequence of the higher incidence of euploid embryos in this group.

Limitations, reasons for caution: Classification was based on TE samples biopsied from blastocysts during PGT-A. As only a fraction of the cells from each embryo are assessed, some mosaic embryos may be incorrectly classified as fully euploid or aneuploid. However, this misclassification is expected to have little impact on the overall conclusions.

Wider implications of the findings: Poor sperm parameter patients are predisposed to generate mosaic embryos. This predisposition should be discussed during the counselling of couples considering PGT-A due to MF. Sperm centrioles are responsible for the first mitotic spindle organisation. Impaired centriole function in suboptimal sperm might explain the increased post-fertilisation chromosome segregation error rates.

Trial registration number: Not applicable

O-296 Single-cell genome-wide bisulfite sequencing for assessing the role of DNA methylation in spermatozoa.

"Abstract withdrawn by the authors"

O-297 Genetic and Epigenetic Characterization of Globozoospermic Men to Tailor Assisted Reproductive Treatment

D. Tavares[1], A. Parrella[1], S. Cheung[1], P. Xie[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can we genomically characterize globozoospermia using various biomarkers and nucleic acid sequencing to determine the best reproductive treatment?

Summary answer: Globozoospermia is associated with specific gene mutations and imbalances. Bioassays can be used to assess this gamete's capacity to support embryonic development and tailor treatment.

What is known already: Round-headed spermatozoa lack an acrosome and have a defect in chromatin compaction, primarily diagnosed by transmission electron microscopy (TEM). The phenotype of globozoospermia is mostly related to an autosomal recessive mutation and is frequently associated with familial inheritance. While few globozoospermia genotypes have been identified, fortunately, this rare defect does not always have complete penetrance. We applied different bioassays and genomic studies to better characterize this gamete's capacity to support embryonic development, as well as to tailor treatments to achieve pregnancy.

Study design, size, duration: Semen parameters, sperm ultrastructural details, protamine content, sperm chromatin fragmentation (SCF), sperm cytosolic factor, and sperm aneuploidy were assessed for 12 globozoospermic men. The genome and transcriptome of 3 men were profiled and compared to specimens from donors with proven fertility. ICSI was performed with or without assisted gamete treatment (AGT) based on diagnostic results of the bioassays. Clinical outcomes of conventional ICSI cycles and subsequent ICSI cycles with AGT were compared.

Participants/materials, setting, methods: Semen analysis was performed on 12 patients. TEM surveyed acrosomal defects and centrosomal integrity. Aniline Blue assay quantified protamine content with ≤20% normal threshold. SCF was measured by TUNEL with ≤15% normal threshold. Sperm cytosolic factor was determined by PLCζ assay with ≥30% normal threshold. Sperm aneuploidy was assessed using FISH with <1.6% normal threshold. Genome and transcriptome were analyzed by NGS and RNA-seq, respectively. AGT was performed by exposing both gametes to calcium ionophore.

Main results and the role of chance: Globozoospermia was defined by the presence of round-headed spermatozoa exceeding 70%. Twelve globozoospermic men (35.8±5 years) had a concentration of 34.4±44x106/ml, 24±25% motility, and normal morphology of 0.1±0.3%. Concurrent testing revealed abnormal protamine content of 53.8±24%, elevated SCF of 19.4±2%, insufficient cytosolic factor of 6.0±4%, and a high aneuploidy rate of 4.4±5%. Complete globozoospermia was confirmed in 3 men by TEM and the absence of PLCζ; genomic analysis identified 2 gene mutations: DPY19L2 and SPATA16. Epigenetic analysis revealed 142 differentially expressed genes compared to the control. We also found an overexpression of both mutant DPY19L2 and SPATA16 genes. To characterize their clinical outcomes, 7 couples (men, 35.8±5 years; women, 32.8±5 years) underwent 22 ICSI cycles yielding a fertilization rate of 31% (85/274), an implantation rate of 13.6% (6/44), and a clinical pregnancy rate (CPR) of 22.2% (4/18), with 1 pregnancy loss. For the remaining 3 couples with complete globozoospermia (men, 37.3±5 years; women, 36.6±6 years), historical ICSI cycles (n=3) yielded a 44% (8/18) fertilization rate, but no implantation. Once treated by AGT (n=4), there was a significant improvement, with a 50% fertilization rate (12/24) (P<0.00001), a 22% implantation rate (2/9), and a 33.3% CPR (1/3), resulting in 1 live birth.

Limitations, reasons for caution: This is the first study that attempts to utilize different bioassays and characterize the genome and epigenome of globozoospermic men in order to tailor reproductive treatment. While this preliminary data is reassuring, the health of the resulting offspring should be investigated.

Wider implications of the findings: The limitations of semen analysis are more apparent in cases of globozoospermia. This study demonstrates the association of this rare teratozoospermia to gene structure and function. Ultrastructural assays and genomic studies can be used to characterize this gamete's capacity to support embryonic development and to tailor treatments maximizing reproductive outcome.

O-298 Average sperm head area: a novel risk factor for sperm aneuploidy in idiopathic male infertility

M. Ruiz - Jorro[1], M. Ferrer-Buitrago[2], J.J. Bataller-Sánchez[3], A. Barberá-Alberola[3], X. Vendrell-Montón[4], C. Calatayud-Lliso[5]

[1]CREA Medicina de la Reproducción SL, Reproductive Andrology, Valencia, Spain ; [2]CREA. Medicine de la Reproducción SL, Research and Development, Valencia, Spain ; [3]CREA Medicina de la Reproducción SL, Andrology Laboratory, Valencia, Spain ; [4]Sistemas Genómicos. Grupo Biomédico Ascires, Reproductive genetics, Paterna, Spain ; [5]CREA Medicina de la Reproducción SL, Reproductive Medicine, Valencia, Spain

Study question: Is increased average of sperm head area (ASHA) a risk factor of sperm aneuploidy in patients consulting for infertility?

Summary answer: Increased ASHA values are associated with sperm aneuploidy in patients in whom altered meiosis during spermiogenesis is not initially suspected.

What is known already: Sperm aneuploidy test is aimed at patients experiencing recurrent implantation failure (RIF) or pregnancy loss (RPL). Likewise, patients with high FSH levels due to a testicular failure are prone to accumulate meiotic errors during spermiogenesis. Although sperm aneuploidy is detected in up to 15 % of infertile men, the risk of chromosomal aberrations increases to 40% in patients with factors such as RIF, RPL or suspected testicular failure. Fluorescence *in situ* hybridation (FISH) is employed to analyze sperm aneuploidy. This costly test is usually requested after observing repeated reproductive failures. Finding early indications to assess sperm aneuploidy remains a challenge.

Study design, size, duration: To determine the cut-off value for ASHA, we initially analyzed a total of 142 patients who showed normal FISH results (control group). The positive predictive value of ASHA was further assessed in a first retrospective study, which included a total of 250 patients experiencing RIF, RPL or testicular failure (Group 1). The validation of ASHA was assessed in a total of 22 patients who did not refer RIF, RPL or testicular failure (Group 2).

Participants/materials, setting, methods: Patients enrolled in CREA IVF program participated in the present study, after signing an informed consent form. ASHA cut-off value was established according to the value at percentile 95. Two semen samples were analyzed per patient according to WHO-V-manual. Sperm parameters, such as: sperm concentration, motility, morphology and ASHA were evaluated using the CASMA commercial software ISAS. Samples were stained employing the Diff-quick kit. FISH analysis (5 chromosomes) was performed using Metafer-4 software.

Main results and the role of chance: ASHA cut-off value was established as ≥14,8 μm^2 in the control group. Group 1 revealed an incidence of altered FISH of 41,2%. Furthermore, ASHA showed lower variability amongst the studied samples (p<0,002) and higher positive predictive value to detect altered FISH (73,9%) than other sperm parameters such as concentration (56,5%), total sperm count (58,8%) and morphology (46,7%). To reduce the potential bias associated with the retrospective data (patients with suspected risk of sperm aneuploidy), the predictive value of ASHA was further validated in a prospective analysis. Sample size was adjusted to detect at least 30 % difference from the basal 15 % incidence reported in a global population of infertile patients. All patients in Group 2 showed normal testicular function, with FSH values lower than 10 mUI/ml (4,81 ± 2,83). Sperm parameters in group 2 were: concentration (20,79 ± 26,47 million sperm/ ml), motility (44,95 ± 14,58) and morphology (1,55 ± 0,74%). The mean ASHA value in group 2 was 15,22 ± 0,64, with an incidence of sperm aneuploidy of 59,09%. This prospective analysis reveals that patients with ASHA values > 14,8 μm^2 show a higher incidence of chromosomal aberrations in sperm than a global population of infertile men (p<0,05).

Limitations, reasons for caution: The present study evaluates a limited number of patients. Further analysis in a broader population of patients with idiopathic infertility is needed to confirm the present findings.

Wider implications of the findings: ASHA is a sperm parameter which indicates the risk of sperm aneuploidy from the first sperm analysis. Its assessment contributes to reduce the time to advise PGT-A, and consequently the time to conceive in some infertile couples. Our findings provide novel insights in the field of androgenetics and male infertility.

Trial registration number: Not applicable

O-299 Attributing ICSI Fertilization Failure to the Responsible Gamete

P. Chung[1], S. Cheung[1], P. Xie[1], A. Parrella[1], D. Keating[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Is there a way to identify and effectively treat the gamete responsible for complete fertilization failure (CFF) with ICSI?

Summary answer: Screening the male gamete for the presence of PLCζ may identify the specific gamete responsible for ICSI CFF and guide treatment in subsequent cycles.

What is known already: ICSI is capable of overcoming defects of the zona pellucida and sperm acrosomal dysfunction, allowing fertilization. However, although rare, CFF with ICSI can occur due to oocyte activation deficiencies, either oocyte-related or due to the absence of sperm-activating factors. Most treatment approaches of CFF with ICSI described in the literature involve different methods of oocyte activation (AOA), yielding inconsistent results. These approaches may overlook cases of CFF that occur despite apparently normal gamete characteristics and often due to ooplasmic dysmaturity.

Study design, size, duration: Over 20 years, couples with ≤10% ICSI fertilization were identified. Seventy-six men were screened for the presence of PLCζ. Couples with oocyte-related OAD (n=52) underwent subsequent ICSI with tailored stimulation. Those with sperm-related OAD (n=24) were further screened by mouse oocyte activation test (MOAT) before undergoing subsequent ICSI with assisted gamete treatment (AGT). Consenting men (n=4) underwent a genomic evaluation by NGS. ICSI outcome was compared between treatment and historical cycles of the same couple.

Participants/materials, setting, methods: A total of 114 couples, with female partners ≤37 years of age and male partners with a sperm concentration of ≥1x10^6/ml, had fertilization rates of ≤10% despite injecting ≥3 oocytes (IRB 0712009553). PLCζ assessment was performed, confirmed by MOAT and DNA/RNA sequencing. In subsequent cycles, couples with oocyte-related OAD were treated by modulating *in-vivo/vitro* maturation time, while sperm-related OAD cases were treated by exposing both gametes to calcium ionophore. Clinical outcomes were compared.

Main results and the role of chance: A total of 114 couples (maternal age, 33.8±4 yrs; paternal age, 36.9±5 yrs) with a 9.1% ICSI fertilization rate were identified. Consenting male partners were screened, and 52 couples were identified as having oocyte-related OAD. These couples underwent subsequent ICSI cycles with tailored superovulation, yielding significantly higher fertilization (59.0% vs. 2.1%; *P*<0.0001) and clinical pregnancy (28.6% vs. 0%; *P*<0.0001) rates. Thirty clinical pregnancies resulted in 25 deliveries and 5 pregnancy losses. A total of 32 babies were born, 15 boys and 17 girls, with no major or minor congenital malformations.

Twenty-four couples (maternal age, 35.6±5 years; paternal age, 39.8±6 years) were confirmed as having sperm-related OAD following PLCζ and MOAT tests. In some men, DNAseq showed a PLCZ1 deletion, corroborating the initial screening. Deletions of genes associated with spermiogenesis and embryo development (PIWIL1, BSX, NLRP5), and the absence of subacrosomal perinuclear theca (PICK1, SPATA16, DPY19L), were also found. In these couples, AGT treatment provided higher fertilization (42.1% vs. 9.1%; *P*<0.05) and clinical pregnancy (36% vs. 0%; *P*<0.05) rates compared to the historical cycles. Six patients have successfully delivered, with offspring displaying normal development at 3 years of age.

Limitations, reasons for caution: In this prospective cohort study, while we controlled for maternal age-related aneuploidy, confounding factors cannot be excluded with certainty. Although PLCζ and MOAT assays need further validation, they serve an important purpose in identifying gamete-specific causes of CFF and in preventing the overuse of calcium ionophore treatment.

Wider implications of the findings: This is the first attempt to identify a gamete-specific OAD in couples with ICSI CFF. Those with an oocyte-related OAD can be treated in a subsequent cycle with a modified superovulation protocol, preventing AGT overuse. For those with sperm-related OAD, genomic analysis helped to identify the related genes involved.

SESSION 72: PREGNANCY LOSS: WHAT TO CONSIDER

08 July 2020 Parallel 4 14:00 - 15:15

O-300 Results of a highly significant, prematurely halted Dutch multicenter randomized double-blinded placebo-controlled study of pretreatment with mifepristone to misoprostol in early pregnancy failure (triple m)

L. Hamel[1,2], J. Van den Berg[1], S. Coppus[3], M. Snijders[2], F. Vandenbussche[4]

[1]Radboud University Medical Centre, Obstetrics and Gynaecology, Nijmegen, The Netherlands ;
[2]Canisius-Wilhelmina Hospital, Obstetrics and Gynaecology, Nijmegen, The Netherlands ;
[3]Maxima Medical Centre, Obstetrics and Gynaecology, Veldhoven, The Netherlands ;
[4]Kreiskrankenhaus Mechernich GmbH, Obstetrics and Gynaecology, Mechernich, Germany

Study question: Is, in early pregnancy failure (EPF), the sequential combination of mifepristone with misoprostol superior to misoprostol alone in terms of complete evacuation of the uterus?

Summary answer: In early pregnancy failure, the sequential combination of mifepristone with misoprostol is highly superior to misoprostol alone in reaching complete evacuation of the uterus.

What is known already: In case of EPF, women can choose from either expectant, medical or surgical management. Surgical intervention carries a risk of complications, however medical treatment appears to be a safe alternative. When the Dutch common practice of at least one week of expectant management is adhered to, current medical treatment with misoprostol alone has complete evacuation rates just above 50%. Shortly after the start of this trial, Schreiber et al (NEJM 2018) reported in a non-blinded trial that pretreatment with Mifepristone appears to be more successful when treating instantaneously after EPF is diagnosed.

Study design, size, duration: This study is a multicenter, randomized, double-blinded, placebo-controlled trial executed at 18 hospitals in the Netherlands. Results of the pre-planned interim-analysis, performed after 50% (N=232) of patients were enrolled, led to a premature halt of the study, due to highly significant outcomes. The study started on June 27th 2018, the 232nd inclusion was achieved in September 2019. When the decision was made to stop this trial prematurely, in total 342 woman had been randomized.

Participants/materials, setting, methods: Women with a diagnosis of EPF between 6-14 weeks gestation were included after at least one week of expectant management. They were randomized between pretreatment with mifepristone 600mg or placebo, both followed by two doses of misoprostol 400µg orally on day three and four. Ultrasonography was performed 15-20 days after treatment and, if required, repeated 4 weeks later to assess successful treatment, defined as absence of gestational sac in utero and endometrial thickness <15 mm.

Main results and the role of chance: After performing an interim-analysis of 50% of the pre-calculated required number of patients (n=232), as stated in advance in the study protocol, complete evacuation of the uterus was found to be 77,1% in the mifepristone group versus 52,9% in the placebo group (p=0.000). After 6 weeks of follow-up, the need for curettage was 10,2% in the mifepristone group compared to 31,9 % in the placebo group (p=0.000). Because these results met the predefined stopping rule, the Data Safety Monitoring Board instructed us to stop the study, since the difference between the two groups had already been proven beyond doubt, in favor of pretreatment with mifepristone. There were no concerns regarding the safety of the patients enrolled in the study. At the ESHRE 2020 annual meeting, follow-up for all 342 randomized women will be completed, and a full analysis of the treatment effect can be reported.

Limitations, reasons for caution: There is no consensus about the definition of 'successful treatment', or the optimal treatment regimen for EPF regarding dose or routes of administration of medical treatment for EPF.

Wider implications of the findings: In addition to adjustment of the Dutch national guideline concerning EPF, these results contribute to the improvement of medical management of EPF around the world. Especially in low income countries, this will lead to an extensive improvement of both the effectiveness and accessibility of proper medical treatment of EPF.
Trial registration number: NCT03212352

O-301 Reproductive performance following application of hyaluronic acid gel after dilatation and curettage for miscarriage in women with at least one previous curettage

A. Hooker[1], R. De Leeuw[2], J. Twisk[3], J. Huirne[2]

[1]Zaans Medical Center ZMC, Department of Obstetrics and Gynaecology, Zaandam, The Netherlands ;
[2]Amsterdam UMC- location VU University Medical Center- Amsterdam- the Netherlands., Department of Obstetrics and Gynecology-, Amsterdam, The Netherlands ;
[3]Amsterdam UMC- location VU University Medical Center- Amsterdam- the Netherlands., Department of Epidemiology and Biostatistics, Amsterdam, The Netherlands

Study question: Does intrauterine application of auto-crosslinked hyaluronic acid (ACP) gel, following dilatation and curettage (D&C) improve reproductive outcome in women with at least one previous D&C.
Summary answer: Application of ACP gel after D&C for miscarriage in women with at least one previous D&C.seems to have a favorable effect on subsequent reproductive outcome
What is known already: Application of auto-crosslinked hyaluronic acid (ACP) gel, in women who experienced at least one previous D&C undergoing D&C for miscarriage, resulted in a significant lower rate of IUAs, 13.0% versus 30.6%, relative risk (RR) 0.43 (95% CI 0.22-0.83, *P*=.013, lower mean adhesion score and significant less moderate to severe IUAs. Although subsequent fertility is a key outcome, data on reproductive performance following application of ACP after D&C for miscarriage remain limited.
Study design, size, duration: This was a follow-up study of a prospective randomized trial, conducted in one university and seven university-affiliated teaching hospitals in the Netherlands. Women with a miscarriage of < 14 weeks with at least one previous D&C, were randomized to D&C plus ACP gel (intervention) or D&C alone (control). A hysteroscopy was performed after 8-12 weeks to detect intrauterine adhesion (IUAs). In case IUAs were encountered, adhesiolysis was executed.
Participants/materials, setting, methods: To evaluate reproductive outcomes, participants of the PAPA-study were approached between December 2017 and April 2018. Participants (n=139) received questionnaires by post or email at least 30 months after randomization. The questionnaires consisted of 45 items related to received interventions, complications, menstrual pattern, contraceptive use, the desire to become pregnant, conception and outcome of subsequent pregnancies. The primary outcome was ongoing pregnancy.
Main results and the role of chance: The response rate in the intervention group was 93.1% and in the control group 95.5%. Baseline characteristics were comparable in both groups. The median duration of follow-up was slightly longer in the intervention group, 40.6 months (SD 2.7) versus 39.2 months (SD 3.6) in the control group. Ongoing pregnancies were recorded in 74.6% in the intervention group versus 67.2% in the control group, OR 1.33 (0.63-2.82). The miscarriages rate was 20.9% versus 37.5% respectively, OR, 0.44 (95% CI 0.18-0.90, *P*=.05). The live birth, ectopic pregnancy and TOP rates were not significantly different. In women wishing to conceive, ongoing pregnancies were recorded in 94.3% versus 71.7% , OR 4.84 (1.51-15.51) and more live births, 86.8% versus 70.0% in the control group OR, 2.82 (95% CI 1.07-7.42; *P*=.04) The median time to conception leading to a live birth was 21.9 versus 36.1 months, hazard ratio 1.46 (0.96-2.48).
Limitations, reasons for caution: The main limitation is that the PAPA-study was designed and powered for the presence of IUAs and not for long-term reproductive outcomes. Therefor the outcomes should be interpreted with caution.
Wider implications of the findings: The current study shows that application of ACP seems to have a favorable effect on reproductive performance. Our results should be confirmed in a large prospective study of sufficient power. .
Trial registration number: NTR 3120

O-302 First contact at implantation in humans: Endometrial epithelium induces trophectoderm differentiation to invasive syncytiotrophoblast.

P. Ruane[1], L. Parsons[1], T. Garner[1], P. Babbington[1], S. Kimber[2], A. Stevens[1], M. Westwood[1], D. Brison[1], J. Aplin[1]

[1]University of Manchester, Maternal and Fetal Health, Manchester, United Kingdom ;
[2]University of Manchester, Division of Cell Matrix Biology and Regenerative Medicine, Manchester, United Kingdom

Study question: How does the human embryo breach the endometrial epithelium at implantation?
Summary answer: Embryo attachment to the endometrial epithelium induces the formation of multinuclear syncytiotrophoblast from trophectoderm, which goes on to breach the epithelial layer.
What is known already: A significant proportion of assisted reproduction treatments fail due to unsuccessful implantation. The trophectoderm of the blastocyst-stage embryo attaches to the endometrial epithelium before breaching this barrier to implant into the endometrium. While historical histology suggested invasive syncytiotrophoblast after the embryo has breached the epithelium, *in vitro* models are required to understand the processes of human embryo implantation.
Study design, size, duration: Fresh and frozen human blastocyst-stage embryos (n=46) and human trophoblast stem cells were co-cultured with an endometrial epithelial cell line to model implantation *in vitro*. Systems biology approaches with published transcriptomic datasets were used to model implantation *in silico*.
Participants/materials, setting, methods: Human embryos surplus to treatment requirements were consented for research. Day 6 blastocysts were co-cultured with Ishikawa endometrial epithelial cell line monolayers until day 8, and trophoblast stem cell spheroids were co-cultured for 48h. Morphology was assessed by immunofluorescence microscopy, and trophoblast differentiation by RT-qPCR and ELISA. Human blastocyst, trophoblast stem cell and endometrial organoid transcriptomic datasets were used with hypernetwork analysis and random forest machine learning to identify gene networks associated with implantation.
Main results and the role of chance: The majority of embryos (37/46, 80.4%) breached the Ishikawa cell layer, and syncytiotrophoblast was observed in all of these. Sites where a single point of breaching had occurred always consisted of syncytiotrophoblast (7/7). Multiple (up to 7), independent syncytiotrophoblast regions were seen in 26/46 (56.5%) embryos. Human trophoblast stem cell spheroids co-cultured with Ishikawa layers also exhibited synscytiotrophoblast formation upon breaching the epithelium. RT-qPCR demonstrated epithelium-induced upregulation of syncytiotrophoblast genes CGB (p=0.03), OVOL1 (p=0.04) and SDC1 (p=0.008), and ELISA revealed stimulation of hCG secretion (p=0.03). Receptive endometrial organoid surface transcriptome was used to identify trophectoderm surface binding partners and hypernetwork analysis established a group of 24 trophectoderm receptors that were highly connected within the transcriptome. Of these, 14 genes are differentially expressed in trophoblast stem cell-syncytiotrophoblast differentiation ($p<0.047$-8.7^{-9}), and random forest machine learning assigned 20/24 genes to processes driving this differentiation pathway ($p<0.01$). *In vitro* embryo and stem cell models, and *in silico* models, all suggest that syncytiotrophoblast formation from trophectoderm is induced by attachment to the endometrial epithelium and this cell type pioneers embryo invasion.
Limitations, reasons for caution: *In vitro* and *in silico* models may not recapitulate the dynamic interactions embryo-endometrial interactions that occur *in vivo*. The influence of other cellular compartments in the endometrium, including decidual stromal cells and leukocytes, was not recapitulated in these models.
Wider implications of the findings: Understanding the mechanism of human embryo breaching of the epithelium and the gene networks involved is crucial to improve implantation success rates after assisted reproduction. Moreover, early trophoblast lineages form the blueprint for the placenta and thus underpin fetal growth trajectories, pregnancy health and even offspring health.
Trial registration number: NA

O-303 Comparison of DNA methylation patterns of parentally imprinted genes in placenta derived from IVF conceptions in two different culture media

C. Mulder[1], T. Wattimury[1], A. Jongejan[2], C. De Winter-Korver[1], S. Van Daalen[1], R. Struijk[1], S. Borgman[1], Y. Wurth[3], D. Consten[3], J. Van Echten-Arends[4], S. Mastenbroek[1], J. Dumoulin[5], S. Repping[1], A. Van Pelt[1], A. Van Montfoort[5]

[1]Amsterdam UMC - Location AMC, Center for Reproductive Medicine- Amsterdam Reproduction and Development Research Institute ., Amsterdam, The Netherlands ;
[2]Amsterdam UMC- location AMC, Bioinformatics Laboratory- Clinical Epidemiology- Biostatistics and Bioinformatics- Amsterdam Public Health Research Institute- Amsterdam UMC, Amsterdam, The Netherlands ;
[3]St. Elisabeth Hospital, Center for Reproductive Medicine, Tilburg, The Netherlands ;
[4]University Medical Center Groningen, Section of Reproductive Medicine, Groningen, The Netherlands ;
[5]Maastricht University Medical Center, Department of Obstetrics & Gynaecology- GROW School for Oncology and Developmental Biology, Maastricht, The Netherlands

Study question: Is there a difference in DNA methylation status of imprinted genes in IVF derived placentas where embryo culture was performed in HTF versus G5 medium?
Summary answer: We found no statistically significant differences in the mean DNA methylation of imprinted genes in placentas derived from IVF conceptions cultured in HTF versus G5.
What is known already: Animal studies indicate that the embryo culture environment affects the DNA methylation status of the embryo. In humans, birthweight is known to be affected by the type of embryo culture medium used. The effect of embryo culture media on pregnancy, birth and child development may thus be mediated by differential methylation of parentally imprinted genes in the placenta.
Study design, size, duration: DNA methylation status of imprinted genes was determined in human placenta derived from IVF conceptions exposed to HTF or G5 embryo culture medium. Placenta samples (n=43 for HTF, n=54 for G5) were collected between 2010 and 2012 as part of a multi-centre randomized controlled trial in the Netherland comparing these embryo culture media. Placenta samples from 69 naturally conceived live births collected during 2008-2013 in the Netherlands were used as reference material.
Participants/materials, setting, methods: To measure the DNA methylation status of differentially methylation regions (DMRs) associated with parentally imprinted genes, we opted for an amplicon-based sequencing strategy on an Illumina MiSeq sequencing platform. DNA was isolated and 34 differentially methylated regions associated with well-defined parentally imprinted genes, were amplified in a two-step PCR procedure before sequencing using MiSeq technology. Sequencing data were analysed in a multivariate fashion to eliminate possible confounding effects.
Main results and the role of chance: We found no statistically significant differences in the mean DNA methylation status in any of the imprinted DMRs in placentas derived from IVF conceptions cultured in HTF or G5 culture medium. We also did not observe any differences in the variance in methylation per amplicon between the two culture medium groups. A separate surrogate variable analysis also demonstrated that the IVF culture medium was not associated with the DNA methylation status of these DMRs. The mean methylation level and variance per CpG was equal between HTF and G5 placenta. Additional comparison of DNA methylation status of IVF placenta samples with naturally conceived placenta samples revealed no statistically significant differences in mean amplicon and CpG methylation between G5, HTF and naturally conceived placenta. However, the number of placenta samples exhibiting outlier methylation levels was higher in IVF placenta compared to naturally conceived ($p<0.00001$). Also, we were able to identify 37 CpG sites that uniquely displayed outlier methylation in G5 placentas and 32 CpG sites that uniquely displayed outlier methylation in HTF. In 8/37 (G5) and 4/32 (HTF) unique outliers CpGs, a medium specific unique outlier could be directly correlated to outlier methylation of the entire amplicon.
Limitations, reasons for caution: Due to practical reasons, not all placentas were collected during the trial and we collected the placentas from natural conceptions from a different cohort, potentially creating bias. We limited ourselves to 34 imprinted DMRs and we studied only the placenta tissue and no other embryo derived tissues.
Wider implications of the findings: It has often been postulated that imprinting mediates the effects of embryo culture conditions on pregnancy, birth and child development. We did not detect any statistically significant effects of embryo culture conditions on methylation status of imprinted genes in the placenta, therefore other unexplored mechanisms may underlie these effects.
Trial registration number: Placental biopsies were obtained under Netherlands Trial Registry number 1979 and 1298.

O-304 Risk factors for ectopic pregnancy after in vitro fertilization treatment: a case-control study

V. Trindade[1], M.R. Hentschke[1], V.C. Dornelles[2], A.T.F. Kira[1], T. Colombo[1], B. Cunegatto[3], L. Okada[3], A. Petracco[4], J.D.R. Michelon[5], B.E.P. Da Costa[2], M. Badalotti[4]

[1]Fertilitat - Center for Reproductive Medicine, Research, Porto Alegre, Brazil ;
[2]Pontifical Catholic University of Rio Grande do Sul, School of Medicine, Porto Alegre, Brazil ;
[3]Fertilitat - Center for Reproductive Medicine, Laboratory, Porto Alegre, Brazil ;
[4]Fertilitat - Center for Reproductive Medicine, Director, Porto Alegre, Brazil ;
[5]Fertilitat - Center for Reproductive Medicine, Medical Team, Porto Alegre, Brazil

Study question: Is it possible to identify risk factors for ectopic pregnancy after *in vitro* fertilization?
Summary answer: Tubal factor, previous miscarriage, D3 embryo transfer, two or more embryos transferred per cycle and oocyte recipient cycles were associate with ectopic pregnancy after IVF.
What is known already: Ectopic pregnancy is an obstetrical disease that is potentially associated with maternal death at first trimester. It is one of the well-known complications following IVF with embryo transfer (ET), as its incidence can reach 0.9-11% compared to 1–2% in spontaneous pregnancies. The etiology of a higher EP rate in an IVF-ET cycle remains unclear and the strategies to decrease its rates are limited.Thus, it is important to identify accurate risk factors for EP, as it represents not only a life-threatening event but also a lost opportunity for couples who sought assisted reproduction treatments.
Study design, size, duration: Retrospective case-control study performed at an assisted reproduction clinic in southern Brazil. To select the control group, a ratio of 1:4 was applied and collected from 4666 cycles that resulted in a clinical pregnancy after IVF-ET. In the end, 499 patients who underwent IVF cycle and evolved to clical pregnancy were included. The data refers to a period from 2001- 2019 and were collected from electronic records.
Participants/materials, setting, methods: The 499 patients were separated into groups: Group 1, who presented EP diagnose (n=90) and Group 2, intrauterine pregnancies (IUP) (n=409). Data were presented as mean ± standard deviation or percentage. Student t test, Mann–Whitney U-test, and Chi-square test or Fisher's exact test were applied. Multiple logistic regression analysis was performed to assess risk factors for EP. Statistical significance was defined as $p < 0.05$.
Main results and the role of chance: When compared Group 1 with Group 2 the following results were observed: Tubal factor infertility (35.6% *vs*. 21.1%, p=0.005) (OR 2.0 [1.2-3.4], p=0.004); History of previous miscarriage (15.1% *vs*.7.1%, p<0.05) (OR 2.0 [1.02–4.29], p=0.044); number of transfers in D3 embryo (69.2% vs. 54.0 p=0.028)(OR 1.9 [1.08 - 3.33], p=0.025); two or more embryos transferred (OR 2.5 [1.12–5.70], p=0.025). Even though we excluded oocyte recipient patients (ORP) from the analyzes above, we found a difference in ORP rate when comparing Group1 and group 2 (9.4% (10/106) vs. 3.0 % (13/434), p=0.007), (OR 3.3 [1.41 - 7.98] p = 0.005). No significant differences were observed in the analysis of female and male ages, body mass index, number of mature oocytes, sperm concentration, follicle-stimulating hormone,antral follicle count, male factor, ovulation factor, previous EP, previous pelvic surgery, endometrial thickness, embryo classification, protocol with agonist or antagonist or fresh versus frozen ET.
Limitations, reasons for caution: Retrospective study with limited number of patients. In addition, even though results show that oocyte recipient patients seems more likely to have an ectopic pregnancy, this data should be carefully interpreted given sample size.
Wider implications of the findings: Findings demonstrated a higher risk for EP in the group of patients who had tubal factor and previous miscarriage history. D3 transfer and more than one embryo per transfer were also associated

with higher EP risk. In high risk patients, it is reasonable to advise blastocyst and single embrio transfer.
Trial registration number: not applicable

O-305 Ultra-long administration of GnRH-a before in vitro fertilization does not improve the clinical pregnancy rate in women with mild endometriosis. A prospective, randomized, controlled trial

A. Kaponis[1], E. Panagodimou[1], G. Hadjopoulos[2], M. Paschopoulos[2], I. Georgiou[2], V. Paraskevaidis[2], K. Zikopoulos[2], K. Tsiveriotis[1], F. Taniguchi[3], G. Adonakis[1], T. Harada[3]

[1]Patras University School of Medicine, Ostetrics & Gynecology, Patra, Greece ; [2]Ioannina University School of Medicine, Obstetrics & Gynecology, Ioannina, Greece ; [3]Tottori University Faculty of Medicine, Obstetric and Gynecology, Yonago, Japan

Study question: Is there any beneficial effect of GnRH-a administration, post-laparoscopically, in the fertility of women with mild endometriosis who underwent in vitro fertilization (IVF) procedures?
Summary answer: The clinical pregnancy rate in mild endometriosis women who received GnRH-a, post-laparoscopy, did not improve compared with women who did not receive this regime.
What is known already: GnRH-agonists have long been administered for the treatment of endometriosis, however, their use postoperatively, in women with mild endometriosis has been linked with controversial results. Several studies associated prolonged use of GnRH-a before IVF with a higher pregnancy rate, while others showed no statistically significant improvement. On the other hand, long-term pituitary desensitization regimes may lower ovarian response to gonadotropins, affecting the success of assisted reproduction procedures.
Study design, size, duration: This is a prospective, randomized, controlled trial. Six hundred infertile women were recruited during a 15-year interval (May 2004- December 2018). Four hundred of the afore-mentioned women diagnosed with mild endometriosis (ASRM stage I-II), while 200 from tubal factor infertility (group C). Patients with endometriosis were divided randomly in those who received GnRH-a, for three months before an IVF attempt (group A, n=200) and those who did not (group B, n=200).
Participants/materials, setting, methods: Women aged 29-38 years, were recruited from three tertiary University hospitals (Ioannina and Patras, Greece; Yonago, Japan). There were no demographic discrepancies between groups. Long protocol for ovulation induction was used. TNF-a, IL-1β, IL-6, IL-8, and IL-1ra levels were measured in the follicular fluid (FF) of all women. Fertilization Rate (FR), Implantation Rate (IR), quality of embryos, and clinical pregnancy rate (PR) were evaluated and compared between the different groups.
Main results and the role of chance: Women with endometriosis who received the long-acting GnRH-a (group A) presented significantly decreased concentrations of the FF's cytokines compared with those who did not receive similar treatment (group B). This applied to TNF-a, IL-1β, IL-6, and IL-8 ($p < 0.001$). In women with endometriosis, FR and PRs were lower compared to women with tubal infertility. A statistically significant difference was observed only in the FR between women of group A and women of group B (group A: 72.7, 95%CI: 70.50-74.90 vs. group B: 61.7, 95%CI: 59.20-64.20, $p<0.05$). Embryo quality did not improve after administration of GnRH-a. The percentage of grade 1 embryos was comparable between the three groups (group A: 24.5, 95%CI: 21.50-27.50; group B: 21.6, 95%CI: 18.80-24.40; and control group: 26, 95%CI: 22.70-29.30). IR did not differ significantly between women of the three groups (group A: 18.4%, 95%CI: 14.6-22.2%; group B: 17%, 95%CI: 13-21%; group C: 19.3, 95%CI 15.5-23.1). Women of group A presented higher PR than women of group B however, this difference was not statistically significant (OR: 1.16, 95%CI: 0.73, 1.84, p=0.52). The study population is homogenous, adequately powered and the risk of bias reduced due to random allocation of women to the intervention or control group.
Limitations, reasons for caution: The long period for completion of the trial is a limitation of the current study. Active endometriotic lesions were cauterized before any reproduction procedure. This treatment might hided any beneficial effect of GnRH-a administration. Data on miscarriages and live birth rates are not available.
Wider implications of the findings: This study is expected to guide future management of infertile women with mild endometriosis undergoing IVF-ET. According to our data, these women better proceed directly to IVF-ET, after laparoscopy, since the administration of GnRH-a did not improve their fertility.
Trial registration number: NCT1269125

O-306 Oocyte survival and clinical outcome is impaired in young endometriosis patients after fertility preservation (FP).

A. Cobo[1], J. Giles[2], S. Paolelli[2], A. Coello[1], B. Vallejo[1], J. Serrano[1], J.A. García-Velasco[3], J. Remohí[2]

[1]IVIRMA-Valencia, IVF Laboratory-Cryopreservation Unit, Valencia, Spain ; [2]IVIRMA-Valencia, Ob/Gyn, Valencia, Spain ; [3]IVIRMA-Madrid, Ob/Gyn, Madrid, Spain

Study question: Is oocyte survival and clinical outcome impaired in endometriosis patients after FP when compared to elective freezers?
Summary answer: Oocyte survival, implantation, pregnancy and cumulative live birth rates are impaired in young (≤35y) patients with endometriosis.
What is known already: FP should be considered in women with endometriosis due to the progressive reduction in the ovarian reserve. In spite of the high incidence of the disease and the increasing number of endometriosis-women who have oocytes vitrified for FP, very little is known about the efficacy of the strategy in these cases. Currently, there is evidence of successful outcomes achieved after oocyte vitrification for elective FP (EFP), although the age of the patient is one of the most limiting factors. In this study, we compare the results achieved by endometriosis-patients after FP to those achieve by EFP patients according to age.
Study design, size, duration: Retrospective study including 485 (≤35y: N=123 and >35y: N=518) women with endometriosis and 641 (≤35y: N=123 and >35y: N=518) EFP patients. All women included had their oocytes vitrified for FP and returned to use their oocytes to attempt pregnancy.
Participants/materials, setting, methods: The Cryotop method was used for oocyte vitrification. Within the endometriosis group, 97.7% of patients were diagnosed with stage III-IV endometriosis and 47.8% had ovarian surgery prior to FP. Oocyte survival, implantation rate and clinical outcome were compared between endometriosis and EFP groups according to age (≤35y vs <35y). Values are expressed as mean and 95% confidence intervals (CI). Chi-square tests were used to compare the categorical data. $P<0.05$ was considered as statistically significant.
Main results and the role of chance: Mean age of patients with endometriosis by the time of FP was 35.7 ± 3.7 and 37.6 ± 3.5 for EFP patients. Lower outcomes were achieved in the group of women with endometriosis aged ≤35y ($P<0.05$): oocyte survival was 85.1% (95%CI 83.8-86.5) vs. 91.4% (95%CI 89.6-93.2), implantation rate was 38.6% (95%CI 45.7-63.8) vs. 54.5% (95%CI 33.9-43.3), clinical pregnancy rate was 49.2% (95%CI 42.9-55.5) vs.65.9% (95%CI 57.9-73.9), ongoing pregnancy rate was 40.9% (95%CI 34.7-47.1) vs. 57.7% (95%CI 49.4-66), and CLBR was 61.9% (95%CI 56-67.8) vs. 68.8% (95%CI 59.4-78.2) respectively ($P<0.05$). In older patients (>35y) all the parameters were comparable: 80.8% (95%CI 78.9-82.6) vs. 82.1% (95%CI 80.9-83.3) for oocyte survival, 28.3% (95%CI 23.1-33.5) vs. 33.8% (95%CI 28.1-39.4) for implantation, 41.4% (95%CI 34.0-48.8) vs. 36.5% (95%CI 32.5-40.5) for clinical pregnancy, 29.6% (95%CI 22.7-36.5) vs. 27.7% (95%CI 23.9-31.5) ongoing pregnancy and 28.4% (95%CI 19.7-37.7) vs. 25.5% (95%CI 21.1-29.9) for CLBR in endometriosis vs EFP respectively (NS).
Limitations, reasons for caution: Retrospective nature of the study. The lower number of patients diagnosed as stages I-II makes it difficult to compare by the stage of the disease.
Wider implications of the findings: The lower oocyte survival and the impaired implantation and reproductive potential observed in young endometriosis patients confirms the negative impact of the disease in the ovarian reserve

and in the oocyte quality. FP should be counseled to endometriosis patients at young ages in order to increase their future pregnancy chance.
Trial registration number: Not applicable

O-307 ICSI treatment does not result in improved live birth rates compared to conventional IVF in couples with endometriosis: An analysis of 10,047 treatment cycles

H. Kamali[1], I. Gamaleldin[2], A. Kaura[3], P. Wilson[4], V. Akande[1]

[1]Bristol Centre for Reproductive Medicine, Clinical team, Bristol, United Kingdom ; [2]North Bristol NHS Trust, Women and Childrens Health, Bristol, United Kingdom ; [3]Imperial College NHS Healthcare Trust, Medical statistics, London, United Kingdom ; [4]Bristol Centre for Reproductive Medicine, Embryology, Bristol, United Kingdom

Study question: Is ICSI associated with improved reproductive outcomes over conventional IVF in couples with endometriosis related infertility (ERI) only?
Summary answer: Compared to conventional IVF, ICSI results in reduced fertilisation failure but is not associated with improved implantation, clinical pregnancy or live birth rates in ERI
What is known already: Endometriosis can affect up to 50% of women with infertility. As well as anatomical distortion, the condition can also negatively affect oocyte quality, embryogenesis and implantation through altered folliculogenesis, sperm phagocytosis, impaired fertilisation and embryotoxicity. ICSI, which is typically used for male factor infertility and known to result in improved fertilisation rates compared with conventional IVF, is increasingly being used in the cohort of patients with ERI to try and overcome these effects. However, there are no large-scale studies directly assessing the benefit of ICSI over conventional IVF with regards to reproductive outcomes in women with ERI.
Study design, size, duration: Anonymised data on all IVF and ICSI treatment cycles performed in the UK from years 1991 – 2016 were retrospectively obtained from the Human Fertility and Embryology Authority (HFEA). Women under 40 having their first treatment cycle using fresh embryos with a diagnosis of ERI only were included.
Participants/materials, setting, methods: Primary outcome was live birth rate. Secondary outcomes were fertilisation rate, implantation rate and clinical pregnancy rates. Outcomes were further stratified by age group (<35, 35-37, 38-39) and time period to account for improved LBR over time. Data were analysed using logistic regression and controlled for age, number of oocytes collected, and number of embryos transferred.
Main results and the role of chance: A total of 10,047 women had ERI of which 80.3% (8,075) had IVF compared with 19.7% (1,972) who underwent ICSI. The proportion of couples with ERI having ICSI increased from 6.3% in 1991-2000 to 23.7% in 2011-2016. Rates of total fertilisation failure (TFF) were lower with ICSI compared with IVF (3.7% versus 6%, p-value <0.001). However, in women with ERI, ICSI did not result in an improved live birth rate (OR 1.05, CI 0.94-1.17, p-value 0.42), clinical pregnancy rate (OR 1.06, CI 0.95-1.17, p-value 0.33) or miscarriage rate (OR 1.07, CI 0.82-1.39, p-value 0.62) compared with conventional IVF. The absence of improved reproductive outcomes with ICSI compared to conventional IVF in women with ERI was consistent across all age groups and different time periods.
Limitations, reasons for caution: As a retrospective study, our analysis depends on previously recorded data, therefore certain key variables (endometriosis stage, presence/absence of endometriomas, clinic specific protocols and duration of infertility) could not be accounted for. The reported cause of infertility is based on the treating clinician's classification and may be inconsistent.
Wider implications of the findings: In couples with ERI, ICSI results in reduced TFF compared with conventional IVF. However, this does not translate to an improvement in post fertilisation reproductive outcomes, including live birth rate. These findings do not support the use of ICSI over conventional IVF for treatment of couple with ERI.
Trial registration number: NA

O-308 A prospective randomized comparative study of laparoscopic ovarian cystectomy and ablation versus transvaginal cyst aspiration in infertile patients with Endometrioma undergoing IVF – ET treatment

S. Saha[1], H.H. Shirazee[1], M. Murmu[1]

[1]North Kolkata Infertility & IVF Centre, Reproductive Medicine, Kolkata, India

Study question: Is transvaginal endometriotic cyst aspiration better than laparoscopic ovarian cystectomy for preservation of ovarian reserve?
Summary answer: Better ovarian reserve in transvaginal cyst aspiration group achieve more number of oocytes and embryos resulting in significantly higher cumulative pregnancy rate.
What is known already: Laparoscopic cystectomy causes decreased ovarian reserve due to loss of normal ovarian tissue and thermal damage leading to poor reproductive outcome.
Study design, size, duration: In this Randomized, Control Trial over 2 years (July 2017 to June 2019), 104 infertile patients of 20-36 years of age with endometrioma were divided into- Group A and Group B comprising 52 patients in each group
Participants/materials, setting, methods: In this study Group A-52 patients had laparoscopic chocolate cystectomy followed by 4 weekly injection GnRH-a depot(3.75 mg) for 3months followed by IVF-ET treatment whereas Group B-52 patients received 4 weekly Injection GnRH-a depot(3.75 mg) for 3months followed by transvaginal chocolate cyst aspiration and underwent IVF-ET treatment . Patients in both groups were evaluated for ovarian reserve, no. of oocyte retrieved, fertilization rate, No. of embryo, implantation rate, pregnancy rate & outcome.
Main results and the role of chance: In Group A & Group B, mean no of baseline antral follicles and AMH were 2.1 ±0.9 Vs 4.8 ± 0.6 ($p< 0.05$) and 1.98 ± 0.8 Vs 3.1 ±1.2 ($p< 0.01$) respectively. Baseline FSH was significantly more in Gr A (9.1± 1.4 Vs 6.6±1.3, $p= 0.04$). The number of average oocyte retrieved was significantly more in Gr B (7.2±2.2 vs 4.8±2.8, $p<0.05$). Cumulative pregnancy rate per ovum pick up cycle is significantly more in Gr B (60.4% vs 45.1% , $p<0.05$).
Limitations, reasons for caution: As this study is of short duration with small number of patients so widespread multicentric study comprising large number of subjects is requirred to cone to a definitive conclusion.
Wider implications of the findings: Treatment cost and patient's morbidity is less in group B with better ovarian reserve leading to more number of oocytes retrieved and number of good quality embryo available for transfer. Cumulative pregnancy rate following single ovum pick up cycle is significantly more in transvaginal cyst aspiration group.
Trial registration number: Not applicable

O-309 Endometrial scratching in women undergoing their first In Vitro Fertilisation (IVF) cycle: results from the UK Multicentre Endometrial Scratch Randomised Controlled Trial

M. Metwally[1], R. Chatters[2], C. Pye[1], M. Dimairo[2], D. White[2], S. Walters[2], J. Cohen[3], T. Chater[2], K. Pemberton[2], T. Young[2], R. Lomas[1], E. Taylor[1], S. Laird[4], L. Mohiyiddeen[5], Y. Cheong[6]

[1]Sheffield teaching hospitals, Reproductive medicine, Sheffield, United Kingdom ; [2]The University of Sheffield, Clinical Trials Unit, Sheffield, United Kingdom ; [3]Hull York Medical School, Hull Health Trials Unit, Hull, United Kingdom ; [4]Sheffield Hallam University, Biosciences and Chemistry, Sheffield, United Kingdom ; [5]Manchester University Hospitals, Reproductive Medicine, Manchester, United Kingdom ; [6]The University of Southampton, Reproductive Medicine, Southampton, United Kingdom

Study question: Does endometrial scratching (ES) in the mid-luteal phase prior to first time IVF/ICSI increase the chances of achieving a clinical pregnancy and live birth?
Summary answer: Endometrial Scratch performed prior to the first cycle of IVF/ICSI does not increase the chances of achieving a pregnancy and live birth.
What is known already: Endometrial Scratch is currently being provided in some fertility units where women are having IVF/ICSI for the first time. The most recent 2019 systematic review shows poor evidence to support this practice. Current studies are single centre, of relatively small size and/or involve heterogeneous or unselected populations. Further evidence is therefore required from a large multi-centre randomised controlled trial looking at a homogenous population of only women undergoing first time treatment and expected to be good responders in order to minimise heterogeneity.
Study design, size, duration: A multicentre, pragmatic, open-label, individually randomised parallel-group trial recruited women at 16 fertility centres

across the UK from July 2016 to Oct 2019. We planned to recruit 1044 women (522 per arm) to preserve a power of 90% and 5% two-sided type I error assuming a 30% live birth rate in treatment as usual (TAU), a 10% absolute difference between TAU and Endometrial Scratch (ES) arms (more likely to change practice), and 5% dropout rate.

Participants/materials, setting, methods: Women aged ≥18 and ≤37 undergoing their first IVF cycle, BMI <35 kg/m^2 and expected to be good responders were eligible. ES was undertaken in the mid-luteal phase prior to IVF/ICSI. Women were randomised 1:1 to either ES or IVF/ICSI (TAU), using a web-based stratified block randomisation. The primary outcome was live birth (LBR); secondary outcomes included clinical pregnancy (CPR), implantation (IR), ectopic pregnancy (ER), miscarriage (MR), preterm delivery (PDR), stillbirth (SBR) rates and safety.

Main results and the role of chance: 1048 women were randomised TAU (n=525) and ES (n=523). Mean age and BMI (standard deviation) was 32.5(3.4) years and 24.5 (3.3) kg/m^2. Baseline characteristics were similar between arms. In the ES arm, 86.6% (453/523) received the ES procedure. IVF/ICSI was received by 94.1% (494/525) in the TAU and 95.0% (497/523) in the ES arm. For the primary outcome, LBR was 37.1% (195/525) in the TAU and 38.4% (201/523) in the ES (Unadjusted: *difference*, 1.3% [95%CI, -4.6% to 7.2%]; *relative risk*, 1.03 [95%CI, 0.89 to 1.21]; *odds ratio*, 1.06 [95%CI, 0.82 to 1.36]; P-value = 0.667).

For the secondary outcomes, CPR was 40.6% (213/525) in TAU and 42.4% (222/523) in ES arm (Unadjusted: *difference*, 1.9% [95%CI, -4.1% to 7.8%]; *relative risk*, 1.05 [95%CI, 0.91 to 1.21]; *odds ratio*, 1.08 [95%CI, 0.84 to 1.38]; P-value = 0.538). All the other secondary outcomes (IR, EPR, MR, MBR, PDR, and SBR) were all similar between arms.

Adverse events and serious adverse events in women were similar between arms. No deaths or neonatal deaths were reported. Only 1.2% (3/258) of born babies had severe congenital abnormalities reported in the TAU arm only.

Limitations, reasons for caution: The study did not include a sham procedure in the Treatment As Usual arm but this is unlikely to have influenced the study outcomes Furthermore, the study is applicable to the demographic and ethnic distribution of the population in the UK as no overseas centres were included.

Wider implications of the findings: Endometrial scratch is currently performed for women undergoing first time IVF/ICSI in some centres. This study provides conclusive evidence that Endometrial Scratch is not beneficial in this population and suggests that it is time to stop this practice.

Trial registration number: ISRCTN23800982

SESSION 74: OOCYTE AND EMBRYO EVALUATION

08 July 2020 Parallel 6 14:00 - 15:15

O-310 Optical coherence microscopy as a novel tool for quality assessment of mammalian oocytes and embryos

A. Ajduk[1], M. Fluks[1], A. Sobkowiak[1], S. Tamborski[2], M. Szkulmowski[2]

[1]University of Warsaw, Faculty of Biology, Warsaw, Poland ; [2]Nicolaus Copernicus University, Institute of Physics, Torun, Poland

Study question: We wished to examine whether optical coherence microscopy (OCM), a novel technique of label-free live-cell imaging, can be used in the oocyte/embryo quality assessment.

Summary answer: OCM allows for non-invasive imaging of the intracellular architecture of oocytes and embryos. These morphological data can be predictive of oocyte/embryo developmental potential.

What is known already: Fluorescence microscopy (including its confocal version) allows for detailed structural and dynamic studies of single cells, but requires fluorescent markers to visualize cellular architecture and may cause short- and long-term photo-damage. Bright-field microscopy, although non-invasive, does not provide detailed structural information. OCM is a promising alternative, as it does not require sample pre-processing or labeling and is capable of providing three-dimensional images of intracellular structures, such as nuclei (with chromatin conformation and nucleoli), metaphase spindles and network of endoplasmic reticulum cisterns and mitochondria. It is believed that these morphological parameters can be useful for oocyte/embryo quality evaluation in IVF protocols.

Study design, size, duration: We tested the OCM on mouse oocytes and embryos, focusing so far on immature (so-called germinal vesicle, GV) oocytes and compacted morulas. We analyzed over 400 GV oocytes and over 400 morulas in order to verify whether OCM scanning affects their developmental capabilities and whether morphological data obtained by OCM (chromatin conformation in GVs and number of nuclei in morulas) correlate with their developmental potential.

Participants/materials, setting, methods: GV oocytes were isolated from ovaries whereas morulas were obtained by in vitro fertilization of ovulated oocytes. OCM scans of GVs and morulas provided morphological information that was correlated with their developmental potential tested as the ability to mature and react to fertilization (for GVs) or to achieve a blastocyst stage with well-differentiated embryonic cell lineages (for morulas). We also tested whether scanned oocytes/embryos differ in their developmental capabilities from their non-scanned counterparts.

Main results and the role of chance: We showed that OCM allows for a precise assessment of chromatin conformation in mouse GV oocytes (surrounded by cumulus cells or denuded) and for the selection of oocytes with so-called SN (surrounded nucleoli) chromatin conformation that have higher developmental potential. GVs scanned by OCM matured in vitro with the same speed and efficiency as non-scanned control oocytes and developed similar Ca^{2+} response to a fertilizing spermatozoon, indicating that OCM scanning did not affect them negatively. We also showed that OCM provides data that allows for a precise nuclei (i.e. cell) count in compacted mouse embryos and that the number of nuclei (cells) at the compacted morula stage correlates with the embryo's ability to form high-quality blastocysts. Morulas scanned by OCM developed to the blastocyst stage with similar efficiency as their non-scanned counterparts, although the differentiation of the primitive endoderm (PE) cells was slightly delayed. The number of PE cells in scanned embryos was lower at day 4.0 than in non-scanned embryos, but the difference disappeared at day 5.0, suggesting that the developmental potential of the embryos was not significantly disturbed by the OCM.

Limitations, reasons for caution: We tested OCM only on mouse embryos and in the case of other species, additional tests are required. Moreover, further experiments testing the potential effect of OCM on the post-implantation embryo development are necessary (and currently in progress).

Wider implications of the findings: Our data indicate that OCM is a non-invasive imaging technique and that it provides morphological information about mammalian oocytes and embryos inaccessible for standard bright-field microscopy. Therefore, it can be an interesting alternative for imaging techniques used currently in assisted reproduction protocols.

Trial registration number: n/a

O-311 Development of an Advanced Quality Control Bioassay for Assisted Reproductive Technologies

K. Sakurai[1], A. Tran[1], V. Tovar[1], R. Newman[1], N. Ciray[1]

[1]Fujifilm Irvine Scientific, Research and Development, Santa Ana, U.S.A.

Study question: Could embryos expressing GFP-tagged POU5F1, a transcription factor critical for embryonic development during preimplantation development, be used to detect adverse conditions resulting during ART practices?

Summary answer: The *Pou5f1-GFP* embryos detected suboptimal conditions as early as 48hours of exposure and subsequently after 96 hours.

What is known already: Growing concerns about safety of ART on human gametes and embryos have been raised by the observation of compromised embryo development and the outcome of the treatment during ART laboratory procedures performed under suboptimal conditions. Incorporating evaluations of gene expression essential for preimplantation development in an assay for screening materials and conditions could benefit risk assessment. Zygotic *Pou5f1* gene expression, essential for mouse development, starts around the 4-cell stage and later restricted to ICM. Mouse embryos expressing GFP under control of *Pou5f1* regulators formed a relevant functional assay for testing ART products prior to clinical implementation (Gilbert et al., 2016).

Study design, size, duration: *Pou5f1-GFP* transgenic mouse lines expressing GFP-tagged POU5F1 were generated to utilize nuclear localization of POU5F1 and to detect adverse culture conditions and epigenetic defect during preimplantation. *Pou5f1-GFP* expression were also used to visualize blastomere nuclei for cell counting in live cells. *Pou5f1-GFP* embryos were cultured for 96hrs under optimal or suboptimal oil overlay to observe POU5F1-GFP expression at different stages of mouse embryo development (from 2PN to expanded/hatching blastocyst).
Participants/materials, setting, methods: *Pou5f1-GFP* one-cell embryos (fresh or frozen) were cultured to blastocysts under uninterrupted conditions up to 96 hours in Continuous Single Culture Medium-Complete (CSCM-C, FUJIFILM Irvine Scientific) with control or suboptimal oil overlay (5, 7.5, or 10% adulterated oil) and observed daily. B6 one-cell embryos typically used in the standard mouse embryo assay (MEA) were cultured in parallel. Embryo development was evaluated at 48 hours (% ≥8-cell) and 96 hours (% Blastocyst) quantitatively and qualitatively, respectively.
Main results and the role of chance: Transgenic mice expressing *Pou5f1-GFP* are viable and fertile, and successful germline transmission and temporally and spatially regulated gene expression were confirmed. Zygotic *Pou5f1-GFP* gene expression started around the 4-cell stage and peaked after culturing for 72hrs, consistent with earlier reports. The nuclear localization of POU5F1-GFP in mouse embryos enabled a quantitative approach to the assay. The *Pou5f1-GFP* embryos cultured with 5, 7.5, and 10 % suboptimal oil overlays showed a noticeable delay in development (at 48hrs and 96hrs compare to the control and MEA groups). Fresh and frozen *Pou5f1-GFP* embryos performed similarly in detecting suboptimal conditions.
Limitations, reasons for caution: As observed with other mouse traits, embryo yields are correlated to harvesting efficiency.
Wider implications of the findings: *Pou5f1-GFP* embryos can be used in the one-cell mouse embryo assay to examine the effect of culture conditions during preimplantation development. With the heightened sensitivity, the functional impact of materials and procedures on overall embryo development including embryo health and defects can be adroitly evaluated in live cells.
Trial registration number: not applicable

O-312 Follicular fluid levels of IL-10 are associated with oocyte fertilization and early embryo development.

L. Hartigan[1], L. Glover[2], H. Groarke[2], L. O'Shea[3], M. Wingfield[4]

[1]Merrion Fertility Clinic and National Maternity Hospital- Dublin- Ireland, Merrion Fertility Clinic and National Maternity Hospital- Dublin- Ireland, Dublin, Ireland ; [2]Merrion Fertility Clinic, Merrion Fertility Clinic, Dublin, Ireland ; [3]University College Dublin, School of Agriculture and Food Science, Dublin, Ireland ; [4]Merrion Fertility Clinic and National Maternity Hospital, Merrion Fertility Clinic and National Maternity Hospital, Dublin, Ireland

Study question: Do follicular fluid cytokine profiles predict the developmental potential of an oocyte in ART?
Summary answer: Follicular fluid IL-10 levels were higher in follicles where oocytes failed to fertilize or develop to blastocyst than oocytes that developed to Day 5 blastocysts.
What is known already: Embryo quality is greatly influenced by the oocyte and follicular microenvironment from which it originates. Follicular fluid contains a range of factors that play important signaling roles, including steroid hormones, metabolites, growth factors and cytokines. Inflammatory cytokines mediate functional and structural changes associated with follicle growth and early oocyte maturation. In previous work, our group identified follicular fluid AMH and progesterone levels as predictors of oocyte and embryo quality and developmental capacity. In this study, we adopted a similar approach to further investigate follicular fluid cytokines and their association with oocyte development.
Study design, size, duration: This was a prospective study of women undergoing IVF/ICSI treatment in our fertility clinic.Women with diagnoses of PCOS or endometriosis were excluded (n=30).Follicular fluid (FF) was collected from the first follicle aspirated during oocyte retrieval.The corresponding oocyte was individually cultured to track its outcome.FF was assigned one of 3 groups: Group 1: oocyte failed to fertilise (n=14); Group 2:oocyte fertilized but failed to reach blastocyst (n=29);Group 3:oocyte developed into a Day 5 blastocyst (n=29).
Participants/materials, setting, methods: Study participants were similar with regard to age, BMI, parity, AMH levels, antral follicle count and number of oocytes collected. FF cytokine protein levels were assayed using a commercially available multiplex array (Cytokine 30-Plex Human Panel, ThermoFisherScientific) on the Luminex multiplex assay platform (Conway Institute, University College Dublin). Data were analyzed using GraphPad Prism; cytokine levels were compared using Kruskal–Wallis with Dunn's multiple comparison test and Bonferroni correction ($p<0.05$ considered significant).
Main results and the role of chance: FF levels of the inflammatory cytokines TNFa ($p=0.037$), IL-6 ($p=0.031$), IL-5 ($p=0.021$) and IL-10 ($p=0.002$) were higher in follicles where the oocyte failed to develop to blastocyst (Group 1 and 2) than those where the oocyte developed to Day 5 blastocyst (Group 3). Following Bonferroni correction to control for multiplex analysis (18 cytokines), only differences in IL-10 levels retained statistical significance ($P<0.05$). Area-under-the-curve (AUC) of IL-10 as a predictor of oocyte development to a Day 5 blastocyst in this patient cohort was found to be 0.73 (95% CI 0.618-0.85; $p<0.001$). Nineteen FF samples had IL-10 levels <9pg/ml, 14 of which were from oocytes that successfully developed to blastocyst stage. IL-10 threshold levels <9pg/ml (sensitivity 48%, specificity 88%, prevalence rate 40% in this cohort) correspond to a positive predictive value (PPV) of 73.4% with 26.6% chance of a false positive test result, a negative predictive value (NPV) of 72.1% with 27.9% chance of a false negative result and an odds ratio (OR) of 7.093 (95% CI 1.57-4.32; $p<0.001$).
Limitations, reasons for caution: The study cohort was limited in size, and clinical pregnancy rates and live birth outcomes are not yet available.
Wider implications of the findings: A robust, non-invasive biomarker of oocyte competence would have a major impact on the prediction of ART success, including likely success of oocyte vitrification for an individual woman. This study shows that FF IL-10 may help predict the ability of an oocyte to fertilise and to reach blastocyst stage.
Trial registration number: not applicable

O-313 Evaluation of fragmented embryos – what is the best way to predict its implantation potential?

S. Lahav-Baratz[1], I. Blais[1], M. Koifman[1], M. Dirnfeld[1,2]

[1]Division of Reproductive Endocrinology and IVF Lady Davis Carmel Medical Center- Haifa- Israel, Department of OB/GYN, Haifa, Israel ; [2]Technion – Israel Institute of Technology- Haifa- Israel, Ruth and Bruch Rappaport Faculty of Medicine-, Haifa, Israel

Study question: Can we predict the potential of fragmented embryos to implant, by using the general and our "in-house" model for embryo selection in a time-lapse incubator?
Summary answer: The algorithms developed for embryos evaluation by morphokinetics, significantly increase the accuracy of a single embryo selection in our laboratory, including embryos with fragmentation.
What is known already: Fragmentation in IVF embryos has been a marker for embryo deselection. Extensive fragmentation may be associated with reduced blastocyst formation and with increased incidence of chromosomal abnormalities. However, some of those embryos may yield pregnancy and delivery of a healthy child. The cut-off of fragmentation rate which still enables achievement of pregnancy is not defined clearly. Using models, based on time-lapse technology, (general models, and lab-specific), may contribute to the selection of embryos with fragments.
Study design, size, duration: In this retrospective study, 4210 embryos which were incubated to the blastocyst stage in the EmbryoScope between 2013 and 2019 were analyzed. Three hundred seventy nine embryos, which had more than 5% fragmentation, were included in the study. Embryos were selected for transfer or freezing versus de-selection, based primarily on the general model for day 5 provided by Vitrolife and then re-examined by our lab-specific algorithms.
Participants/materials, setting, methods: Embryo fragmentations were measured using EmbryoScope tools by a senior embryologist. Percentage of fragmentation was documented twice for every embryo: at the first cell division and in their maximum volume. The patterns of fragments accumulation during embryos development were followed. Data was analyzed using statistical methods for fragmentation with regards to patient's

age, insemination method, blastocyst formation, embryos transfer or freezing, known implantation data (KID) of the embryos, clinical pregnancy and live birth rates.

Main results and the role of chance: Up to 32% fragmentation the specific model score and fragmentation percent was found to be an independent variables. Embryos with up to 20 ± 12% fragmentation still had high score according to the first division time and usually transferred or cryopreserved. Significant difference in the fragmentation rate was found between embryos which reached the blastocyst stage and embryos which failed: 15± 11% and 36± 20% respectively ($p<0.0001$).

Fragmentation appeared usually at the first division and worsening was observed during the 3th or 4th divisions.

While no difference was found in fragmentation between embryos of standard IVF or ICSI, age had a significant negative effect on fragmentation ($p< 0.0001$). In this population of fragmented embryos, 33 of 379 embryos resulted in a delivery of a healthy child, 104 were negative and for 242, information is not available mainly due to freezing without thawing.

In 92.8% of the patients more than 1 embryo was with fragments.

In 64% of the patients fragmented embryos found in more than one cycle. All positive KID (known implantation data) had maximum of 30% fragmentation except one embryo with 43% fragmentation that was implanted and a healthy baby was born.

Limitations, reasons for caution: Although fragmentation was analyzed meticulously by experienced embryologists, measurement may be less accurate during late divisions. Prospective randomized studies are required to confirm these findings.

Wider implications of the findings: We suggest that fragmented embryos should be examined primarily according to their division timing. A specific model can contribute to a better selection. Although rare, even embryos with as much as 40% fragmentations and appropriate division timing may develop into a blastocyst which implant and results in a live birth.

Trial registration number: 0010-19-CMC

O-314 Assessment of the predictive value of mitochondrial DNA as a biomarker of embryo viability

M. Galain[2], M. Fabbro[2], S. Menazzi[2], R. Anria[1], J. Ponte[2], F. Nodar[3], S. Papier[1], C. Fernandez[2]

[1]Cegyr, Clinical, Buenos Aires, Argentina ;
[2]Cegyr, Genetics, Buenos Aires, Argentina ;
[3]Cegyr, Embryology, Buenos Aires, Argentina

Study question: Is the mitochondrial DNA (mtDNA) content related to female age, embryo morphology, ploidy, blastocyst implantation rate, pregnancy rate, and live birth rate?

Summary answer: There was a significant difference in mtDNA levels according to embryo ploidy and maternal age, but no difference regarding implantation, pregnancy and live birth outcomes.

What is known already: The mtDNA content of trophectoderm cells is related to the energy supply of the blastocyst, which could affect its implantation ability. It has been proposed that the quantity of mtDNA in trophectoderm (TE) biopsy cells can serve as a new biomarker of embryo viability. This information could help to maximize the success rate of single embryo transfers (SET) in ART by selecting embryos with the highest potential to achieve a live birth. However, the application of a score based on mtDNA is controversial and highly discussed.

Study design, size, duration: A cohort of 1528 embryos from 349 couples undergoing preimplantation genetic testing for aneuploidy between 2016 and 2019 was retrospectively included. Mosaic embryos (between 20%-80%) were excluded from this analysis. Blastocyst quality was established according to Gardner grading system and grouped in: high (3-6AA and 4-6AB), mid (any BB, 1-3AB and 1-2AA) and low (any AC, CA, BC, CB or CC) quality.

Participants/materials, setting, methods: The embryo ploidy and the mtDNA content were determined using NGS and bioinformatics algorithms. The mtDNA value was mathematically corrected according to embryo aneuploidy and gender. βhCG > 15 IU was considered to be positive for biochemical pregnancy. Ongoing pregnancy was defined as having a visible gestational sac with a fetal heartbeat at 8 weeks after SET. For the statistical analysis T-test, Kruskal-Wallis and Pearson correlation were applied. A p-value< 0.05 was considered statistically significant.

Main results and the role of chance: The average maternal age was 33.6 (21-46 years). From the 1528 blastocysts assessed, 624 were euploid (40,8%), 377 aneuploid (24,7%) and 527 mosaic embryos (34,5%). mtDNA was significantly different between euploid and aneuploid embryos ($p=0.0000038$) and between embryos from younger (≤37 years, n=592) and older women (>38 years, n=409) ($p=0.0002$). A positive correlation of mtDNA with maternal age was observed, but only in the group of older women the aneuploid blastocysts contained higher mtDNA vs. euploid embryos ($p=0.003$). There was no significant difference in mtDNA between high, mid and low quality euploid embryos and between the different grades of TE (A, B and C). However, a difference was found between aneuploid and euploid embryos in the mid and low quality categories. Regarding the pregnancy outcome, 264 euploid embryos were transferred, resulting in 112 ongoing pregnancies (42%) and a 61% live birth rate (n=69). There was no difference in mtDNA content between the positive βhCG vs negative βhCG, the ongoing pregnancies vs the non-pregnant group and the live birth vs abortions.

Limitations, reasons for caution: The study is limited by its retrospective nature. A higher sample size or a prospective randomized design in future studies would corroborate the current findings. Caution should be taken while comparing these results to other reported studies since the same quantification methodology is not always used.

Wider implications of the findings: This study contributes evidence that mtDNA quantification in euploid embryos has no clinical impact on pregnancy outcome. mtDNA score adds no value when selecting which embryo to transfer. It is unlikely that mtDNA quantification alone will be able to solve the complex scenery of embryo reproductive competence.

P-001 Effect of sperm selection method by cumulus oophorus complexes and conventional sperm preparation method on sperm quality and DNA fragmentation for assisted reproduction techonology

W. Naknam[1], L. Salang[1], J.S. Sothornwit-[1], S. Amnatbuddee[1], K. Seejorn[1], T. Pongsritasana[1], S. Sookkasame[1]

[1]Department of obstetrics and gynecology Khon Khane university, obstetrics and gynecology, Khon Khane, Thailand

Study question: Are the effectiveness of sperm quality and DNA fragmentation different between sperm selection method by cumulus oophorus complexes and conventional sperm preparation method ?
Summary answer: Spermatozoa selected using COCs were likely to be effective in terms of sperm quality and DNA fragmentation.
What is known already: Spermatozoa are commonly selected for intracytoplasmic sperm injection (ICSI) visually under an optical magnification microscope based on motility and morphology. However, this method does not reveal the genomic integrity of the spermatozoa.Cumulus oophorus complexes (COCs) encircle the oocyte and contains cumulus cells and extracellular matrix (ECM). ECM is a main component in hyaluronic acid (HA), which is produced by COCs after an LH surge.The head of mature spermatozoa have a hyaluronan specific receptor that bind with hyaluronan. During natural fertilization, only one healthy spermatozoon can passthrough the COCs and zona pellucida and penetrate into the ooplasm for fertilization.
Study design, size, duration: This was a prospective experimental study. Thirty normal semen samples under the World Health Organization (WHO)'s 2010 eligibility criteria were collected and processed using conventional sperm preparation methods from June to October 2018.
Participants/materials, setting, methods: The prepared sperm were divided into two groups. Spermatozoa in the study group were selected based on their ability to penetrate a layer of COCs via COCs selected model. In the control group, spermatozoa were kept in culture medium under similar conditions. The selected-sperm were evaluated based on sperm quality and DNA fragmentation.
Main results and the role of chance:
Thirty normal semen samples were recruited. Spermatozoa that were able to passthrough the COCs had significantly higher sperm motility parameters than the control group (curvilinear velocity [VCL; 143.5 vs 122.2; $P < 0.01$], average path velocity [VAP; 83.6 vs 69.3; $P < 0.01$], straight-line velocity [VSL; 67.95 vs 60.45; $P < 0.01$]). The percentage of normal spermatozoa morphology in the COCs group was significantly higher than in the control group (21.70 % vs 18.76%). In addition, there was significantly less DNA fragmentation in the COCs group than in the control group (18.83 vs 10.83).
Limitations, reasons for caution: The limitation of this study, we did not evaluate other sperm functions, such as sperm capacitation, acrosome reaction, and spermatozoa-zona binding. However, these processes are unnecessary in ICSI because the ICSI usually bypass these processes.
Wider implications of the findings: The spermatozoa that were able to passthough COCs had higher sperm motility parameters, higher rates of normal morphology, and lower DNA fragmentation. It may be advantageous to implement this process during ICSI.This study showed that implementing a sperm selection method using an COCs model before ICSI may improve fertility outcomes.
Trial registration number: HE 611250

P-002 Sperm retrieval surgery in male infertility cancer survivors can result in live births.

H. Hibi[1], S. Miho[1], S. Megumi[2], F. Noritaka[2], A. Yoshimasa[2]

[1]Kyoritsu General Hospital, Urology, Nagoya, Japan ; 2Asada Ladies Clinic, Gyenecology, Nagoya, Japan

Study question: To determine the viability of sperm retrieval surgery in male infertility cancer survivors to restore the possibility of biological fatherhood.
Summary answer: Successful sperm retrieval was achieved in 40% cancer survivors, and 24% survivors became a biological fatherhood.
What is known already: Sperm cryopreservation can be offered to men with cancer prior to undergoing gonadotoxic treatments such as chemotherapy. However, cryopreservation of sperm prior to treatments is rarely done, whilst after treatment, it is severely compromised due to azoospermia or ejaculatory dysfunction.
Study design, size, duration: To determine the viability of sperm retrieval surgery in male infertility cancer survivors to restore the possibility of biological fatherhood. Data from 1,525 male infertility patients who consulted in our clinic between 2009 and 2018 were analysed. From this database, a retrospective analysis was done to identify patients with a history of past cancer treatment and who underwent surgical sperm retrieval due to azoospermia or ejaculatory dysfunction.
Participants/materials, setting, methods: Twenty-five patients were diagnosed as having azoospermia or ejaculatory dysfunction after cancer treatments. Type of cancers were testicular cancer (8 cases), hematologic cancer (6), colorectal cancer (3), osteosarcoma (2), kidney cancer (2), extragonadal cancer (2), gallbladder cancer (1), and rhabdomyosarcoma (1). Sperm retrieval surgery was performed using vasal sperm aspiration in 4 cases, epididymal sperm aspiration (2), testicular microdissection (18), and onco-testicular sperm extraction (1).
Retrieved sperm were cryopreserved for future ICSI treatment in our center.
Main results and the role of chance: Motile sperm were recovered in 10 cases (10/25; 40%), whereas immotile sperm in 2. No sperm was obtained in 13 (52%) cases. Six healthy deliveries were achieved with intracytoplasmic sperm injection following use of motile sperm in each of six cases (24%).
Limitations, reasons for caution: The size of our sample was limited due to the rarity of cancer cases in our clinic.
Wider implications of the findings: Successful sperm retrieval was achieved in 40% cancer survivors, and 24% survivors became a biological fatherhood. On the other hand, some patients abandoned infertility treatment due to the costs associate with sperm retrieval surgery and fertility treatment.
Trial registration number: Not applicable

P-003 Quantitative analysis of the sHLA-G protein in seminal plasma

A. Schallmoser[1], **N. Sänger**[1]

[1]*University Hospital Bonn, Department of reproductive medicine, Bonn, Germany*

Study question: To examine the paternal levels of the immunoregulatory sHLA-G protein in seminal plasma during IVF treatment and to investigate possible correlations with age and pregnancy outcome of the female partner.
Summary answer: High sHLA-G levels in seminal plasma of the male partner appear not to be required for pregnancy
What is known already: Recent studies revealed that maternal and embryonic contributions impact on HLA-G protein expression and might contribute to pregnancy success or failure.

Also in seminal fluid, different levels of sHLA-G have been detected.
Study design, size, duration: Retrospective study. 106 samples from male donors were obtained between March and October 2018.
Participants/materials, setting, methods: Analysis of 106 paternal samples during IVF treatment. Semen was separated from seminal plasma using a density gradient consisting of a 90% lower layer and a 45% upper layer. Enzyme linked immunosorbent assay (ELISA), SDS-PAGE and Western blot were performed to analyze and confirm the sHLA-G values in paternal seminal plasma and TESE samples.
Main results and the role of chance: We observed a significant negative correlation of male age with total sHLA-G amount (P 0.023, R −0.221) in seminal plasma. Testicular biopsy samples were analyzed and tested positively with sHLA-G ELISA. No significant difference of sHLA-G levels in seminal plasma and pregnancy outcome of the female partner was detected. We observed a statistically significant difference between female age [P = 0.010, Mann-Whitney U test] and pregnancy outcome. As expected, more ideal embryos and less non-ideal embryos were transferred in the pregnancy group. In univariate regression only female age significantly predicted pregnancy outcome (OR 0.896, 95% CI 0.81-0.99, P = 0.026), while male age showed a trend to significance (P = 0.075). Semen quality and sHLA-G were not significant. In multivariate logistic regression including all parameters, a trend for an independent predictive value of female age was still detected (OR 0.911, 95% CI 0.81-1.03, P = 0.123).
Limitations, reasons for caution: Study was retrospective and not randomized with a small sample size.
Wider implications of the findings: We observed a significant correlation of male age with total sHLAG amount. Our analysis showed a wide spread of sHLA-G protein levels in seminal plasma samples of male donors, supporting reports of previous studies. The determination of the origins of HLA-G in seminal fluid require further detailed studies.
Trial registration number: non applicable

P-004 Biomarkers of stress and male fertility

A. Steiner[1], **T. Spitzer**[2], **F. Sun**[3], **R.M. Coward**[4], **K. Hansen**[5], **S. Krawetz**[6], **N. Santoro**[7], **J. Trussell, C**[8]

[6]*Wayne State University School of Medicine, Department of Obstetrics and Gynecology, Detroit- MI, U.S.A. ;*
[7]*University of Colorado School of Medicine, Obstetrics and Gynecology, Aurora-Colorado, U.S.A. ;*
[8]*Upstate University Hospital, Urology, Syracuse- NY, U.S.A.*

Study question: Does stress, as measured by salivary α-amylase and cortisol, negatively impact male fertility, as measured by semen parameters and couple pregnancy and live birth rates?
Summary answer: Biomarkers of stress in males are not negatively associated with semen parameters or pregnancy and live-birth rates. Salivary cortisol is positively correlated with sperm count.
What is known already: Stress induces elevation in salivary cortisol and α-amylase. Prior studies have shown that women with high levels of salivary α-amylase have reduced fertility compared to women with normal values. A prior study of males suggested that higher levels of stress, as measured by a four-item questionnaire, was associated with poorer sperm quality. The impact of stress, as measured by salivary biomarkers, on male fertility is not known.
Study design, size, duration: 94 infertile men with sperm concentration ≤15M/ml, motility ≤ 40%, or normal morphology ≤4% enrolled in the Males, Antioxidants, and Infertility (MOXI) Trial, were included in this prospective cohort study. Couples were followed for up to 6 months. Couples attempted to conceive naturally during the first 3 months and with clomiphene citrate with intrauterine insemination in months 4 through 6 if not pregnant.
Participants/materials, setting, methods: Men provided a first morning salivary sample and semen sample at baseline. Salivary samples were analyzed for α-amylase and cortisol. Semen parameters and DNA fragmentation were measured in the semen samples. The associations between salivary α-amylase and cortisol and semen parameters or DNA fragmentation were assessed using linear regression models adjusting for male age. Salivary levels were dichotomized at the 80th percentile. Pregnancy and live birth rates in couples were compared using chi square testing.
Main results and the role of chance: Salivary levels of α-amylase were not associated with semen parameters or DNA fragmentation. Salivary levels of cortisol were not associated with DNA fragmentation or normal sperm morphology. For every 1 unit increase in salivary cortisol the total sperm count increased by 18.1 million (95% CI: 4.5-31.73), and the total motile sperm count increased by 12.6 million (95% CI: 4.5-20.6). Pregnancy rates did not differ for partners of males in the highest quintile of α-amylase (26% and 27%, p= 0.92) or cortisol (44% and 24%, p=0.11) compared to partners of males with lower values. Live birth rates did not significantly differ for partners of males in the highest quintile of α-amylase (21% and 20%, p=1.0) or cortisol (38% and 17%, p=0.07) compared to partners of males with lower values.
Limitations, reasons for caution: Men enrolled in the trial were infertile with abnormal semen parameters. These results are not generalizable to men without infertility.
Wider implications of the findings: Among infertile males, stress, as measured by salivary α-amylase and cortisol, does not appear to negatively impact male fertility, and higher levels of cortisol may increase sperm count. Future studies should investigate whether stress impacts semen parameters among men in the general population.
Trial registration number: Clinical Trials.gov NCT02421887

P-005 Alternations of sperm protein profiles to elucidate the mechanism of impaired spermatogenesis by cancer chemotherapy

T. Takeshima[1], **K. Shinnosuke**[1], **Y. Yasushi**[1]

[1]*Yokohama City University Medical enter, Department of Urology- Reproduction Center, Yokohama City- Kanagwa, Japan*

Study question: This study aims to analyze alterations in proteomic profiles and validate selected protein biomarkers of spermatozoa in men with history of undergoing cancer chemotherapy.
Summary answer: Cancer-associated protein was identified by liquid chromatography-mass spectrometer analysis and database searching. And the protein was validated by Western-blotting.
What is known already: As advanced cancer treatments have improved the prognosis of cancer survivors, these treatments such as chemotherapy have been known to cause harmful effect on fertile capacity. A few studies reported the alternation in proteins of spermatozoa between cancer patients and healthy donor and some proteins with different expression levels were identified between two groups.
Study design, size, duration: This research is a cross-sectional cell-line research of control versus treatment. A group of patients with a history of anticancer drug administration in cancer diagnosis was assigned as "cancer group"(n=3), and a fertile donor group was assigned as "control group"(n=3). Written informed consent was obtained from all patients and this study design was approved by institutional review board of Yokohama City University Medical Center.

Participants/materials, setting, methods: The original diseases of cancer group were non-Hodgkin malignant lymphoma(n=2) and soft tissue tumor(n=1). Measuring the total sperm count by CASA, they were adjusted to 6 million in all specimens, and protein concentration was adjusted by BCA assay. After trypsin digestion and desalting, the expressed proteins in spermatozoa were analyzed by LQ-MS/MS and database searching was performed in two groups. Validation was performed for the proteins with different expression levels by Western-blotting.
Main results and the role of chance: A total of 1,152 proteins and 5,268 peptides were identified by global proteomics in both groups. Sorted by max fold change of expressions (>5 folds) and ANOVA ($p<0.01$), 29 proteins were identified. Of these identified proteins, we focused on one protein, which is cancer-associated protein highly expressed in digestive tract and urinary tract. In sperm of patients with cancer, this protein was overexpressed 54.8-folds more than that of fertile donor. This protein co-works with other protein of T-cell proliferation factor. Regimens of cancer chemotherapy patients in cancer group received were ABVD and IFM, ADM, and VCM therapy, respectively.By the Western-blotting, expression of this protein was validated.
Limitations, reasons for caution: Limitations of this research was inability to compare the sperm before and after the administration of cancer chemotherapy, because spermatozoa were all cryopreserved for fertility preservation before treatment.
Wider implications of the findings: It was speculated that T cell proliferation was induced by interaction between these proteins after induction of cancer chemotherapy. Functional analysis of these proteins would provide clue to the mechanisms of impaired spermatogenesis after cancer chemotherapy.
Trial registration number: not applicable

P-006 Outcomes of Microsurgical Varicocelectomy in Men with Severe Oligospermia

F. Tenorio Lira Neto[1], A.D.F. Cavalcanti Filho[1], M.M.F. Santana[1], T.D. Silva[1], M.A.S. Freire[1], E.D.P. Miranda[2]

[1]Instituto de Medicina Integral Prof. Fernando Figueira, Department of Urology, Recife, Brazil ;
[2]Universidade Federal do Ceará, Departmen of Urology, Fortaleza, Brazil

Study question: Is microsurgical varicocelectomy useful in men with severe oligospermia?
Summary answer: Microsurgical varicocelectomy provides significant improvements in semen analysis parameters of men with severe oligospermia, allowing the couples to choose less invasive treatments.
What is known already: According to the literature, men with severe oligospermia (sperm concentration < 5 million sperm/mL) have a lower chance of semen analysis parameters (SA) improvement after microsurgical varicocelectomy (MV) when compared to men with mild or moderate oligospermia. However, recently, some authors have shown that MV can improve the SA parameters in some severe oligospermic men, potentially allowing for less invasive and costly assisted reproductive techniques.
Study design, size, duration: This is a retrospective cohort study in 38 consecutive men with severe oligospermia and clinically palpable varicocele who underwent MV by two male fertility specialists between June 2016 and September 2019.
Participants/materials, setting, methods: We included those men and who had at least one postoperative SA, and excluded those who were azoospermic. Baseline demographic and clinical characteristics, intraoperative findings, pre- and postoperative SA parameters, and SA improvement were evaluated. Semen analysis Improvement was defined as an increase of more than 10% in total progressive motile sperm count (TMSC).
Main results and the role of chance: Thirty-eight participants were included in the study. The mean age of the participants was 34 (±9) years, and bilateral varicoceles were present in 70% of the men. Regarding preoperative SA, the median sperm concentration was 1.4 (±3.1) x 10^6/mL, the median progressivel motility was 10 (±25) %, and the median TMSC was 0.2 (± 1.3) x 10^6. Intraoperative findings were, mean number of ligated veins of 11.9 on the left side and 9.3 on the right side; mean diameter of the largest vein of 3.5 mm on the left side and 2.6 mm on the right side. After a median follow-up of 120 (±60) days, 79% of the participants improved their TMSC, with a median improvement of 1.3 (±11.2) x 10^6. Furthermore, 24% of the participants achieved a TMSC greater than 5 million, giving them the possibility of intrauterine insemination, and 19% achieved a TMSC greater than 20 million.
Limitations, reasons for caution: The small number of participants and limited follow-up are the main limitations of this study
Wider implications of the findings: Although advanced techniques of assisted reproduction are commonly offered as a first line therapy for men with severe oligospermia caused by varicocele, this study demonstrates that microsurgical varicocelectomy can improve the SA parameters of such men, allowing these couples to choose less invasive treatments.
Trial registration number: not applicable

P-007 Effect of a high fat diet on the spermatogenesis in an obese mouse model

L. Ramos[1], D. Komninos[2], G. Van der Heijden[1], T. Van Herwaarden[3], A. Kiliaan[4], I. Arnoldussen[4]

[1]Radboudumc, Obst. & Gynaecology. div. Reproductive medicine intern 791, NIJMEGEN, The Netherlands ;
[2]Radboud University, Faculty of Biology, Nijmegen, The Netherlands ;
[3]Radboudumc, Medical Laboratory, Nijmegen, The Netherlands ; 4Radboudumc, Anatomy, Nijmegen, The Netherlands

Study question: Which changes in spermatogenesis are found in an obese/overweight Ldlr-/-.Leiden mouse model by using a high fat diet (HFD) ?
Summary answer: This study demonstrates that diet induced obesity leads to impaired testicular structure, probably due to the disturbance of the hypothalamic-pituitary-gonadal (HPG) axis.
What is known already: Obesity can disturb one or more of these regulatory factors, leading to impaired spermatogenesis and subsequently impaired fertility. To understand the effects of obesity on fertility at a cellular level, this study analysed the testes of low-density lipoprotein receptor knock-out (Ldlr-/-.Leiden) mice, which received a high fat diet and as such developed the typical symptoms related to obesity.
Study design, size, duration: Knock-out mice with a normal diet (chow diet, n=15- control group) or a high fat diet (HFD, n=15) were used. Hormonal blood levels, bodyweight of the animals at 36 weeks of age and analysis of adipose tissue (percentage of fat deposits) were measured. Differential diet started at 3 weeks of age until week 36 that the mice were sacrificed. Both testis (one fixed in Boiun and one snap frozen) were used for further analysis.
Participants/materials, setting, methods: For histological evaluation, Sertoli cells, spermatocytes and spermatids were counted, and morphological analyses of the testes were performed after haematoxylin-eosin stain. For analysis of sperm cell quality, a TUNEL (terminal deoxynucleotidyl transferase dUTP nick end labelling) staining was performed on testes slices to quantify the apoptotic cells. In addition, a chemical staining with chromomycin A3 (CMA3) was performed on spermatozoa obtained from the epididymis to examine the chromatin compaction of the sperm cell.
Main results and the role of chance: At 36-weeks of age, the control group mean weight was 37.82 ± 1.23 grams while the HFD fed mice was 49.56 ± 0.90 grams. The HFD fed mice had significantly more mesenteric and inguinal fat compared to the mice on a control diet (($p<0.001$). Plasma measurements of cholesterol, triglycerides, insulin, leptin, and testosteron were al significantly higher in HFD fed mice. No significant differences in the relative and absolute number of seminiferous tubules in the testis slides between both groups was observed. But, the HFD fed mice had a significantly increased number of loosely arranged cells in the seminiferous tubules, which a lower spermatids:spermatocytes ratio. The morphology of the seminiferous tubules in the testes was aberrant and the spermatogenic cycle of the seminiferous epithelium was disturbed in the testes of the HFD mice.

No significant increase of TUNEL-positive cells were observed between groups. CMA3 measurements (chromatin condensation) did not differ between groups (HFD mice= 3.5% ± 2.0; control=(2.4% ± 0.89) but it was increased compared to the wild type C57BL/6 mice (aprox.1% CMA3-positive cells).
Limitations, reasons for caution: In this study only mice with a LDL-receptor mutation were used. Our findings can be partly related to this mutation effect in the cells next to dietary feeding. The addition of a wild type mice with a normal of HFD diet will help to evaluate the effect of fat consumption.

Wider implications of the findings: These results are a substantial addition to the emerging evidence of the negative impact of obesity on male fertility, which is of great societal impact and will help with counselling and treatment of infertile couples.
Trial registration number: Not applicable

P-008 Evaluation of a fully automated semen quality analyzer (LensHooke™ X1) for home-based monitoring

A. Agarwal[1], M.K. Panner Selvam[1], C.T. Hsu[2]

[1]Cleveland Clinic, American Center for Reproductive Medicine, Cleveland, U.S.A. ; [2]The Taiwanese Association of Andrology, Male Infertility, Taipei City, Taiwan R.O.C.

Study question: Can LensHooke™ X1 serve as a home-based semen quality monitoring (SQM) device and offer accurate test results?
Summary answer: LensHooke™ X1 semen quality analyzer offers not only a user-friendly experience for at home use, but it also provides accurate and reproducible results.
What is known already: At-home semen analysis is a choice for men who are reluctant to visit the diagnostic laboratory for semen testing. Although home-based semen quality analyzers (HBSQA) are available in the market, the information regarding post-surgical SQM using HBSQA is not available in the literature. Most HBSQA tests for only one or a few parameters at a time and their results cannot replace laboratory analysis of semen specimen. LensHooke™ X1 semen quality analyzer, a fully automated portable device, measures more than 3 semen parameters and provides real-time results for user, making it a good candidate for semen quality monitoring.
Study design, size, duration:
(1) Accuracy evaluation: 20 participants performed sperm concentration and motility analysis using X1.
(2) Reproducibility, precision and usability evaluation: To simulate at home SQM, 45 participants (28 Male, 17 Female) measured the concentration of latex beads using X1 at home device. Tests were performed once a week for a period of 5 months (20 readings). Following the completion of the trial, 45 questionnaires were filled out to evaluate user experience.
Participants/materials, setting, methods:
(1) Semen analysis was conducted on 3 seminal aliquots from each leftover specimens. Sperm concentration and total motility were initially assessed by medical technologist using Makler™ counting chamber. Participants with no experience in lab work (n=10) and trained-lab professionals (n=10) subsequently performed semen analysis on these samples using X1 analyzer.
(2) To evaluate user-experience of X1 device, we recruited 45 participants of different age and educational background.
Main results and the role of chance:
(1) For the evaluation of accuracy in semen analysis, the results of semen testing by either the participants with no experience in lab work (n=10) or trained-professionals (n=10) presented high degree of accuracy in concentration (90 % vs 93 %) and total motility (90 % vs 90 %) compared to reference value. There were no significant differences between concentration and motility results between the two groups (p = 0.84; p = 0.94). This suggests that users can operate X1 and obtain accurate results without hands-on experience or additional training.
(2) Results from 45 participants showed a very high reproducibility (>98.6 %) for the measurement of latex beads concentration. Moreover, the questionnaire shows 96% (±5.73%, 95% CL) positive feedback on the overall impression of X1 and up to 98% (±4.09%, 95% CL) satisfaction rate with an average score of 3.32 out of 4 points. The current data indicates that LensHooke™ X1 is an accurate, reproducible and user-friendly device.
Limitations, reasons for caution: Use of latex beads instead of semen samples to evaluate the reproducibility and usability of LensHooke™ X1 may not mimic the results of a semen sample.
Wider implications of the findings: LensHooke™ X1 is an easy-to-use SQM device which appears to be well suited for long term monitoring of semen quality after reproductive surgery as well as for short term SQM. Future studies to evaluate the performance of LensHooke™ X1 for post-medical or surgical intervention specimens will be useful.
Trial registration number: CS17027

P-009 Semen exosomes upregulated trophocytes migration and invasion and its effects on trophocytes angiogenesis via the Notch1/NF-κB signaling pathway

Z. Xiao[1], P. Jiali[1]

[1]Wuhan University, Renmin Hospital, Wuhan, China

Study question: Does semen exosomes (Exos) affect trophocytes (Tros) biological behaviors and angiogenesis? And how does it work?
Summary answer: Semen Exos could promote Tros migration, invasion and angiogenesis via the Notch1/NF-κB signaling pathway, have no significantly effect on cell cycle and apoptosis.
What is known already: At present, researches on Tros mainly focus on the maternal, including hormone level, inflammatory factors, growth factors, etc. The study on the regulation of Tros biological behavior by semen may provide a new direction for elucidating maternal-fetal interface modeling.
Studies have shown that intrauterine infusion of SP can improve the implantation rate of IVF-ET. Semen Exos mainly exists in SP, it's considered to be an important medium for micro-environmental regulation of reproductive function. RNA-seq studies have shown semen Exos can regulate the expression of genes in endometrium. However, the effect of semen Exos on Tros has not been studied.
Study design, size, duration: 40 cases of normal quality semen (according to the WHO 5th edition standards) were collected to extract semen Exos at Renmin Hospital of Wuhan University. To investigate whether semen has an effect on Notch-1 expression in villus, a total of 12 villus (6 cases of pregnancy by IVF-ET as test group and 6 cases of pregnancy in natural way as the control) were collected for immunohistochemical staining.
Participants/materials, setting, methods: Exos were extracted and identified from 40 volunteers and Notch-1 were measured in villus from 6 patients conceived through IVF-ET and 6 patients conceived naturally. The human trophoblast cell line (HTR-8/SVneo cells) were co-cultured with 10ug/ml semen Exos for 48h. Then CCK-8 assay, transwell assay, flow cytometry, and angiogenesis assay were performed to determine cell proliferation, migration, invasion, apoptosis, cell cycle and tube formation. Q-PCR and western-blot analysis were performed to determine RNA and proteins.
Main results and the role of chance: Exos were successfully extracted from semen and identified by transmission electron microscopy, NTA analysis and western-blot analysis. After co-cultured with semen Exos, HTR-8/SVneo cells migration, invasion and tube formation were increased significantly ($P<0.05$, n=3). And the expression of HTR-8/SVneo cells biological function-related mRNA and protein, like Notch-1, NF-κB-VEGF, VEGFR-1, VEGFR-2 were significantly increased ($P<0.05$, N=3). While there were no significant changes in cell cycle and apoptosis ($P>0.05$, N=3). Mechanistic studies showed Notch-1 signaling pathway played an important role. The expression of Notch-1 in villus from patients conceived by IVF-ET was significantly lower than the control group. Furthermore, the semen Exos promoting effects could be significantly attenuated by Notch-1 inhibitor.
Limitations, reasons for caution: It remains unclear that which substance in semen Exos is the upstream signal of notch-1 signaling pathway.
Wider implications of the findings: The study of roles of semen Exos of maternal-fetal interface modifying is of great significance not only in exploring the origin of reproduction, but also in preventing and controlling pathological pregnancy, improving IVF-ET pregnancy outcome, developing new contraceptives, and improving the reproductive rate of rare animals.
Trial registration number: not applicable

P-010 Easy, efficient and safe sperm separation for IUI and IVF

A. Arav[1], Y. Barak[2], A. Komsky-Elbaz[3], D. Reches[4], D. Kalo[4], Z. Roth[4], Y. Natan[5], P. Patrizio[6]

[1]Fertilesafe Ltd., R&D, Nes-Ziona, Israel ; [2]Dr. Yona Barak Laboratory, Laboratory, Rosh Haayin Il, Israel ; [3]Department of Animal Science- Faculty of Agricultural- Food and Environmental Quality Sciences- the Hebrew University of Jerusalem-, Animal Science, Rechovot, Israel ; [4]Department of Animal Science- Faculty of Agricultural- Food and Environmental Quality Sciences- the Hebrew University of Jerusalem-, Animal Science, Rechovot, Israel ; [5]Fertilesafe, Animal Science, , Israel ; [6]Obstetrics- Gynecology & Reproductive Sciences- Yale Fertility Center & Fertility Preservation, In Vitro Fertilization, New Haven, U.S.A.

Study question: Is it possible to do easy and simplified sperm separation procedure using a new device named E. Sep.
Summary answer: E.Sep is an efficient and easy to use device allowing sperm separation from semen for IUI/IVF directly into a syringe by thermotaxis through micropores.
What is known already: Conventional separation of sperm includes various technologies such as two-step washing technique, density gradient centrifugation (DGC) and swim up. These techniques expose sperm to several noxious conditions such as: reactive oxygen species (ROS), contaminants present in the media or freezing solutions, air, pipetting, centrifugation steps, temperature shifts.
Study design, size, duration: Experimental research carried out in two different centers using animal and human sperm samples.
Participants/materials, setting, methods: Frozen/thawed bull semen (n=5) were mixed and processed (3 replicates) with 'swim-up' using three different techniques: regular swim-up (RSU); E.Sep in horizontal and E. Sep in vertical position. Spermatozoon mitochondrial membrane potential ($\Delta\Psi m$), ROS levels and acrosome membrane integrity were evaluated by flow cytometry, using specific kits (IMV Technologies). In humans, 3 fresh ejaculates were pooled and processed as 2 separated samples. Sperm concentration, motility and morphology (WHO 2010) was assessed before and after separation.
Main results and the role of chance: The animal experiments showed significantly higher $\Delta\Psi m$, reflected by the ratio of polarized/depolarized mitochondria, in E. Sep sperm groups compared to RSU (0.7 ± 0.30 vs. 0.3 ±0.01; P < 0.02). The $\Delta\Psi m$ tended to be higher in vertical E. Sep group (2.1± 0.45; P <0.1), compared to horizontal E. Sep. The oxidation level, reflected by the percentage of viable spermatozoa exhibiting ROS, was significantly lower in horizontal E. Sep (23.5% ± 5.83) and vertical E. Sep (4.8% ±1.24) compared to RSU (53.0% ± 2.00 ; P <0.008 and P<0.0007 , respectively). Acrosome integrity was significantly higher in horizontal E. Sep (13.1 ± 3.06%) and vertical E. Sep (29.4± 6.41) compared to RSU (3.2 ± 1.61%; P<0.02 and P<0.05, respectively).In the first human sperm pilot study (pool of 3 samples) we performed horizontal E. Sep. After 18 min at 37°C the number of motile sperm recovered in the syringe (volume 0.2mL) was $6x10^6$ with 12% normal morphology as compared to 3% normal morphology and 9.6 $x10^6$ motile sperm in the equivalent 0.2 mL unprocessed semen sample. In the second trial we recovered 4 $x10^6$ total motile sperm compared to 6 $x10^6$ in the unprocessed semen sample.
Limitations, reasons for caution: Further studies with higher number of patients and various sperm quality parameters, are currently planned.
Wider implications of the findings: This easy and safe method can be use for IUI, IVF and ICSI.
Trial registration number: not clinical trial

P-011 Examination of Spermatozoa CatSper membrane channel proteins by immunohistochemical method and investigation of their relationship with sperm parameters in normozoospermia

S. Yazıcı[1], T. Irez[2]

[1]T.C Biruni University, Histology and Embryology, İstanbul, Turkey ;
[2]Yeniyüzyıl University, Histology and Embryology, İstanbul, Turkey

Study question: Is the expression of Sperm CatSper protein related to sperm parameters?
Summary answer: It was determined that the concentration of the spermatozoa is related to the CatSper positive sperm ratio.No significant relations were detected with the Sperm motility.
What is known already: CatSper is a sperm-specific, voltage-dependent, Ca^{+2}-selective, pH-sensitive and positive-load channel, and also provides the passage of calcium ions. CatSper Cation Channels contribute directly to the mobility of the sperm, regulate acrosome reaction, and balance the intracellular pH. It is considered that the mutations and disorders in any subunit of the CatSper structure cause infertility. In a trial that was conducted in mice, the loss of α-subunits caused infertility. For this reason, it is an important cation channel for sperm hyperactivation and male fertility.
Study design, size, duration: In this prospective and controlled study, the 18-35 year-old normozoospermic male patients who applied to the Cebeci Hospital UYTE Center of Ankara University, Cebeci Hospital, between December 2018 and August 2019 were included. The Semen analysis was carried out according to WHO 2010 Criteria.
Participants/materials, setting, methods: Semen samples were taken from 50 patients who were diagnosed with normospermia. The sperms were prepared with the Swim-Up Method, and spread slides were prepared, and the İmmune Fluorescent Staining Method was used for CatSper protein. The Student's **t**-test and Pearson Correlation Test were used for statistical analyses.
Main results and the role of chance: The CatSper Protein was detected with the IHC Method in Principal Peace Region with the middle part. The relation of CatSper-positive sperms with sperm morphology and concentration was found to be statistically significant (p<0.05). No statistical significance was detected with sperm motility (p>0.05). The present study examined the effects of CatSper Channels on reproduction, and showed that it will open new ways to treat male infertility and for contraceptive purposes.
Limitations, reasons for caution: The inclusion of only 50 normospermic patients, and working with Swim Up samples in the study caused limitations in terms of the sampling.
Wider implications of the findings: The results of our study have the quality of pioneering future studies to investigate the relations of CatSper-expressing cells with pregnancy. It is aimed with a new study project that IVF results are investigated in terms of male infertility and unexplained infertility.
Trial registration number: None

P-012 Intra-Uterine Insemination (IUI): Is there an upper cut-off level of the Number of Motile Spermatozoa Inseminated (NMSI)? An analysis of 2.642 IUI cycles.

L. Delaroche[1], H. Caillou[2], F. Lamazou[1], E. Genauzeau[1], P. Meicler[1], P. Oger[1], C. Dupont[3], P. Humaidan[4]

[1]Ramsay Santé, Hôpital Privé de Parly 2- IVF Center, Le Chesnay, France ;
[2]Capionis, Capionis, Bordeaux, France ;
[3]Sorbonne Université, Saint Antoine Research center- INSERM équipe Lipodystrophies génétiques et acquises. Service de biologie de la reproduction-CECOS- AP-HP- Hôpital Tenon, Paris, France ;
[4]Aarhus University, The Fertility Clinic- Skive Regional Hospital Faculty of Health, Skive, Denmark

Study question: Does an upper cut-off level of the NMSI exist, above which the Live Birth Rate (LBR) is negatively affected?
Summary answer: No upper cut-off level for NMSI was found in IUI cycles. However, the LBR correlated positively with the NMSI until 30 million.
What is known already: Several authors tried to determine a lower threshold of post-washed motile sperm in IUI. However, to date no data have been published regarding a possible upper cut-off level of motile sperms, above which the LBR is negatively affected. Importantly, IVF laboratories are often used to diluting sperm preparations when the NMSI exceeds 10 million. The objective of this study was to determine the predictive value of the post-washing NMSI on the LBR.
Study design, size, duration: A total of 2.642 IUI cycles carried out from January 2010 to July 2018 with an NMSI >1 million were retrospectively analyzed. Patients under the age of 43 years were stimulated, using either clomifene citrate, FSH or combinations. Sperm was prepared by swim-up selection. IUI cycles using donor sperm or frozen-thawed sperm were excluded. The institutional review board approved the study and all patients gave written informed consent to the use of their data.
Participants/materials, setting, methods: A multivariate logistic regression model was used to assess the influence of NMSI of >10-20, >20-30 and >30 million on LBR compared to a NMSI of >1-10 million. In addition to NMSI, this model was adjusted for all clinically relevant factors, i.e. having demonstrated their influence on LBR as part of a preliminary selection step, using univariate logistic regression. The odds ratio (OR) and their 95% bilateral confidence interval from the multivariate model were calculated.
Main results and the role of chance: A total of 2.642 IUI cycles in 1.036 couples were included. Mean female age was 33.5 ± 4.4 years at the time of the first IUI. The mean NMSI per cycle was 9.0 million [1-97]. The LBR increased with the NMSI until 30 million without any maximum threshold (AUC = 0.5438). Using NMSI categories, the LBR per IUI cycle was 14.4%, 17.8%, 22.9% and 6.8% for NMSI between >1-10, >10-20, >20-30 and >30 million, respectively (p=0.003). Univariate analysis showed that the NMSI, female age, the number of mature follicles and the estradiol level on day of ovulation trigger, the cycle rank and the etiology individually influenced the LBR. Multivariate analysis,

adjusted for clinically relevant factors, showed that the LBR was 1.49 and 1.76 times higher when IUI was performed with a NMSI of >10-20 million (OR [95%CI] = 1.49 [1.10; 2.01]) and of >20-30 million (OR [95%CI] = 1.76 [1.07; 2.91]), respectively compared to IUI with an NMSI of >1-10 million (p=0.0119).

Limitations, reasons for caution: Although more than two thousand cycles were included and the main outcome was LBR, the design was retrospective and all cycles were performed in a single center.

Wider implications of the findings: The LBR after IUI can be optimized by inseminating a maximum of motile sperms. IUI preparations should not be diluted when more than 10 million motile sperms are obtained. It remains to be determined whether a dilution is necessary beyond 30 million. These preliminary results call for a prospective RCT.

Trial registration number: COS-RGDS-2019-09-004-DELAROCHE-L

P-013 Men's waist circumference in relation to infertility treatment outcomes among couples undergoing assisted reproductive technologies

H. Bian[1,2], L. Mínguez-Alarcón[3], I. Souter[4], J. Chavarro, E.[1,5,6]

[1]Harvard T.H. Chan School of Public Health, Department of Nutrition, Boston, U.S.A. ;
[2]Peking University School of Public Health, Institute of Reproductive and Child Health and Department of Epidemiology and Biostatistics, Beijing, China ;
[3]Harvard T.H. Chan School of Public Health, Department of Environmental Health, Boston, U.S.A. ;
[4]Massachusetts General Hospital Fertility Center and Harvard Medical School, Vincent Department of Obstetrics and Gynecology, Boston, U.S.A. ;
[5]Harvard T.H. Chan School of Public Health, Department of Epidemiology, Boston, U.S.A. ;
[6]Channing Division of Network Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, U.S.A.

Study question: Is there an association between men's waist circumference and ART outcomes?

Summary answer: Men's waist circumference was inversely related to pregnancy and live birth rates among couples undergoing ART independently of men's and women's body mass index (BMI).

What is known already: Female adiposity, overall and central, has been related to worse ART outcomes. Likewise, men's obesity has been related to poor semen quality and may also have a negative effect on ART outcomes. Waist circumference as a measure of central obesity is also negatively associated with semen quality parameters in men of subfertile couples. Whether men's waist circumference impacts a couple's fertility independently of their and their partner's BMI is unknown.

Study design, size, duration: We utilized data from the Environment and Reproductive Health (EARTH) Study, a prospective cohort study, which recruited subfertile couples seeking evaluation and treatment at the Massachusetts General Hospital Fertility Center. Measurement of waist circumference was introduced to the study in October 2009. This analysis includes 179 couples undergoing ART utilizing their own gametes, with complete anthropometric information, recruited through January 2019.

Participants/materials, setting, methods: Men's and women's height, weight and waist circumference were measured on-site at baseline by trained personnel. Clinical treatment outcomes were extracted from the medical records. We analyzed the association of men's waist circumference and clinical outcome measures using cluster-weighted generalized estimating equation models to account for repeated treatment cycles of the same couple and adjust for men's age, BMI, height, race, education level, smoking status, and women's age, BMI, waist circumference and height.

Main results and the role of chance: Men's median (interquartile range, IQR) age, waist circumference, and BMI were 36.6 years (32.9-40.1), 95 cm (89-103) and 26.5 kg/m^2 (24.2-29.1), respectively. The correlation coefficient of men's waist circumference and BMI was 0.58 (P <0.0001). The correlation coefficients between men's and women's BMI and waist circumference were 0.29 and 0.40 (P <0.0001), respectively. Men's waist circumference was unrelated to fertilization rate overall and when IVF and ICSI cycles were separately examined. However, men's waist circumference was inversely related to clinical outcomes, including implantation, clinical pregnancy and live birth rates per initiated cycle. For each 5 cm increase in men's waist circumference, the odds (95% CI) of implantation, clinical pregnancy and live birth per initiated cycle decreased by 14% (2-24%), 12% (2-21%) and 9% (1-17%), respectively, after accounting for anthropometric and demographic characteristics of both partners. Results were comparable when waist circumference was modeled in categories using tertiles of the observed distribution, when using WHO suggested cutoffs for abdominal obesity, when restricting analyses to men with a normal BMI, and when restricting the analyses to fresh embryo transfer cycles.

Limitations, reasons for caution: As is the case of all observational studies, residual confounding cannot be ruled out. In addition, it is not known whether these findings are generalizable to couples attempting conception without medical assistance.

Wider implications of the findings: Men's abdominal adiposity, as measured by waist circumference, may adversely impact ART outcomes, even in the absence of obesity as defined by BMI cutoff values. These results suggest that central obesity may be an independent risk factor for male factor infertility.

Trial registration number: not applicable

P-014 Testicular sperm extraction (TESE) and genetic analysis feedback in a non-obstructive azoospermic man presenting a 46,XY/46,XX constitutional chimerism.

X. Ferraretto[1], J.F. Hermieu[2], M.A. Llabador[1], E. Amar[3], A. Hercent[4], J.P. Siffroi[4]

[1]AP-HP - Hôpital Bichat-Claude Bernard, Service de Biologie de la Reproduction, Paris, France ;
[2]AP-HP - Hôpital Bichat-Claude Bernard, Service d'Urologie, Paris, France ;
[3]Cabinet d'Andrologie Victor Hugo, Andrologie Urologie, Paris, France ;
[4]AP-HP – Hôpital d'Enfants Armand Trousseau, Département de Génétique Médicale, Paris, France

Study question: What is the sex ratio of spermatozoa incoming from spermatogenesis of a man presenting a 46,XY[70%]/46,XX[30%] constitutional chimerism?

Summary answer: Sex ratio of testicular spermatozoa analysed by fluorescent in situ hybridization (FISH) was 1:1, confirming that spermatogenesis is only conducted by 46,XY spermatogonia.

What is known already: Constitutional chimerism results from in utero fusion of two different zygotes in one single embryo. However, its prevalence is not well known, and only a few cases of 46,XY/46,XX chimerism have been reported to date. Moreover, no clinical case has been published on the exploration of spermatogenesis in 46,XY/46,XX chimerism by FISH analysis performed on spermatozoa after TESE.

Study design, size, duration: We studied a 35 years old patient with non-obstructive azoospermia. The patient was not issued from a twin pregnancy and had no history of heterologous stem cell transplantation. He presented a normal male phenotype but with a clinical bilateral testicular hypotrophy (left=4mL and right=8mL). Hormonal exploration results were: FSH=16.0UI/L, LH=10.5UI/L, Testosterone=3.68ng/mL and Inhibin B=18pg/mL. Genetic analyses performed on peripheral blood cells showed a 46,XY[70%]/46,XX[30%] chimeric karyotype, and no chromosome Y azoospermic factor (AZF) deletion.

Participants/materials, setting, methods: A bilateral TESE was performed by a senior urological surgeon. Sperm extraction was performed using swim-up and centrifugation. A few normal motile spermatozoa were retrieved on both sides and frozen. Remaining fresh testicular tissue was used for sperm analysis by FISH using direct hybridization probes coding for X (DXZ1) and Y (DYZ3) chromosomes and for chromosome 18 (D18Z1) as control of haploidy. FISH was performed separately on spermatozoa retrieved from right and left testicular tissue

Main results and the role of chance: On the right side, 96 nuclei were observed and results showed nearly identical rates of X and Y bearing spermatozoa: nuc ish(DXZ1x1,D18Z1x1)[45]/(DYZ3x1,D18Z1x1)[51]. Similar results were found on the left side after the analysis of 100 sperm nuclei: nuc ish(DXZ1x1,D18Z1x1)[49]/(DYZ3x1,D18Z1x1)[51].

These results highlight a 1:1 sex ratio on spermatozoa analysed from both testicular tissues, thus strongly suggesting that spermatogenesis was initiated from 46,XY spermatogonia. Performing FISH separately on both sides limited the risk of error and the role of chance.

Frozen testicular sperm was used in intracytoplasmic sperm injection (ICSI) and resulted in the birth of a healthy boy following the first embryo transfer.
Limitations, reasons for caution: Given that phenotypes are highly variable in this type of patient and are also related to the proportion of the two cellular contingents, our results in terms of presence of testicular spermatozoa and genetic analysis cannot be applied to all patients with 46,XX/46,XY chimerism.
Wider implications of the findings: This clinical case shows that it is possible to find usable sperm with a 1:1 sex ratio after TESE. These data can be used to inform future patients with this genetic abnormality about the safety and potential success of this procedure, without transmitting this genetic abnormality to their offspring.
Trial registration number: not applicable

P-015 A systematic review of at-home semen analysis technologies: A potential supplement to the fertility clinic?

F. Willendrup[1], E. Andersen[1], C. Panayotidis[2]
[1]ExSeed Health ApS, Denmark, Copenhagen, Denmark ;
[2]Gynaecology, Gynaecology, Isle of Wight, United Kingdom

Study question: The aim was to determine the use and validity of current at-home semen tests (HST), and their screening potential of male subfertility.
Summary answer: Most HST's are user friendly, accurate and effective diagnostic tools for primary and secondary care services.
What is known already: Semen analysis remain the main tool for diagnosis of male fertility status. Conventional spermograms use either automated or manual evaluation under a microscope. A basic predictive parameter is the Total Motile Sperm Count, which correlates well with pregnancy outcomes. HST provide an immediate result on basic semen parameters increasing the flexibility and easiness for the men. Although HST technologies are recently commercialised the general gynaecologists, practitioners and fertility specialists are not aware about their existence. The use of HST in primary and secondary care could improve the early correction of subfertility conditions and potentially improve pregnancy rates.
Study design, size, duration: The research protocol followed the published methodology for Preferred Reporting Items for Systematic Review and Meta-Analysis Protocols (PRISMA-P), including their extension for Diagnostic Test Accuracy (PRISMA-DTA). The literature search included online databases with a predefined search strategy. Additional search was performed across online markets to find available tests not yet included in scientific reporting. All published material up to and including 12th of January 2020 was included.
Participants/materials, setting, methods: All available HST's were detected via research online, including any relevant applications in App Store (iOS) and Google Play (Android). All articles published on testing methods or devices used for analysing semen samples at-home or outside the conventional laboratory were included. Each technology and test were reviewed based on adapted predefined checklist from PRISMA-DTA.
Main results and the role of chance: 12 home sperm tests were identified and included in this review. Across the technologies, seven test methods were identified for the semen analysis, including manual microscope, automated microscope, microfluidics antibody reaction, paper-based antibody reaction, paper-based antibody reaction, microfluidic centrifugation, and mail-in tests. Some of them were smartphone enabled while others were paper-based. The accuracy of these tests was between 95-98 % and the "time until results" ranged between a few seconds to several days.

The majority of HST's give qualitative information on either the concentration or motile concentration. Most of the HST provide only the user with interpretation of the single sperm parameter result.

New high tech HST's include more in-depth analysis of several parameters. It is suggested by the authors that HST's can now aid further in improving patient experience and fertility awareness.
Limitations, reasons for caution: Material for some of the tests is unreliable, incomplete and subject to commercial imperatives. The study did not assess user experience and reproductive outcomes.
Wider implications of the findings: Our review shows that some HST are now measuring multiple sperm parameters, as well as reaching a high accuracy, making them valid tools for semen analysis. We propose a way for these technologies to overcome current clinical limitations, to improve patient care and ultimately treatment outcomes.
Trial registration number: Not applicable

P-016 Improvement of semen parameters by pre-conception care for male partners of infertility couples

A. Komiya[1,2], N. Uchida[3], A. Kuga[3], M. Ibayashi[3], K. Hiraoka[3], K. Kawai[3], T. Ichikawa[1]
[1]Chiba University Hospital, Urology, Chiba, Japan ;
[2]Kameda IVF clinic Makuhari, Urology, Chiba, Japan ;
[3]Kameda IVF clinic Makuhari, Reproductive Medicine, Chiba, Japan

Study question: This study was conducted to analyze whether lifestyle modification as a part of preconception care could improve semen parameters among the male partners of couples who visited a fertility clinic.
Summary answer: Lifestyle modification as a part of pre-conception care for male partners improved semen parameters without urologic intervention.
What is known already: Pre-conception care is the provision of biomedical, behavioral and social health interventions to women and couples before conception occurs. It aims at improving their health status, and reducing behaviors and individual and environmental factors that contribute to poor maternal and child health outcomes. Such care is also required for male partners of infertility couples. Recent Japan's National survey for male infertility revealed that 42.1% of male factor infertility was idiopathic, suggesting that at least some of these were caused by inappropriate lifestyle factors.
Study design, size, duration: This is a single-arm, single-center, retrospective observation study for a duration of one year after June in 2018 with 203 consecutive subjects.
Participants/materials, setting, methods: Non-azoospermic male partners of infertility couples were enrolled and asked about their lifestyles. Median age of male patients was 35 years old. These patients were promoted to modify their inappropriate lifestyles as pre-conception care before urologic evaluation. The lifestyles include factors such as smoking, chronic alcohol use, inappropriate underwear use, excessive body weight, length of abstinence and so on. Semen parameters was compared between before and after the promotion by student T or chi-square tests.
Main results and the role of chance: Forty-seven men (23.2%) were current smokers. 94 (46.3%) were chronic alcohol users. The lifestyles elevating scrotal temperature including fitted underwear and/or excessive time bathtub/sauna use were found in 150 (73.9%). Body mass index (BMI)=or>30 was found in 16 (7.9%). Blood tests revealed hypogonadism in 27 (13.3%), zinc deficiency in 30 (14.8%), abnormal lipid metabolism in 58 (28.6%), abnormal liver function in 42 (20.7%). Palpable varicoceles were found in 41 (20.2%). Erectile dysfunction was found in 80 (39.6%). Most of patients (200, 98.5%) had at least one factor. Then, changes in semen parameters were compared before and after the promotion of lifestyle modification. Median intervals of semen analyses were 28 days. Abstinence was decreased from 3.7 to 2.8 days in average (p=0.0135). Oligozoospermia was decreased from 99/203 cases (48.8%) to 77/197 (39.1%, p=0.0511). Asthenozoospermia was decreased from 160/203 (78.8%) to 91/196 (53.6%, p<0.0001). Oligoasthenozoospermia was decreased from 81/203 (39.9%) to 47/196 (23.7%, p<0.0001). Total motile sperm count was improved from 18.7±27.3 million to 33.1±44.6 million (mean±standard deviation, p<0.001). However, such improvement was not significant in those with palpable varicocele (4.7±25.0 million increase, p=0.2488), hypogonadism (22.3±58.4 million increase, p=0.0685), BMI=or>30 (33.1±69.2 million increase, p=0.0753), and zinc deficiency (8.3±34.2 million increase, p=0.1947).
Limitations, reasons for caution: This study was a single-arm, single-center, retrospective study with relatively small sample size. Results could be different if the study is conducted by double-arm, multi-center and prospective fashion in larger sample size.
Wider implications of the findings: Most of male partners of infertility couples had lifestyle and/or medical factors to decrease semen quality. Promotion of lifestyle modification should be attempted before and during urological/medical intervention. However, a short-term modification was not enough in those with varicocele, hypogonadism, zinc deficiency and excessive BMI.
Trial registration number: not applicable

P-017 A new small-molecule inhibitor of BRDT shows reversible male contraception effect in mice model

X. Li[1], S. Wu[1], J. Hou[1], M. Yin[2], W. Xu[3]

[1]Sichuan university, West China Second University Hospital, West China School of Medicine ;
[2]Central South University, Department of Dermatology- Huan Engineering Research Center of Skin Health and Disease- Hunan Key Laboratory of Skin Cancer and Psoriasis- Xiangya Hospital, Changsha, China ;
[3]Sichuan university, Joint Laboratory of Reproductive Medicine- SCU-CUHK- Key Laboratory of Birth Defects and Related Diseases of Women and Children- Ministry of Education- West China Second University Hospital, West China School of Medicine

Study question: To date, a reversible, reliable and oral medication to male contraceptive has not been successfully applied in the clinic.
Summary answer: We have discovered a dose-dependent small molecule Inhibitor of BRDT that can reversibly achieve male contraception through oral medication in animal experiments.
What is known already: Effective male contraceptives include condoms and vasectomy, but these methods are not ideal for all men. The bromodomain (BRD) and extra-C terminal domain (BET) protein family consists of four members (BRD2, BRD3, BRD4 and BRDT). These bind to acetyl lysine (KAc) residues on the tails of histones H3 and H4, and regulate chromatin structure and gene expression. The testis-specific BET member, BRDT, is essential for the normal progression of spermatogenesis and mutations in the Brdt gene result in complete male sterility in mice model. Therefore, promising method acts by blocking Brdt involved in the process of spermatogenesis for male contraception.
Study design, size, duration: We used 60 male mice divided into six groups (0mg/kg, 1mg/kg, 2mg/kg, 3mg/kg, 4mg/kg, 5mg/kg) treated daily from 6 to 14 weeks with NHWD-870, a potent BRDT inhibitor. After drug or vehicle treatment, mice were either sacrificed or mated to females while continuing to receive NHWD-870.
Participants/materials, setting, methods: C57BL/6 mice model, gene cloning, mouse contraceptive studies, hematoxylin-eosin staining, sperm counts and motility, sex hormone radioimmunoassay, immunohistochemistry, western blot, Immunofluorescence.
Main results and the role of chance: NHWD-870 was the most potent inhibitor of BRDT with a biochemical IC50 of 2.5 nM, 13.1nM, 2.3nM, 13.93nM on GC1, GC2, TM3 and TM4 cell lines proliferation. We tested spermatogenic effects of NHWD-870 administered to male mice. High dose groups (4mg/kg and 5mg/kg) had a significant reduction to 74.4% in testis weight compared control. Epididymal sperm number was reduced to 5% of control and sperm motility was decreased to 3% of control. Moreover, high dose group showed sterility mated with normal females. Biochemical study showed that the BrdT expression is dose-dependantly decreased in these mice model. Low dose (1mg/kg, 2mg/kg and 3mg/kg) groups had no difference in testis weight and fertility but sperm number and motility was decreased compared with control. After withdrawal the drug about 25 days, the high dose group males had recovery of the fertility, testis weight and sperm number.
Limitations, reasons for caution: Mice treated with NHWD-870 showed decreased level of testosterone in serum. High dose drug also lead to decreased body weight after 6 weeks treatment.
Wider implications of the findings: By optimizing the structure of the NHWD-870, it could be possibly used in human as an oral medication for reversible male contraception.
Trial registration number: Not applicable

P-018 Live birth rate of patients where sperm selected using microfluidic technique in high DNA fragmentation index sperm samples

F. Khan[1], K.D. Nayar[1], G. Kant[1], M. Singh[1], S. Mishra[1], S. Gupta[1], R. Bhattacharya[1], K.D. Nayar[1]

[1]Akanksha IVF Centre- Mata Chanan Devi Hospital, Reproductive Medicine, New Delhi, India

Study question: Does microfluidic sorting technique help in increasing live birth rate in patient with high DNA fragmentation index (DFI) sperm samples?
Summary answer: Sperm selected by microfluidic sorting are associated with significant increase in live birth rate, clinical pregnancy rate and reduced miscarriage rate.
What is known already: DNA damage is unrecognisable in living sperm prior to insemination and an increased sperm DNA fragmentation index has been associated with lower fertilization rates, impaired embryo development and reduced pregnancy rates. Standard semen processing techniques are associated with centrifugation, which may induce reactive oxygen species and DNA damage. Microfluidic systems are capable of working with small volume samples and have high sensitivity and low response time. This technique helps to improve the efficiency of sample preparation, enable consistency in embryo culturing and reduce human error. It has been demonstrated that microfluidic technique could provide sperm with significantly reduced DNA damage.
Study design, size, duration: A prospective randomised control study was conducted from 1st August 2017 to 31st December 2018. One hundred and nighty eight patients were randomised by computer generated list and divided into 2 groups. Group A (n=100) , in which sperm were processed by microfluidic sperm sorter while in group B (n=98), sperm were processed by density gradient technique and morphologically normal motile sperm were injected by Intracytoplasmic sperm injection (ICSI) technique in all mature oocytes.
Participants/materials, setting, methods: The study period included all normozoospermic patients with high DNA fragmentation index (>25%) while oligospermic, asthenozoospermic samples, patients with poor ovarian reserve and advanced age were excluded from the study. All A grade embryos were vitrified and transferred in frozen embryo transfer cycle. Both groups were compared on the basis of fertilisation rate, day 3 grade A embryo development rate, clinical pregnancy rate, miscarriage rate and live birth rate.
Main results and the role of chance: Cycle characteristics (female age, length of stimulation, gonadotrophin dose, number of oocytes and number of transferred embryos) were similar in both groups.

Between the two groups, there was a significant increase observed in group A over group B in day 3 grade A embryo development rate (60% vs. 38%, p-0.003), clinical pregnancy rate (62% vs. 41%, p-0.004) and live birth rate (46% vs. 29%, p-0.011), while a significant decrease in miscarriage rate (12% vs. 25%, p-0.028). On the other hand there was no statistical difference observed in fertilisation rate (82% vs. 78%, p-0.80).
Limitations, reasons for caution: Larger randomised control studies are needed to strengthen these results.
Wider implications of the findings: We have demonstrated that sperm sorted by microfluidic not only helps in selection of sperm with better DNA integrity but also increased live birth rate. Using it in routine practice can help in reducing the negative effect of reactive oxygen species and thus improve pregnancy rate and live birth rate.
Trial registration number: MCDH/2017/35

P-019 Male dietary fat intake and fecundability: a preconception cohort study

L.A. Wise[1], A. Wesselink[1], S. Willis[1], E. Mikkelsen[2], K. Tucker[3], A.S. Dam Laursen[2], K. Rothman[1], E. Hatch[1]

[1]Boston University School of Public Health, Department of Epidemiology, Boston, U.S.A. ;
[2]Aarhus University Hospital, Department of Clinic Epidemiology, Aarhus, Denmark ;
[3]University of Massachusetts at Lowell, Biomedical & Nutritional Sciences, Lowell, U.S.A.

Study question: To what extent does male dietary fat intake influence fecundability?
Summary answer: We observed little overall association between intakes of total fat, and most fat subtypes, and fecundability.
What is known already: Higher intakes of saturated fat and *trans* fatty acids have been associated with poor semen quality and low testosterone levels, whereas higher intakes of omega-3 fatty acids have been associated with improved semen quality in some studies. There have been few preconception cohort studies of male diet and fecundability.
Study design, size, duration: Pregnancy Online Study (PRESTO) is an ongoing North American prospective preconception cohort study. Analyses were restricted to 446 couples attempting conception for ≤6 cycles at enrollment during 2013-2020.

Participants/materials, setting, methods: Men aged ≥21 years completed an online baseline questionnaire on demographic, medical, and anthropometric factors. Ten days after enrollment, they completed a validated food frequency questionnaire (DHQ II). Their female partners completed bimonthly follow-up questionnaires for up to 12 months or until pregnancy. We used proportional probabilities regression to estimate fecundability ratios (FR) and 95% CIs for associations of % energy from total fat and fat subtypes with fecundability, adjusting for energy and other covariates.

Main results and the role of chance: Intakes of total fat, saturated fat, mono-or poly-unsaturated fat, or trans fat intake were not appreciably associated with fecundability. FRs (95% CIs) comparing the top vs. bottom quartiles of dietary fat intake were 1.00 (0.73-1.36) for *trans* fatty acids, 1.15 (0.84-1.57) for omega-3 fatty acids, 0.78 (0.56-1.08) for omega-6 fatty acids, and 1.23 (0.93-1.64) for the ratio of omega-3 to omega-6 fatty acids.

Limitations, reasons for caution: We observed little overall association between male intake of total fat, and most fat subtypes, and fecundability. Weak associations were seen for intakes of omega-6 fatty acids and the ratio of omega-3 to omega-6 fatty acids, though associations were imprecise.

Wider implications of the findings: These data contribute to the limited existing literature on the association between male diet, specifically fat intake, and fecundability. Although numbers were small, these findings indicate that male dietary intake of fat is not a strong determinant of fecundity.

Trial registration number: NICHD grants R21HD072326, R01 HD086742, and R03 HD090315

P-020 L-carnitine in seminal plasma correlated with semen parameters and sperm DNA fragmentation

L. Ye[1], W. Huang[1], M. Song[1], J. Han[1], Y. Peng[1], T. Wu[2], Y. Zeng[3,4]

[1]*Shenzhen Zhongshan Urology Hospital, Department of Andrology and Urology, Shenzhen, China ;*
[2]*Shenzhen Zhongshan Urology Hospital, Department of Reproductive Immunology, Shenzhen, China ;*
[3]*Shenzhen Zhongshan Urology Hospital, Fertility Center, Shenzhen, China ;*
[4]*Shenzhen Zhongshan Urology Hospital, Shenzhen Key Laboratory for Reproductive Immunology of Preimplantation, Shenzhen, China*

Study question: Is there any relationship between L-carnitine in seminal plasma and sperm count, motility, morphology and DNA integrity?

Summary answer: L-carnitine in seminal plasma was positively corelated with sperm count, progressively motile sperm, morphologically normal sperm as well as sperm DNA fragmentation.

What is known already: L-carnitine, presenting in testis and epididymis, is involved in sperm maturation and it is used as antioxidants in therapy of idiopathic male infertility. Evidence showed that oral L-carnitine can improve sperm parameters including total sperm count, concentration, progressive motility, vitality, and morphology in infertile men. Moreover, recently publications indicated that L-carnitine preserves the sperm membrane and DNA integrity. But limited researches investigated the relationship of L-carnitine in semen and sperm parameters as well as sperm DNA fragmentation.

Study design, size, duration: Data of semen analysis from January 2017 to December 2019 were involved and divided into normozoospermic group and non-normozoospermic group according to WHO guideline. Total content of L-carnitine in seminal plasma, sperm DNA fragmentation index (DFI) and semen parameters including sperm numbers, motility and morpology were retrospectively analyzed. For all the included study subjects, the leukocytes count in semen less than 1×10^6/ml.

Participants/materials, setting, methods: Sperm count and motility were analyzed by computer assisted sperm analysis (CASA) system, while sperm morphology was examined after Diff-Quik rapid staining procedure. L-carnitine in seminal plasma was determined by high-performance liquid chromatography. DFI was calculated from sperm chromatin structure analysis (SCSA). Content of L-carnitine and DFI of normozoospermic group abnormal group and was compared by Mann-whitney U test. Bivariate correlation analysis was used to explore the relationship between L-carnitine and sperm paraments and DFI.

Main results and the role of chance: A total of 4437 subjects were enrolled in the study and normozoospermic group contained 2591 cases while non-normozoospermic group contained 1846 cases. Median value of L-carnitine in seminal plasma was significantly higher in normozoospermic group [458.78(439.92) nmol per ejaculate] than that in non-normozoospermic group [347.58(447.61) nmol per ejaculate] (P<0.001). Mean value of DFI in normozoospermic group was6.97% (6.07%), which was lower than DFI in abnormal group [14.51% (13.41%)] (P<0.001) Content of L-carnitine in semen was positively corelated with total sperm count, percentage of progressively motile sperm and percentage of morphologically normal spermatozoa, whose coefficient of correlation was 0.580 (P<0.001), 0.150 (P<0.001) and 0.131 (P<0.001) respectively. Moreover, L-carnitine in seminal plasma was negatively corelated with DFI, whose coefficient of correlation was 0.065 (P<0.001).

Limitations, reasons for caution:
It is a single-center study and the above results were from retrospective analysis

Wider implications of the findings:
The above results can be used as references in oral L-carnitine of treatment in improving semen paraments and the choice of antioxidants in reducing sperm DNA fragmentation.

Trial registration number: Not Applicable

P-021 The relationship between seminal leukocytes and oxidative stress markers in semen

S. Kuroda[1], T. Takeshima[1], Y. Yumura[1]

[1]*Yokohama City University Medical Center, Department of Urology- Reproduction center, Yokohama, Japan*

Study question: Does leukocyte concentration in semen and semen parameters correlate with oxidative stress markers?

Summary answer: Seminal leukocytes concentration was strongly correlated with ROS level in semen, and ORP was more negatively correlated semen parameters than ROS.

What is known already: Reactive oxygen species (ROS) in semen has been reported to have negative effect to male fertile capacity, and recent studies reported the efficacy of oxidation-reduction potential (ORP) which reflects the balance of oxidants and antioxidants in semen. The source of ROS in semen is considered as immature spermatozoa and seminal leukocytes though the detail is still unknown. Pyospermia, globally defined as the presence of more than one million leukocytes in 1 mL of semen, is considered as an indicator for genital infection and inflammation.

Study design, size, duration: Between November 2018 and July 2019, 50 infertile males who visited our hospital were enrolled. All patients underwent semen analysis and measurement of ROS and ORP levels and the concentration of leukocytes in semen. The correlation between these values were analyzed retrospectively.

Participants/materials, setting, methods: ROS level in semen was measured using Monolight 3010™ Luminometer. Before and after adding 40 mL of 100 mmol/L luminol to 500 mL of semen sample, the subtraction of the integrated chemiluminescence was measured between 0 and 200 seconds. ORP level per sperm concentration (sORP) was measured using MiOXSYS System™. The concentration of leukocytes were evaluated using myeloperoxidase staining (Endtz test). The relationships between these values and semen parameters were evaluated using non-parametric correlation analysis.

Main results and the role of chance: The average patient's age was 37.1 (20-53). ROS level was positively correlated with leukocyte concentration (ρ=**0.646, p<0.001)** although sORP didn't show significant correlation. Both ROS level and sORP showed negative correlation with sperm concentration and motility significantly, although the Spearman correlation coefficient was higher in sORP than in ROS (ρ= -0.873 vs -0.425, -0.547 vs -0.228, respectively). sORP was also negatively correlated with straight velocity and mean amplitude of lateral head displacement (mean ALH). When the positive cut-off value of ROS level was set 4332 RLU as previously reported, ROS was positive more than 1.1×10^5/ml of leukocytes in semen according to ROC curve (AUROC= 0.862) .

Limitations, reasons for caution: This study is retrospective and single center analysis with small number.

Wider implications of the findings: Seminal leukocyte was considered as a source of ROS in semen. ROS was positive even under the global definition of pyospermia, thus fewer leukocytes than definition may have adverse effects to sperm quality through ROS generation. ORP have potential as keener biomarker to reflect the sperm quality than ROS.

Trial registration number: not applicable

P-022 Does Testicular Sperm Aspiration have a place in the Management of Non-Obstructive Azoospermia Patients?

A. Majzoub[1], K. Khalafalla[1], H. Elbardisi[1], S. Alsaid[1], M. Arafa[1]

[1]Hamad Medical Corporation, Urology, Doha, Qatar

Study question: Are there any clinical predictors that could help in selecting non-obstructive azoospermia (NOA) candidates for testicular sperm aspiration (TESA)?
Summary answer: TESA may be offered for patients with a serum FSH level <7.5IU/L and average testicular size >7.75ml
What is known already: Microsurgical testicular sperm extraction (m-TESE) is the gold standard surgical sperm retrieval technique allowing magnified evaluation and biopsy of a large area of testicular tissue thereby increasing the overall sperm retrieval rate (SRR). However, while a small quantity of testicular tissue is presumably extracted during m-TESE, the procedure can have detrimental effects on testicular function evidenced by the resulting temporary or permanent state of hypogonadism postoperatively. Furthermore, microTESE is expensive, time-consuming and requires a skilled microsurgeon who may not be available in certain places. These facts advocate that TESA may still be of value in the management of NOA patients.
Study design, size, duration: This was a retrospective study of 394 patients with NOA who underwent their first trial of surgical sperm retrieval over a period of 5 years. Patients with NOA based on the presence of one or more of the following: 1) histopathology denoting defective spermatogenesis; 2) high gonadotropins; 3) scanty number of sperm retrieval; 4) genetic abnormality were included. We excluded patients with proven obstructive azoospermia or who performed surgery due to causes other than azoospermia.
Participants/materials, setting, methods: Data including age, testicular size, serum hormones, genetic tests and histopathologic results were collected. All patients underwent a staged retrieval procedure starting with TESA and proceeding to m-TESE. Multivariate logistic regression analysis was used to assess the impact of different factors on the outcome. ROC curve was performed to identify the cut-off value for significant variables. The likelihood for positive TESA-SRR was calculated for each significant variable and for all variables combined using regression analysis.
Main results and the role of chance: TESA was the sole procedure in 31% of patients while two-thirds of patients underwent m-TESE. Overall, SRR with TESA was 26.7% while with m-TESE was 42.3%. Patients with positive TESA had significantly larger testicular size (10.39 ± 0.6 vs. 7.15 ± 0.3, p<0.001) and significantly lower FSH (6.44 ± 0.7 vs. 14.1 ± 0.8) and LH levels (4.03 ± 0.3 vs. 7.15 ± 0.4 (p<0.001 for both) than those with a negative TESA. The highest SRR was observed in men with hypospermatogenesis (52.6%) followed by Maturation arrest (34.2%), Sertoli cell only (13.2%) and tubular hyalinization (0%) (p<0.001). Multivariate analysis revealed that only testicular size (OR 1.084, 95%CI 1.001-1.174, p=0.046) and serum FSH (OR 0.924, 95%CI 0.863-0.989, p=0.024) had a significant impact on SRR with TESA. A testicular size cut-off of 7.75ml (sensitivity 62.9%, specificity 63.4%, AUC=0.674) and FSH cut-off of 7.5IU/L (sensitivity 64.6%, specificity 64%, AUC=0.718) were the best predictors of TESA SRR. TESA was positive in 39.5% of patients with FSH < 7.5 IU/L (OR 3.247, p< 0.001), 34.6% of patients with testicular size > 7.75 ml (OR 2.916, p<0.001) and 42.5% of patients with both FSH < 7.5 IU/L and testes size > 7.75 ml (OR 3.419, p<0.001)
Limitations, reasons for caution: The main limitations are the retrospective design of the study.
Wider implications of the findings: Investigating the predictors for positive SRR with TESA may provide important prognostic evidence that can be used during patient counselling to aid the couple in making sound treatment decisions.
Trial registration number: NA

P-023 The semen microbiome and the impact on sperm function and male fertility: a systematic review and meta-analysis

L. Farahani[1,2], T. Tharakan[2,3], T. Yap[4], J. Ramsay[3,5], C. Jayasena[2,5], S. Minhas[3]

[1]Imperial College Healthcare NHS Trust, Obstetrics & Gynaecology, London, United Kingdom ;
[2]Imperial College, Metabolism- Digestion and Reproduction, London, United Kingdom ;
[3]Imperial College Healthcare NHS Trust, Urology, London, United Kingdom ;
[4]Guy's and St Thomas' NHS Foundation Trust, Urology, London, United Kingdom ;
[5]Imperial College Healthcare NHS Trust, Andrology, London, United Kingdom

Study question: What constitutes the semen microbiome (SM) and what is the impact of the semen microbiome on male fertility and semen parameters?
Summary answer: Specific bacterial species are associated with worsening sperm quality, whilst others are protective, but the association with infertility is uncertain
What is known already: Male factor is attributable in up to 50% of cases of infertility. It is widely known that bacterial infection can impair sperm function. In-vitro studies demonstrate that bacteria can reduce sperm function through mechanisms such as motile sperm agglutination or induction of apoptosis. The use of next-generation sequencing(NGS) techniques has provided a better understanding of the microbiome and has led to the emergence of new therapeutic approaches, and recent studies have highlighted the importance of the changes in the microbiome(dysbiosis) to female reproductive health. Several emerging studies have investigated the impact of the semen microbiome on sperm function and fertility.
Study design, size, duration: A systematic search was conducted in accordance with the Preferred Reporting Items for Reviews and Meta-analysis (PRISMA) statement. The systematic review was registered with PROSPERO (ID CRD42019124483). The databases MEDLINE, OVID and PubMed were searched to identify English language studies related to the identification of bacteria in the semen of infertile and fertile men, between 1st January 1999 and 15th March 2019. Two independent investigators screened abstracts and selected studies and extracted data for meta-analysis
Participants/materials, setting, methods: 54 studies were included, with 50811 subjects. Observational studies were included that identified the seminal microbiome in male subjects, and it's association with fertility and semen parameters. We included studies that analysed semen according to the 1999 or 2010 WHO manual, and where bacteria were identified using NGS, culture or polymerase chain reaction (PCR). We excluded animal studies. The National Institute of Health quality assessment tool was used to grade the studies.
Main results and the role of chance: NGS enabled the detection of greater variety of bacterial genera than culture/PCR. The SM was reported to be rich and diverse in both fertile and infertile men. It is uncertain if the microbiome differs between these groups as only 1 NGS paper studied this (n=77 participants), and found no difference.

Three of the four NGS studies reported clustering of the seminal microbiome with a predominant species. All three studies reported that Lactobacillus and Prevotella were dominant in respective clusters. Lactobacillus was associated with improvements in semen parameters, and had a protective effect on quality. Conversely Prevotella appeared to exert a negative effect on sperm quality.

Bacteriospermia negatively impacted sperm concentration (difference in means(MD) -15.6,95%CI -22.65to-8.65) and progressive motility(PM)(MD -8.105,95%CI -13.568to-2.642). There was an increased prevalence of Ureaplasma urealyticum (UU) in infertile men(OR 2.25, 95% CI 1.47-3.46). UU negatively impacted concentration (MD -13.85,95%CI -20.93to-6.67) and morphology (MD -2.82,95%CI -3.546to-2.1). There was no difference in the prevalence of chlamydia trachomatis (CT) between fertile and infertile men(OR 1.11, 95%CI 0.75-1.65), and CT had no significant impact on routine semen parameters(concentration:MD -8.723,95%CI -19.255to1.809,PM:MD -1.727,95%CI -5.567to2.112, morphology:MD 0.449,95%CI -1.601to2.5). Enterococcus faecalis(EF) negatively impacted total motility(MD -11.03,95%CI -17.845to-4.22), and Mycoplasma hominis(MH) negatively impacted concentration, PM and morphology(p<0.05).
Limitations, reasons for caution: The quality of the evidence ranged from fair to low quality, and although 50,811 total subjects were studied, the numbers in the NGS studies were small (n=385). There was a high degree of heterogeneity in some of the individual meta-analyses and therefore caution must be observed when interpreting the results.
Wider implications of the findings: NGS is a superior method of characterizing the SM. UU, EF, MH and Prevotella negatively impact sperm, whereas Lactobacillus appears to protect sperm, paving the way for novel therapies (e.g.probiotics). The evidence regarding the impact of microbiome on fertility is inconclusive. Couples should be informed that further studies are needed.
Trial registration number: not applicable

P-024 Is there an endocrine contribution to the sexual dysfunction seen in end stage renal disease patients ?

S. Al Said[1], H. Elbardisi[1], K. Khalafalla[1], M. Arafa[1], A. Majzoub[1]

[1]Hamad Medical Corporation, Urology, Doha, Qatar

Study question: Does hormonal disturbance in end stage renal disease patients affect their sexual function ?
Summary answer: Endstage renal disease is commonly associated with sexual dysfunction that is more likely to be attributed to organic causes rather than solely to endocrine disturbances
What is known already: Male sexual dysfunction is commonly prevalent in patients with end stage renal disease (ESRD) and has been partly attributed to the concurrent state of hyperprolactinemia and hypogonadism, often observed in this patient population. The aim of this study was to evaluate the hormone profile and sexual function of ESRD patient, using validated questionnaires, in attempt to explore this association.
Study design, size, duration: This was a prospective study which included 98 patients with end stage renal disease (ESRD) who followed in the outpatient department of a tertiary medical centre over a period of 1 year. Patients receiving treatment for hyperprolactinemia or those known to have an endocrine disorder were excluded in addition to patients receiving medical or surgical treatment for erectile dysfunction (ED) or premature ejaculation (PE).
Participants/materials, setting, methods: Full history details with complete physical general and genital exam was conducted on the included patients. After filling the international index for erectile function-5 and the Arabic index for PE questionnaire, morning serum samples were taken from patients to measure testosterone and prolactin levels. Descriptive statistics was used to report frequency or means of variables. Chi-square test was used to examine associations between categorical variables. P<0.05 was considered statistically significant.
Main results and the role of chance: Out of the 98 ESRD patients, 72 (73.6%) were treated with hemodialysis, 13 (13.2%) with peritoneal dialysis and 13 (13.2%) with medical treatment only. Diabetes mellitus was observed in all patients (type 1, 52%; and type 2, 48%), while hypertension, coronary heart disease and dyslipidemia were detected in 97.1%, 34.3% and 25.5%, respectively. The mean age, serum testosterone and prolactin levels were 52.4 ± 12.1 years, 12.95 ± 6.5 nmol/L and 514.2 ± 592.8mIU/L. Results of the PE index questionnaire revealed that 86 (87.7) patients had PE, 9 (9.1%) probable PE and 3 (3.1%) no PE. With IIEF-5, ED was detected in 96 patients; it was severe in 23 (23.5%), moderate- severe ED in 29 (29.4%), mild-moderate ED in 30 (30.4%) and mild in 14 (14.7%). Patients were divided into 2 groups, one according to prolactin levels (normal and high) and other according to testosterone level (low and normal). 55 patients had high prolactin while 33 had low testosterone levels. No significant differences were observed in IIEF or PE index levels between patients with low/normal testosterone and normal/high prolactin.
Limitations, reasons for caution: This is a single center study.
Wider implications of the findings: Since hormonal disturbance doesn't affect sexual dysfunction, definitive treatment for sexual dysfunction should be started including medical or surgical options.
Trial registration number: NA

P-025 Prospective follow-up of semen parameters in spinal cord-injured patients (FertiSCI): a pilot study

C. Chalas[1], L. Jilet[2], V. Drouineaud[1], C. Patrat[1], J.P. Wolf[1], F. Giuliano[3]

[1]Hôpital Cochin-Port Royal, Biology of Reproduction, Paris Cedex 14, France ;
[2]URC/CIC Paris Descartes Necker Cochin, Biostatitics, Paris, France ;
[3]Hopital R. Poincare APHP, Neuro-urology, Garches, France

Study question: Are men with spinal cord injury (SCI) at risk for semen parameters impairment overtime according to the lesion characteristics and associated genital inflammatory state?
Summary answer: Neither genital inflammatory state, completenesslevel of the lesion,age nor time post SCI, seemed to exert any influence on semen quality over time.
What is known already: Spinal cord injury (SCI) primarily affects young men who have not experienced fatherhood yet. SCI often results in erectile dysfunction and anejaculation during coïtus. Semen parameters are often impaired in SCI patients mostly spermatozoa motility, vitality and typical forms associated with an elevated concentration of leukocytes. SCI patients are at high risk of urinary tract infections and positive spermoculture generating an inflammatory syndrome (IS) and exposing spermatozoa to oxidative stress (OS). Fertility is a major concern in this population and many of them fear that the delay post-SCI can negatively impact sperm quality.
Study design, size, duration: 35 SCI patients aged from 18 to 60 years old able to ejaculate by masturbation or in response to penile vibratory stimulation (PVS) have been enrolled. A prospective longitudinal study was conducted over 18 months with 4 visits to collect medical information focusing on uro-genital tract and concomitant treatments. At each visit a semen analysis was performed with the evaluation of seminal IS and OS. Thirty-five SCI patients have been included.
Participants/materials, setting, methods: Semen analysis was conducted according to WHO recommendations. IS was quantified through granulocyte concentration evaluated by leucoscreen® test and considered positive when >1million/ml and seminal plasma elastase measured by ELISA with a 500 ng/ml positive threshold. OS was assessed using the Tunel assay methodology and analyzed by flow cytometry to measure spermatozoa DNA fragmentation with a 40% positive threshold. Data were compared using Wilcoxon signed rank and the Mann-Whitney-Wilcoxon tests.
Main results and the role of chance: SCI patients mean age of was 29.4 ± 6.4 years with mean age at SCI 21.8 ± 8.3 years. Semen concentration was normal (155.1±231.2 million/ml) associated to a decrease in progressive motility (13.6±12.4%) and vitality (22.7±19.3%) and an increase in morphological abnormalities (typical forms 11.5±11.2%). Mean round cell semen concentration was increased (38.3±37.6 million/ml) as well as granulocyte concentration (46.4±121.1 million/ml). IS and OS were highly positive with a median elastase quantified at 477.4 ng/ml and the DNA fragmentation at 50%. Semen parameters were compared between patients i) positive and negative for IS and OS and ii) in absence or presence of a urogenital i.e. urinary and/or seminal tract (UGI) infection. iii) taking into account the lesion level, the completeness of the lesion, the time elapsed since SCI and age at injury. We could not find any difference in semen parameters in the presence of IS and OS nor when UGI was present. Moreover, neither completeness nor level of the lesion nor time post SCI nor age at injury did seem to influence semen quality. Semen parameters at the first and the last visit were compared in 17 patients and showed no change over time.
Limitations, reasons for caution: The study was conducted in a small sample. Only 28 semen samples were collected at first visit (V1) versus 11 at V4 indicating a high number of patients lost of follow-up. In some cases planed semen analysis has been hindered because of the decrease in semen volume characteristic of SCI.
Wider implications of the findings: Within the limits of the study, there was no significant decline in semen quality overtime. Even preliminary, these findings are essential to reassure SCI men about their future fertility. The present study is not in favor of routine sperm freezing for fertility preservation in SCI patients.
Trial registration number: NCT02144558

P-026 The Efficacy of Repeat Micro TESE after Failed First Attempt in Men with Nonobstructive Azoospermia

E. Bakircioglu[1], O. Ozman[2], S. Tosun[3], B. Numan[3], C. Sami[3], O. Cenk[3]

[1]Istanbul Florence Nightingale Hospital, Urology, Istanbul, Turkey ;
[2]Health Sciences University- Gaziosmanpaşa Taksim Education and Research Hospital, Urology, Istanbul, Turkey ;
[3]Istanbul Florence Nightingale Hospital, In Vitro Fertilization Center, Istanbul, Turkey

Study question: What is the efficacy of repeat micro-TESE in men with non-obstructive azoospermia who failed the first micro-TESE?
Summary answer: Repeat micro-TESE was enabled retrieved sperm in 18.4% of men with NOA who failed the first micro-TESE.
What is known already: Testicular sperm extraction combined with ICSI is the only way for the patients with non-obstructive azoospermia to have their own genetic offspring. Micro-TESE promises high rates of surgical sperm retrieval compared to methods such as testicular sperm aspiration and conventional TESE.

Salvage micro-TESE operation showed successful sperm recovery after failed conventional TESE in many studies in the literature.
Study design, size, duration: This was a retrospective cohort study of 125 men who failed the previous micro-TESE in other institutions that underwent repeat micro-TESE between November 2014 and July 2018. Clinical parameters of the patients were compared for the success of sperm recovery between the patients who were successful for sperm recovery and who have not.
Participants/materials, setting, methods: All of the patients underwent repeat micro-TESE operation. The age of the patients, duration of infertility, serum FSH and total testosterone levels and testicular volumes were compared between the patients who have successful sperm recovery and who have not.
Main results and the role of chance: Sperm was successfully recovered in 23 of 125 (18,4%) men with repeat micro-TESE. The age of patients (33.9±4.7,33.7±5.5; P=0.86), the duration of infertility (7.1±4.3, 6.4±3.5; P=0.47) serum FSH (22.0±13.8, 15.4±13; P=0.29) and total testosterone level (3.4±1.1, 3.1±1.6; P=0.37) did not show a statistical difference between men who have successful sperm recovery and who have not. However, testicular volume was significantly lower in men who have successful sperm recovery (8.2±5.4 ml) compared to men who have not (11.3±5.3 ml, p=0.01). Seven of 14 (50%) men who have diagnosed Klinefelter syndrome (KS) sperm recovery was successful with repeat micro-TESE.
Limitations, reasons for caution: It is a retrospective cohort study. Official records of the micro-TESE operations that the patients had previously were insufficient.
Wider implications of the findings: Our cohort is the largest repeat micro-TESE series in patients who have non-obstructive azoospermia with a failed first attempt. The chance of sperm recovery may enable valuable information for the patients before the decision to repeat micro-TESE.
Trial registration number: Not applicable

P-027 Tubular ectasia of epididymis and rete testis among azoospermia patients

H. Nguyen[1,2], H.H.T. Nguyen[1], C.K. Trinh[1], T.A. Nguyen[1], V.H. Dinh[1]

[1]Andrology and Fertility Hospital of Hanoi- Vietnam, Andrology department, Hanoi, Vietnam ;
[2]Vinmec International General Hospital, Andrology department, Hanoi, Vietnam

Study question: To identify the rate of tubular ectasia of epididymis and rete testis (TEERT) in infertile men with obstructive and non-obstructive azoospermia (OA and NOA).
Summary answer: Rates of TEERT in patients with OA and NOA were 87.8% and 22.5%, respectively.
What is known already: TEERT is a condition mainly relating to the obstruction of seminal tract. With high resolution ultrasound and the routine use of scrotal ultrasonography, this condition is increasingly diagnosed. However, it is often unclear about the clinical significance of this diagnosis.
Study design, size, duration: This monocentric, retrospective study was conducted on 203 infertile men with azoospermia who visited Andrology and Fertility Hospital of Hanoi (AFHanoi) from November 2017 to October 2019 for seeking treatment on infertility.
Participants/materials, setting, methods: Patients were chosen to take part in the study if they had information of clinical examination, serum follicle-stimulating hormone (FSH), testosterone, scrotal ultrasonography performed at AFHanoi. Participants had also to undergoing any of these sperm retrieval procedures i.e. PESA, TESE and micro-TESE in the same hospital.
Main results and the role of chance: There were 123 (60.6%) patients with OA and 80 (39.4%) patients with NOA. Rates of tubular ectasia of epididymis and rete testis in the whole sample was 62.0% (126/203 men). In men with OA, rate of TEERT was 87.8% (108/123 men), whereas in men with NOA this rate was 22.5 (18/80 men). Interestingly, among those with tubular ectasia almost all cases had the condition observed in epididymis (106/108 cases, 98.0%). However, only 2 cases (2%) had the condition observed in rete testis. As expected, sperm retrieval rate in those with TEERT was as high as 96% (121/126 men).
Limitations, reasons for caution: This study is a retrospective cohort study with all associated inherent biases. The findings of this study should be confirmed with further prospective study.
Wider implications of the findings: Our study shows that TEERT is highly prevalent in infertile men with OA and those with TEERT are much likely having their sperm retrieved by a sperm retrieval technique. This finding suggests the predictive value of TEERT in the prediction of OA and sperm retrieval.
Trial registration number: not applicable

P-028 Bicarbonate-dependent alkalinization of acrosomal pH occurs during human sperm capacitation

"Abstract withdrawn by the authors"

P-029 Efficacy of Magnetic Activated Cell Sorting (MACS) in Sperm Selection for Intracytoplasmic Sperm Injection (ICSI)

T.T.H. Tran[1], T.T.C. Bach[1], V.T. Phung[1], T.T. Tran[1], T.L. Dinh[1]

[1]Hospital of Post and Telecoms, Assisted reproductive technology center, Hanoi, Vietnam

Study question: This study investigated if the application of MACS would have a critical effect on ICSI outcome, especially with patients having multiple unsuccessful IVF cycles.
Summary answer: The results of this study suggested favorable influence on patients with multiple failed IVF cycles and highly promising for others.
What is known already: MACS is reported as a possible procedure to help increase ICSI outcome by using annexin V to separate apoptosis sperms. The separation of apoptosis sperms is believed to result in a positive change in sperm quality.
Study design, size, duration: 114 patients were enrolled in this study between February 2018 to January 2020. We analysed the outcome of 52 multiple returning cycle couples who has undergone one MACS/ICSI cycle (group 1) and their most recent non-MACS/ICSI cycle (group 2). We also accessed the outcome of 62 couples who has only has one cycle of IVF done (group 3).
Participants/materials, setting, methods: Group 1 and 2 comprised of 52 multiple returning cycle couples who has undergone one MACS/ICSI cycle and one non-MACS/ICSI cycle. 62 participants in our group 3 has only one IVF cycle and has specifically requested for MACS/ICSI to be performed. In all MACS/ICSI cycles, ejaculated semen was undergone density gradient centrifugation in combination with MACS. Collected sperms were used for routine ICSI. T-Test and Chi-square test were applied.
Main results and the role of chance: Group 1 has higher fertilization rate (67%) than group 2 (59%). Group 2 with non-MACS procedures saw 16 embryo tranfers for the first time and 04 for the second, performed on X couples with 8 couple having no embryos; cumulatively, positive beta-HCG rate was 13%. Whereas in group 1, all but 1 couples had embryos; 19 couples have had embryo transferred, resulted in 45 % positive beta-HCG rate; In group 3, the FR and positive beta-HCG rate respectively was 78% and 51%. In conclusion, there were significant differences in the result of group 1 and 2. For group 3 where patients requested to perform MACS , the result was also very promising.
Limitations, reasons for caution: The sample size of this study participants is small. Further studies with more control groups with sperm and eggs quality analytics is needed to confirm our methodology.
Wider implications of the findings: According to this study, the application of MAC/ICSI is a novel and easy to perform clicician technique with promising results.
Trial registration number: Not applicable

P-030 Severe male factor affects the blastocysts ploidy status

E. Zhylkova[1], O. Feskov[2], O. Somova[3], O. Zozulina[4], A. Feskova[5]

[1]Centre of Human Reproduction Sana-Med, Genetic laboratory, Kharkiv, Ukraine ;
[2]Center of Human Reproduction "Clinic of Professor Feskov A.M.", IVF department, Kharkov, Ukraine ;
[3]Center of Human Reproduction "Clinic of Professor Feskov A.M.", IVF Department, Kharkiv, Ukraine ;
[4]Center of Human Reproduction "Clinic of Professor Feskov A.M.", IVF Department, Kiev, Ukraine ;
[5]Kharkiv National Medical University, Department of Obstetrics- Gynecology and Pediatric Gynecology, Kharkiv, Ukraine

Study question: Does the severe male factor affect the blastocysts ploidy status and IVF outcome?
Summary answer: Severe male factor of infertility affects the blastocysts' aneuploidy. Sperm parameters affect blastocyst morphology. The IVF outcome does not depends on severe pathospermia.
What is known already: Male factor of infertility is responsible for up to 60% of fertility problems worldwide. The development of intracytoplasmic sperm injection (ICSI) has allowed patients with severe oligozoospermia to have children. The question about the effect of severe male infertility on embryo aneuploidy and IVF results is still discussable. Almost 60% of the blastocysts in IVF are aneuploid. Existing data regarding the relationship between embryo morphology and its ploidy are conflicting.
Study design, size, duration: The effect of severe male factor of infertility on the early embryo development was studied. The correlation of sperm parameters with the morphology of blastocysts and PGD and IVF outcomes was examined. The study's protocol was approved by the Center's IRB.
Participants/materials, setting, methods: Totally the DNA samples of 406 preimplantation blastocysts from 117 men diagnosed with severe male factor of infertility and normal karyotype 46,XY were examined using the method of next generation sequencing (NGS). ICSI/IMSI procedure was done. The rates of blastocysts euploidy and IVF outcome were compared with 299 biopsied blastocysts from 67 patients with normal sperm parameters. A chi-squared test and Spearman coefficient were used to perform statistics analysis.
Main results and the role of chance: The rate of blastocysts aneuploidies was significantly higher in group of patients with severe male factor of infertility comparing with the control group (51.1% vs. 33.8% respectively, $\chi^2 = 6.125$, $\chi^2_{critic.} = 3.841$, $P = 0.014$). There was a significant positive correlation between the blastocysts euploidy rates and sperm concentration ($r_s = 0.16$, $P < 0.05$). A significant positive correlation between sperm motility and blastocysts morphology was proved ($r_s = 0.17$, $P < 0.05$). The transfer of one euploid blastocyst was performed in each case for patients in both studied groups. There was no significant difference in IVF outcomes in both groups. The clinical pregnancy rates were 53.8% and 63.2% in group of patients with severe male factor of infertility and in control group respectively (P>0.05).
Limitations, reasons for caution: Blastocyst biopsy can be carried out for the embryos with the high quality of morphology.
Wider implications of the findings: *The* formation of the blastocyst and embryo implantation may be blocked at various stages of development. Performing the PGD test using the high resolution techniques for patients with severe pathospermia results in high IVF outcomes. The necessity of PGD for patients with severe male infertility is proved.
Trial registration number: No number

P-031 Vitamin D supplementation improves the Leydig Cell function in infertile men with persistent vitamin D insufficiency

R. Holt[1]

Study question: Can vitamin D supplementation improve the Leydig Cell function in infertile men?
Summary answer: Yes, high-dose vitamin D supplementation had a beneficial effect on Leydig Cell function in infertile men with low vitamin D and high PTH.
What is known already: Vitamin D is important for calcium homeostasis and bone health, but the spectrum of vitamin D related effects has expanded in recent years. All actions of vitamin D are mediated by the interaction between activated vitamin D (calcitriol) and the vitamin D receptor (VDR) which is expressed in human Leydig cells and thus makes a direct effect of vitamin D on steroidogenesis plausible. Analyses of VDR knock-out (KO) mice revealed impaired reproductive and endocrine function compared with wildtype mice. Furthermore, a few cross-sectional studies reported a positive association between vitamin D and testosterone.
Study design, size, duration: A single-center, randomized clinical trial with 307 infertile men randomized to receive placebo or a single dose of cholecalciferol 300,000 IU followed by 1400 IU + 500 mg of calcium daily for 150 days.
Participants/materials, setting, methods: Men included in the randomized clinical trial were initially referred to our andrological outpatient clinic due to infertility and subsequently invited to participate in the study. The primary endpoint was change in semen quality, while serum testosterone was a secondary endpoint.
Main results and the role of chance: Treatment of infertile men with high-dose vitamin D did not affect sex steroid levels. There was no difference in serum levels of testosterone, estradiol, LH or FSH between vitamin D and placebo treated men. However, a predefined subgroup analysis of men with vitamin D insufficiency and high PTH at baseline had significant higher free testosterone (Δ24%; p=0.027) and free testosterone/LH ratio (Δ34%; p=0.048) after 150 days vitamin D and calcium treatment compared with the placebo-treated men.
Limitations, reasons for caution: Our biggest limitations are the small number of men in the subgroupanalyses. Our findings should be verified in large clinical trials preferably in men with persistent vitamin D insufficiency characterized by low serum 25-OHD and high PTH.
Wider implications of the findings: Our findings suggest an increased awareness on vitamin D status in infertile men which may be important to avoid deterioration of their Leydig Cell function
Trial registration number: NCT01304927

P-032 Study on the specific piRNAs in human seminal plasma as a non-invasive diagnostic indicator before microsurgical testicular sperm extraction

X. Huang[1], **S. Xie**[1]

[1]*Center for Reproductive Medicine- Tongji Medical College- Huazhong University of Science and Technology- China, Department of Andrology, wuhan, China*

Study question: Clinical studies have not found an effective non-invasive test to accurately determine the presence of sperm in the testicles of non-obstructive azoospermia (NOA) patients
Summary answer: Except AZFa and AZFb microdeletion for a small group of NOA, no other reliable diagnostic technique has been widely accepted nowadays.
What is known already: piRNAs are a series of specific small molecule nucleic acid produced in the testis of different mammals. Previously, we compared piRNAs expression profiles in the testicles of NOA patients with successfully identified sperm and those without sperm by using second-generation sequencing. We identified and screened a variety of piRNAs with significant differences between the two groups.
Study design, size, duration: We randomly selected 120 NOA patients who were interested in micro-TESE and collected their ejaculated semen prior to microsurgery for piRNAs detection.
Participants/materials, setting, methods: According to our previous sequencing results, we screen out eight specific piRNAs. Before Micro-TESE performed for a total of 120 NOA cases, these piRNAs in human seminal plasm were detected by Fluorescent quantitative PCR. Each specimen was tested three times. Patients were classified into two groups (successful sperm retrieval [SSR] and unsuccessful sperm retrieval [USR]) after the operation of micro-TESE. Statistics were conducted according to the results of micro-TESE and seminal plasma piRNAs detection.
Main results and the role of chance: Three piRNAs DQ578561, DQ576926 and DQ577970 were found to have significantly higher expressions in the SSR group (51 cases) than the USR group (69 cases).
Limitations, reasons for caution: A relative small sample without pathological classification of testicular tissue in the patients with NOA.
Wider implications of the findings: piRNA DQ578561, DQ576926 and DQ577970 are expected to be new diagnostic indicators for non-invasive prediction of testicular residual sperm in NOA patients, which need further clinical verification with a larger sample size in multiple centers.
Trial registration number: No. 31671551

P-033 A new container with higher success rate for the cryopreservation of testicular tissues and motile spermatozoa from mice and testicular cancer patients

K. Nakata[1], **S. Wakayama**[2], **M. Iijima**[3], **T. Wakayama**[2], **H. Nakata**[3], **A. Mizogami**[3], **N. Yamashita**[4]

[1]*Yamashita shonan yume clinic, Reproductive Medicine Reserch Center, Kanagawa, Japan ;*
[2]*University of Yamanashi, Faculty of life and environmental sciences, Yamanashi, Japan ;*

[3]Kanazawa University, Integrative Cancer Therapy and Urology- Division of Cancer Medicine- Graduate School of medical Science, Kanazawa, Japan ;
[4]Yamashita Shonan Yume Clinic, Doctor division, Kanagawa, Japan

Study question: Is the new container effective for the freezing and thawing of the testicular tissues (TT) and motile spermatozoa?
Summary answer: The new container is effective for the cryopreservation of TT in order to preserve motile spermatozoa from mice and testicular cancer patients.
What is known already: Most men diagnosed with testicular tumors are between ages 15-40. Although the European Association of Urology recommends all testicular cancer patients are referred for semen analysis and cryopreservation prior to treatment, it was reported that 6-24% of testicular cancer patients were azoospermia, 50% were Oligozoospermia. Because testicular cancer patients have a low sperm count and may not be able to collect enough sperm for ART, TT banking is recommended. Commonly, straws or vials have been used for cryopreservation of TT. There are no studies referring to the comparison between different methods. But after thawing, motility of sperm is very low.
Study design, size, duration: Mouse TT was divided into nine groups to examine the effect of the combination of freezing speed (slow vs. rapid), freezing medium (Cellbanker1 vs. Fertiup), and freezing vessel (New container vs. Cryotube), and control (Fresh), repeatedly. That is, SCN, SFN, RCN, RFN, SCC, SFC, RCC, RFC and Control. TT from Testicular cancer patients was divided into two groups using slow freezing, with (Cellbanker1 vs, Sperm freezing) and the new container, that is SCN and SSN.
Participants/materials, setting, methods: Mouse and testicular cancer patient's TT were moved into the physiological saline solution and cut into 2-3 mm pieces with the scissors. Mice TT was frozen in 9 groups, and testicular cancer patient's TT was frozen in 2 groups. After thawing, we observed sperm motility, sperm membrane damage and Caspase-3 assay in mice and testicular cancer patients. Also *In vitro* and *in vivo* development after embryo transfer were assessed in mice.
Main results and the role of chance: The average number of mouse motile spermatozoa after thawing was examined. The motility rate was 25.7±13.6 % in SCN. PI positive rate was 20.0±10.0 in SCN. SCN was significantly higher than the other groups in motility and PI positive rate (P<0.05). The highest rate was obtained when TT was frozen using slow freezing, Cellbanker1 and New container[若山1] . After ICSI, the blastocyst rates were 54.9±13.6 % in SCN, 48.4±25.7 % in SFN, 40.8±16.2 % in SCC, 20.6±25.4 % in SFC and 64.2±10.8 % in Control, respectively. SCN was significantly higher than SFC (P<0.05). Additionally, we obtained fetuses 22.4% in SCN, 22.8% in SFN, 15.4% in SCC, 14.3% in SFC and 42.0% in Control. Five testicular cancer patient's tissues were frozen by SCN or SSN. After thawing, sperm motility rates of 5 patients were 18.9±13.2% (477/2681) in SCN and 29.6±13.2% (1415/4832) in SSN. SSN was significantly higher than SCN (*P*<0.05). PI positive sperm rates of 3 patients were 53.3±20.1% (293/460) in SCN and 29.6±12.5% (159/469) in SSN. SSN was significantly higher than SCN (*P*<0.02). In Caspase-3 assay of 3 patients, negative cell number was 127 in SCN, 255.5 in SSN and 1046.5 in control, respectively.
Limitations, reasons for caution: This is a basic study on a relatively small sample size with limited conditions. The confirmation using larger samples under various conditions may be required. Furthermore, although healthy mouse offspring was obtained, we need to check the safety of using TT frozen-thawed sperm in ART.
Wider implications of the findings: The findings of this study indicate that the new container allows checking inside the seminiferous tubule using microscope. Because it's made of polydimethylsiloxane and the bottom is transparent and very thin. It is also useful for a small number of spermatozoa (K. Nakata, et al. 2019) and testicular tissues cryopreservation.
Trial registration number: No

P-034 Impact of tobacco smoking on the expression level of H2BFWT, TNP1, TNP2, PRM1 and PRM2 genes in spermatozoa

H. Amor[1], M.E. Hammadeh[1]

[1]University of Saarland, Obstetrics and Gynecology, Homburg/Saar, Germany

Study question: Can Tobacco smoke alter the expression level of H2BFWT, TNP1, TNP2, PRM1, and PRM2 genes?
Summary answer: Can Tobacco smoke alter the expression level of H2BFWT, TNP1, TNP2, PRM1 and PRM2 genes in spermatozoa?
What is known already: Various studies were focusing on the mechanisms by which the environmental and lifestyle factors especially smoking influence on the sperm genome and epigenome.

Testis-specific histones like H2BFWT, transition proteins TP1 and TP2 and protamines P1 and P2 are the main nuclear proteins that have a crucial role during the protamination of sperm genome during spermiogenesis. Protamination leads to the elimination of histones carrying epigenetic signals. Thus, protamination take part in the epigenetic regulation of the spermatozoa and any factor changing protamination may be considered as an epigenetic signal like DNA methylation and histone modification influencing the transcription regulation after fertilization.
Study design, size, duration: A prospective controlled trial carried between August 2016 and April 2018 at the Department of Obstetrics and Gynecology, University of Saarland, Germany. 167 semen samples were included in this study and divided into 54 non-smokers (G1) and 113 heavy-smokers (G2).
Participants/materials, setting, methods: After semen purification, total RNA was isolated using Isolate II DNA/RNA/Protein kit then concentration and purity were checked with Nanodrop spectrophotometer ND-2000c. RT-qPCR technique was used for the quantification of the expression level of the five studied genes using miScript reverse transcription and QuantiTect SYBR Green PCR Kits. Protamine deficiency (CMA3+) was assessed by Chromomycine CMA3 staining and sperm DNA fragmentation (sDF) by TUNEL assay.
Main results and the role of chance: In G1, the sperm count (88.09± 63.42 mill/ml), progressive motility (27.31±21.78%), normal morphology (10.87±12.11%), were significantly higher (p<0.01) than G2 (62.17± 51.68 mill/ml; 14.86±10.95%; 4.01±2.88%, respectively).

Whereas, CMA3+ (23.50±14.70%) and sDF (17.41±14.59%) in G1 were significantly lower (p<0.01) than G2 (33.58±21.34%; 27.55±20.01%, respectively).

Protamine mRNA ratio was significantly higher in G1 in comparison to G2 (0.11 ± 0.84 vs. 0.60 ± 1.08; p=0.001). Unlike G1, the protamine mRNA ratio significantly correlates with CMA3+ (r=0.413, p=0.0001) and sDF (r=0.302, p=0.003) in G2.

Moreover, the relative amounts of each studied gene mRNA (mean delta ct) were differentially expressed between G1 and G2 and this difference was highly significant (p<0.01). Besides, H2BFWT, TNP1, TNP2, PRM1, and PRM2 genes were down-regulated in spermatozoa of G2 compared to G1 (Fold change <0.5).
Limitations, reasons for caution: The size number of the sample.
Wider implications of the findings: Studied genes are expressed in a well-organized chronological manner and any alterations from an internal or external factor like smoking my altered this mechanism and thus altered spermiogenesis and sperm function.
Trial registration number: not applicable

P-035 Sperm DNA integrity and human papillomavirus (HPV) infections: a controversy that could be resolved by a new molecular approach

R. Schillaci[1], T. Notari[2], G. Capra[3], M.A. Ragusa[4], M.C. Roccheri[4], A. Perino[3], A. Ferrigno[4], L. Bosco[4]

[1]Centro Interaziendale di Procreazione Medicalmente Assistita- Ospedale "V. Cervello"- Università di Palermo- Italy, Department of Sciences for Health Promotion and Mother-Child Care 'G. D'Alessandro' PROSAMI, Palermo, Italy ;
[2]Check Up Research Unit - Polydiagnostic and Day Surgery Centre - Salerno, Check Up Research Unit - Polydiagnostic and Day Surgery Centre, Salerno, Italy ;
[3]University of Palermo, Department of Sciences for Health Promotion and Mother-Child Care 'G. D'Alessandro' PROSAMI, Palermo, Italy ;
[4]University of Palermo, Department of Biological- Chemical- and Pharmaceutical Sciences and Technologies STEBICEF, Palermo, Italy

Study question: The aim was to determine if HPVs affect spermatozoa DNA integrity. To resolve the discrepancy regarding the association between HPV infections and sperm DNA damage.

Summary answer: To elucidate if HPV impairs DNA integrity, we suggest to investigate HPV DNA positivity in spermatozoa by a differential lysis procedure before TUNEL assay.

What is known already: HPV can influence human fertility, in fact it has been demonstrated that infected couples undergoing assisted reproduction techniques showed an increased risk of pregnancy loss compared with non-infected counterparts.

Recent studies revealed that DNA Fragmentation Index (DFI) was not different in HPV-infected and in non-infected semen samples. Other evidences reported statistically significant differences. Therefore, it remains controversial whether HPV infection in semen is associated to DNA damage.

Moreover, it is known that HPV DNA can be found in the different semen components, then it is necessary to investigate if patients defined as HPV-positive have viral DNA contained in the spermatozoa.

Study design, size, duration: From April 2015 to October 2019, a total of 105 patients: 56 HPV positive and 49 HPV negative, male partners of women with High Grade Squamous Intraepithelial Lesions (HSILs) positive for high risk (HR) HPVs were enrolled in an observational study.

Participants/materials, setting, methods: Patients who met the following inclusion criteria were enrolled: age between 18 and 50 years; partner positive for HR-HPV types; sperm concentration after swim up procedure that exceeded 1 million/ml. Exclusion criteria were: varicocele; cryptorchidism; other genital infections; chemo/radio therapy. Seminal parameters were evaluated according to 2010 World Health Organization guidelines and sperms were then separated by swim-up technique. HPV-DNA was detected and genotyped by reverse hybridization. DFI was evaluated by TUNEL assay.

Main results and the role of chance: As we have previously demonstrated, no statistically significant effect of HPV infection on sperm parameters was observed when we compared HPV-positive total semen samples with respect to HPV-negative counterparts. However samples showing higher viral DNA ratio had lower percentage of progressively motile sperms.

In our experience, DFI values are not different in HPV positive and in negative samples (17% *vs* 20% respectively).

This result could be explained by the following considerations. Our previous data showed that HPV DNA can be identified in every fraction of semen, by differential lysis procedure: spermatozoa, somatic cells and seminal plasma. Different samples can contain HPV DNA in different fractions and a sample could result HPV-positive also in absence of viral DNA into spermatozoa. Therefore, it is necessary to determine which semen fraction contains viral DNA in order to classify samples as positive or negative with respect to spermatozoa infection before to perform TUNEL assay, since DFI is evaluated exclusively into spermatozoa.

Limitations, reasons for caution: Low number of samples because of the difficulty to find male partners agreeable to the enrollment in the study.

Wider implications of the findings: Semen parameters and DFI may have no significant differences with respect to HPV positivity detected by conventional procedures. Therefore, it is advisable to perform the differential lysis procedure in HPV-positive patients to verify in which fraction the virus is located and as a consequence its potential effect on male fertility.

Trial registration number: Not applicable

P-036 Will the use of testicular spermatozoa optimise reproductive outcomes?

R. Mani Raghupathy[1], K.C. Mantravadi[2], D. Rao Gedela[3]

[1]Oasis Centre of Reproductive Medicine, Clinical Embryology, Hyderabad, India ; [2]Oasis Centre for Reproductive Medicine, Clinical Embryology, Hyderabad, India ; [3]Oasis Centre for Reproductive Medicine, Reproductive Medicine, Hyderabad, India

Study question: Will TESA (Testicular Sperm Aspiration) be a beneficial procedure for couples with raised DFI in the male partner.

Summary answer: Testicular spermatozoa obtained surgically from individuals with raised DFI, will benefit the couple in achieving optimal reproductive outcomes

What is known already: Raised DFI (DNA Fragmentation Index) is one of the major causes of male infertility and is known to affect fertilisation, embryo quality, implantation, miscarriage & pregnancy rates after assisted reproduction. ROS is known to attack and damage the spermatozoal DNA happens as spermatozoa travels through the epididymis. And hence it is widely understood and accepted that testicular spermatozoa have a relatively lesser degree of DNA fragmentation. Surgical sperm retrieval techniques have become more refined over the years and now yield good quality testicular spermatozoa

Study design, size, duration: Data was collected retrospectively from 2015, till 2018. SCSA (Sperm Chromatin Structure Assay) was done to assess the DNA fragmentation Index (DFI) of male partner of all couples who had one failed IVF cycle. Those with DFI>30 were identified. Couple with female partners age>35 years were excluded. The Fertilisation, Blastocyst, Implantation, Clinical Pregnancy, Miscarriage, Live Birth rates, along with Perinatal and neonatal outcomes of the subjects were then compared.

Participants/materials, setting, methods: 605 subjects were included in the study based on the pre-requisites Those, who discontinued treatment, or used Donor sperms for ICSI, were excluded. Couple who chose ICSI (Intra Cytoplasmic Sperm Injection) with ejaculate (n=14) were included in the control group, and the study group included all who chose ICSI with TESA obtained spermatozoa (n=37). TESA was done after taking all aseptic precautions and following the defined procedural Standard Operating Protocol.

Main results and the role of chance: The embryo parameters, Fertilisation Rate (TESA = 96.59%; Non-TESA = 89.88%) & Blastocyst Rate (TESA = 33.65%; Non-TESA = 40.95%) in both groups were comparable. The implantation rates were higher for the study group (TESA= 60.0%; Non-TESA = 23.1%) in the control group. Pregnancy induced hypertension and IUGR were not observed in both the groups. The Clinical pregnancy (TESA = 63.2%; Non-TESA = 28.6%) and Live birth rates (TESA = 42.1%; Non-TESA = 28.6%) were better in the study group. 4 subjects in the TESA group have ongoing pregnancy There were no adverse perinatal and neonatal outcomes in the study group. Though Blastocyst rates seemed better in the Non-TESA group, reproductive outcomes were better in the TESA group. And also, the perinatal and neonatal outcomes were confirming the safety of using TESA obtained spermatozoa for ICSI in couples with raised DFI.

Hence, based on the data obtained from the study, it is safe to assume that the use of testicular spermatozoa for raised DFI seems to be a safe and beneficial intervention.

Limitations, reasons for caution: The major limitations of this study is that this is a retrospective study with a small sample size, along with the fact that TESA is an invasive intervention

Wider implications of the findings: Male partners with raised DFI could be offered TESA as a treatment option, benefiting couples with optimal reproductive outcomes.

Trial registration number: Not Applicable

P-037 Body mass index and age correlate with antioxidant supplementation effects on sperm quality: Post-hoc analyses from a double-blind placebo-controlled trial

G.M. Busetto[1], F. Del Giudice[1], A. Virmani[2], E. De Berardinis[1], A. Agarwal[3]

[1]Sapienza University Policlinico Umberto I, Urology, Roma, Italy ; [2]Alfasigma HealthScience, Nutraceuticals, Utrecht, The Netherlands ; [3]American Center for Reproductive Medicine, Andrology Center, Cleveland, U.S.A.

Study question: Is there any correlation between age and body mass index (BMI) with the efficiency of medical therapy for infertile men?

Summary answer: Medical therapy with compounds is more effective in subjects with varicocele younger than 35 years and with BMI <25.

What is known already: The decline of male fertility is an emerging problem and causes for these changes are lifestyle factors and global changes in our eating habits with increasing evidence of obesity. Spermatozoa are vulnerable to lack of energy and oxidative stress as a result of elevated levels of reactive oxygen species. Therefore, it is essential that appropriate nutrients are available during maturation. At present, no studies investigated the correlation of age and body mass index (BMI) with the efficiency of a medical therapy in infertile men.

Study design, size, duration: The present analysis stems from the extensive database that has been created to determine the effects of antioxidant supplementation on semen quality. This database includes 104 infertile patients with oligo- and/or astheno- and/or teratozoospermia with an average age of 32.5 years, enrolled in a randomized, double-blind, placebo-controlled trial. Included

are 52 patients with grade I-III varicoceles and 52 patients without varicocele that were divided into supplementation or placebo groups.
Participants/materials, setting, methods: In accordance with the randomization schedule, subjects received 2 packets of either supplement or placebo daily for 6 months. Semen parameters were evaluated in a standard semen analysis at the beginning of the treatment (V1) and after completing 6 months of therapy (V2). Pregnancy rate was included as a secondary outcome. The present post-hoc analyses were carried out on the samples as categorized by age/BMI and presence/absence of varicocele.
Main results and the role of chance: One of the primary aims of this study was to correlate the results of the semen analysis with BMI and age. In particular, we wanted to see if aging and obesity status would decrease efficacy of the supplementary antioxidant treatment on main sperm parameters (see Tables 1-5). For BMI, a significant difference was observed in the BMI <25 group with varicocele for total sperm count (p=0.0272) and progressive motility (p=0.0159). No statistical significance was observed in the combined classes. The results were partially confirmed by carrying out the Chi-Square test on the data arranged as "Responder/Non Responder". As for the total sperm count, in both the BMI <25 and the combined varicocele group (i.e. BMI <25 and age <35) a statistical difference was observed (p=0.0066 and p=0.0078 respectively). These post-hoc analyses suggest that the nutritional supplement seems to be more effective in subjects younger than 35 years with a BMI below 25.

Looking at other parameters, patients treated with compounds obtained a statistically significant improve of sperm parameters for the following items: total count, progressive and total motility, morphology.

As a secondary outcome, 12 pregnancies occurred during the follow-up time: 10 in the supplementation group and 2 in the placebo group.
Limitations, reasons for caution: Even as a double-blind placebo-controlled study with very strict inclusion and exclusion criteria, we did not include sperm DNA fragmentation. Also, an oxidative stress measure such as ORP was not included. There also may be other factors besides aging and obesity involved, including lifestyle, associated disease and fat distribution.
Wider implications of the findings: In addition to earlier findings regarding improved sperm parameters in supplemented patients, these post-hoc analyses suggest that antioxidant supplementation seems to be more effective on improving sperm parameters in subjects aged less than 35 years old and with BMI below 25.
Trial registration number: NCT04177667

P-038 New insights into the physiopathology of teratozoospermia and its association with sperm DNA defects, apoptotic alterations and oxidative stress

O. Ammar[1], M. Mehdi[2], A. Sallem[2], M. Muratori[3]

[1]Faculty of Medicine University of Monastir-, Laboratory of Histology Embryology and Cytogenetic LR 18-ES 40-, Monastir, Tunisia ;
[2]Faculty of Medicine- University of Monastir, Laboratory of Histology Embryology and Cytogenetics LR 40 ES 18, Monastir, Tunisia ;
[3]Center of Excellence DeNothe, Department of Experimental and Clinical Biomedical Sciences "Mario Serio"- Unit of Sexual Medicine and Andrology, Florence, Italy

Study question: This study set out to determine the level of sperm nuclear DNA damage in patients with isolated poymorphic teratozoospermia and examining its relationship with oxidative stress and apoptosis.
Summary answer: Decreased seminal antioxidant profile may be an important factor involved in the mechanism of sperm cell death-mediated DNA breaks in teratozoospermic semen.
What is known already: Sperm morphological defects is associated with apoptosis.
Study design, size, duration: A total of 89 patients was divided into two groups, men with isolated teratozoospermia (n = 69) and men with normal semen parameters (n = 20) as controls.
Participants/materials, setting, methods: Sperm DNA breaks were evaluated by using acridine orange staining. The proportion of viable spermatozoa with mitochondrial transmembrane depolarization was detected by fluorescence microscopy through the use of MitoPT-JC-1 staining method. Bivariate Annexin V/ 6-CFDA analysis was then carried out to measure the percentage of both viable and dead spermatozoa with phosphatidylserine (PS) externalization. Seminal antioxidant profile (reduced Glutathione (GSHr); Oxidized Glutathione (GSSG); Glutathione-S-transferase (GST)), and total protein sulfhydryl (P-SH) concentrations were measured spectrophotometrically.
Main results and the role of chance: Patient with isolated teratozoospermia, when compared to fertile donors, showed significantly increased level of single sperm DNA breaks, and higher proportions of spermatozoa with phosphatidylserine externalization and mitochondrial depolarisation. Among the different studied oxidative stress seminal parameters, the rates of seminal GSHr, GST and P-SH were significantly decreased in the patient group. However, the seminal levels of GSSG and GST have decreased, but only GST didn't showed a significant difference. Interestingly, significant relationships were found between the studied apoptotic markers and the rate of atypical sperm forms with the incidences of head abnormalities. Furthermore, positive inter-correlations were found between sperm DNA defects, impaired seminal antioxidant profile and the sperm apoptotic markers.
Limitations, reasons for caution: Further combined analysis of oxidative stress, apoptotic markers and nuclear defects should provide complementary measurements for the evaluation of sperm quality and could contribute to provide adequate reproductive and genetic counselling for hypofertile patients with isolated polymorphic teratozoospermia.
Wider implications of the findings: Sperm DNA defects as well as apoptosis and seminal oxidative stress are interlinked in the context of teratozoospermia, and constitute a unified pathogenic molecular mechanism
Trial registration number: not applicable

P-039 In spermatozoa collected after pellet swim up, when total dna fragmentation is higher than 15%, the normal morphologically spermatozoa population shows an increased dna damage.

G. Ruvolo[1], A. Ferrigno[2], M.C. Roccheri[2], E. Cittadini[1], A. Pane[1], C. Simonaro[1], B. Ermini[3], I. Camera[3], A.M. Bruccoleri[1], M. Manno[1], A. Lo bue[1], L. Bosco[2]

[1]Centro di Biologia della Riproduzione, Centro di Biologia della Riproduzione, Palermo, Italy ;
[2]University of Palermo- Palermo- Italy, Department of Biological- Chemical- and Pharmaceutical Sciences and Technologies STEBICEF-, Palermo, Italy ;
[3]CIPA- Centro Italiano di Procreazione Assistita, CIPA- Centro Italiano di Procreazione Assistita, Roma, Italy

Study question: We investigated the DNA Fragmentation Index (DFI) in motile normal morphologically spermatozoa comparing samples with total DFI < 15% Vs ≥ 15% collected after pellet swim up
Summary answer: In the case of DFI ≥15% the percentage of normal morphologically spermatozoa with fragmented DNA is significantly higher than the population with DFI < 15%
What is known already: Intracytoplasmic sperm injection (ICSI) is widely used in the treatment of male infertility. Only morphologically normal spermatozoa are mainly used by embryologists to fertilize an oocyte. Different papers have reported that spermatozoa with apparently normal morphology may have DNA fragmentation. These evaluations suggest that it is possible that normal-shaped spermatozoa but with DNA fragmentation could be easily selected to fertilize oocytes during ICSI. It is known that the presence of an increased proportion of normal spermatozoa with damaged DNA is negatively associated with embryo quality affecting both pregnancy and implantation outcomes after ICSI.
Study design, size, duration: We designed an observational study on 70 male patients. We speculated that the examination of DNA integrity in motile and morphologically normal sperm, collected after pellet swim up, could provide useful information concerning sperm competence, rather than the DFI evaluation in the raw seminal sample. We analyzed data from January 2019 to December 2019. The aim is to demonstrate that DFI in normal morphologically spermatozoa, could be indicated as predictive parameter of ICSI success.
Participants/materials, setting, methods: DFI and traditional semen parameters (WHO, 2010), were evaluated in all patients. DFI was calculated using *in situ* TUNEL assay in at least 250 spermatozoa. By means of NIS-Elements BR 3.10 image analyzer software (Nikon) using images of the same field (light, fluorescence and "merged") it was possible to evaluate sperm morphology associated with DNA fragmentation. Data were analyzed using the Kruskal-Wallis

test, a non-parametric ANOVA, confirmed by restrictive Bonferroni correction using the Dunn's test.

Main results and the role of chance: In this observational study we included 70 oligoasthenospermic patients undergoing ICSI. The patients were classified in 2 groups according to the sperm DFI: Group A (n=35) included those who had a DFI < 15% in the population of sperm collected after swim up. In group B (n= 35) patients with a DFI ≥ 15%. We did not find any statistical difference between the two groups in the traditional sperm parameters like density, motility and morphology.

We observed that, in Group A, the average value of the total of sperm DFI was 9.32% while in Group B was 24.71 % (p< 0.0001). When the analysis was restricted only to spermatozoa with normal morphology, it was observed that among patients of Group B the DFI value was 13.6%, while in A Group the average DFI value was 2.2%, with a strong statistical difference (p<0.0001). DFI calculated on motile, normal morphologically spermatozoa can provide an important information on the probability and risk of injecting, during ICSI procedure, a sperm with normal morphology but with fragmented DNA. This risk is higher if the sperm population collected after pellet swim up has a DFI higher than 15%.

Limitations, reasons for caution: This type of analysis only provides a prediction to select a sperm with fragmented DNA, but does not allow the selection of single spermatozoa with intact DNA to be used for ICSI. Further studies are needed to correlate these data with the clinical outcome.

Wider implications of the findings: Our results suggest that the evaluation of DFI in morphologically motile normal sperm selected after pellet swim up appears to be a more accurate strategy to evaluate the sperm competence, with the aim to improve the ICSI outcomes, than the traditional evaluation of sperm DFI in the whole seminal sample.

Trial registration number: not applicable

P-040 The impact of motility, morphology and presence of testicular spermatozoa on fertilization, embryo development and live birth rates, in fresh and frozen testicular samples

C. Oraiopoulou[1], A. Vorniotaki[1], E. Taki[1], A. Papatheodorou[1], M. Moissidou[1], N. Christoforidis[1], A. Chatziparasidou[1]

[1]Embryolab IVF Clinic, Embryolab, Thessaloniki, Greece

Study question: Does cryopreservation or the quality parameters of testicular spermatozoa in fresh or frozen samples have an impact on fertilization rate, embryo development and live birth rate?

Summary answer: Although live birth rate (LBR) is not directly associated to any parameters examined, morphology and motility of testicular spermatozoa influence the number of available embryos.

What is known already: Almost 5% of couples undergoing IVF treatments are confronted with azoospermia and are counseled towards TESE-ICSI cycles. At the same time, it has been reported that there is no influence of the use of cryopreserved testicular sperm in fertilization rate and live birth rate and in the presence of motile spermatozoa, high embryo quality and pregnancy rates are expected. Motility of the spermatozoa during the ICSI procedure has been associated to live birth, while other studies claim that motility of either fresh or frozen/warmed testicular spermatozoa is the only parameter associated to ongoing pregnancy.

Study design, size, duration: A retrospective cohort study between 01/2014 and 12/2017 was performed in Embryolab IVF Clinic, Greece, including 108 TESE-ICSI treatment cycles. Logistic regression analysis was used to explore the influence of variables (fresh-frozen/warmed testicular tissue, presence/motility/morphology of testicular spermatozoa) in fertilization rate, embryonic development and LBR. Women above 38 years old, frozen oocyte cycles, PGT cycles and couples with abnormal karyotypes were excluded from the study.

Participants/materials, setting, methods: Morphology, presence and motility were graded as: good/motile(1 grade), average/twitcher(2 grades), low/immotile(3 grades) and the sum of grades represented the total quality score for the testicular spermatozoa used for ICSI. Group A included cases with up to total grade 4, while Group B included cases with total grade 5 or higher. Embryo quality was evaluated up to day 3 (good quality: more than 5 blastomeres, less than 20% fragmentation). LBR was calculated per first transfer.

Main results and the role of chance: Fertilization rate was comparable (p>0.05) among fresh and frozen samples for both group A (fresh: n=24, 67%fertilization rate / frozen: n=33, 62% fertilization rate) and group B(fresh: n=23, 47%fertilization rate / frozen: n=38, 43% fertilization rate), with group A spermatozoa (n=27, 64%fertilization rate) performing significantly better compared to group B spermatozoa (n=91, 51%fertilization rate), p<0.05.

Group A spermatozoa produced significantly more good day 3 embryos compared to Group B (p<0.05), in particular 1,56 additional good quality embryos.

Interestingly, fresh Group B spermatozoa performed better than frozen Group B spermatozoa, resulting in significantly more good quality embryos on day 3 (p<0.05).

Furthermore, there was a significant decrease in good quality day 3 embryos, if both morphology and motility were graded as low/immotile (0.75 and 0.45 less good quality embryos respectively, p<0.05).

Although there was a trend for higher cycle cancellation rate in group B comparing to Group A, either fresh or frozen, the difference was not statistically significant.

Overall, although LBR was not affected by any parameter examined, the number of good quality embryos available for transfer was affected by both the quality of testicular spermatozoa used for ICSI and cryopreservation in low quality samples.

Limitations, reasons for caution: The evaluation of "presence" and "morphology" as good/average/bad could have a subjective complexion. However, this variation is eliminated through the grouping of samples.

Accumulative LBR was not calculated, as LBR was based only on the first transfer.

Wider implications of the findings: Since there is cryopreserved testicular tissue of good quality, there is no added value in proceeding to another surgery. However, in low quality samples, the use of fresh testicular spermatozoa could alter the final outcome, since cryopreservation affects the number of available good quality embryos.

Trial registration number: Not applicable

P-041 The effect of prolonged incubation of sperm at testis temperature (35°C) versus room temperature (26°C) on semen parameters

M. Mehrafza[1], C. Ostadian[2], A. Hosseini[3], A. Eftekhari[3], M. Asgharnia[1], S. Aghajani[3], H. Vahabzadeh[3], M. Gholami[3], A. Raoufi[4], S. Samadnia[4], E. Hosseinzadeh[4]

[1]Mehr Fertility Research Center- Guilan University of Medical Sciences- Rasht- Iran, Gynaecology, Rasht, Iran ;

[2]Mehr Fertility Research Center- Guilan University of Medical Sciences- Rasht- Iran, Andrology, Rasht, Iran ;

[3]Mehr Fertility Research Center- Guilan University of Medical Sciences- Rasht- Iran, Embryology, Rasht, Iran ;

[4]Mehr Fertility Research Center- Guilan University of Medical Sciences- Rasht- Iran, Research, Rasht, Iran

Study question: Does prolonged incubation of sperm at 35° C versus room temperature (26 ° C) affect semen parameters and DNA fragmentation index (DFI)?

Summary answer: The concentration and motility of spermatozoa were significantly higher in room temperature than 35°C. However, Temperature had no effect on DFI after 24 h.

What is known already: Currently, cryopreservation is used routinely for prolonged storage of sperm even for one day, which, despite its high cost, can affect the quality of sperm samples. If long-term incubation of sperm in the laboratory environment is possible without affecting its quality, it will be possible to manage the patient's treatment with higher quality and with greater choice**.**

Study design, size, duration: In the present experimental study, sperm samples were collected from 40 participants referred to Mehr Medical Institute, Rasht, Iran, from September 2019 to December 2019.

Participants/materials, setting, methods: Each semen sample was divided into two equal parts and was subjected to swim-up procedures. One group was incubated at 35°C and the other at room temperature, in the darkness. Both groups were evaluated for number, motility (Grade A and B) and morphology at 45 min, 24 h and 48 h intervals. Statistical analysis was

performed using repeated measure analysis of variance (ANOVA) and student´s t-test.
Main results and the role of chance: Sperm concentration (P = 0.007) and motility (P <0.001) was significantly higher in room temperature than 35°C, at three intervals of 45 minutes, 24 hours and 48 hours. However, the mean values of normal morphology spermatozoa was not significantly different between the two groups at three intervals of 45 minutes, 24 hours and 48 hours (P = 0.08). Also, there was no significant difference in DFI at 26 and 35°C after 24 h (P = 0.2).
Limitations, reasons for caution: At the time of the abstract preparation, 20 samples had not been read for DFI.
Wider implications of the findings: Sperm morphology was significantly reduced following prolonged incubation.
Trial registration number: not applicable

P-042 Clinical outcomes in patients with congenital bilateral absence of the vas deferens (CBAVD) undergoing testicular sperm extraction-intracytoplasmic sperm injection (TESE-ICSI)

T. Ishikawa[1], S. Mizuta[1], K. Yamaguchi[1], H. Matsubayashi[1], T. Takeuchi[2], K. Kitaya[1]

[1]Reproduction Clinic Osaka, Reproductive Medicine, Osaka, Japan ; [2]Reproduction Clinic Tokyo, Reproductive Medicine, Tokyo, Japan

Study question: What is the fertilization rate, embryonic development, and clinical outcome for TESE-ICSI using testicular spermatozoa among obstructive azoospermia (OA) including CBAVD couples?
Summary answer: Clinical pregnancy rate (CPR) per embryo transfer (ET) by testicular sperm did not differ significantly between CBAVD and other OA patients.
What is known already: OA is caused by congenital including bilateral absence of the vas deferens (obstructed in the long term) or acquired (vasectomy, inguinal hernioplasty in childhood, etc.). It is known that long-term obstruction is related to a defect of spermatogenesis, however, clinical outcomes after ICSI with testicular sperm in the etiology OA, classified as congenital or acquired causes have hardly been investigated.
Study design, size, duration: We performed a retrospective study based on two reproduction centers in Japan and evaluated 206 NOA patinets including 50 cases with CBAVD performed in our clinic between September 2013 and December 2019. In addition, a total of 108 TESE-ICSI cycle with 47 couples for CBAVD and 293 TESE-ICSI cycles with 138 couples for other obstruction were performed. Sperm retrieval rate was 100% and TESE-ICSI was performed with only motile spermatozoa.
Participants/materials, setting, methods: The diagnosis of CBAVD is based on normal-size testes (>16mL), normal FSH and nonpalpable vas deferens. The diagnosis of OA also required confirmation of normal spermatogenesis by testicular biopsy. TESE-ICSI cycles were evaluated in embryonic development rates and CPR. Additionally, paternal and maternal age, numbers of oocytes retrieved, baseline FSH, LH and E2 levels of women, and FSH, LH and Testosterone of men were compared between the two groups.
Main results and the role of chance: The wives age at ICSI was 33.9±4.4 years for CBAVD and 35.9±5.1 years for other obstruction. The sperm retrieval rate with TESE was 100%, in which motile spermatozoa were retrieved and used for ICSI for all patients. Two pronuclei (2PN), blastocysts development, and good-quality blastocysts rates were 57.2%, 44.8%, and 19.6% in CBAVD and 64.0%, 53.3%, and 23.0% in other obstruction, respectively. 2PN and blastocysts development rate in CBAVD was significantly lower than in other obstruction (P<0.001). However, no significant difference was found in good-quality blastocysts rates. Embryo transfer was performed 44 couples with CBAVD patients undergoing TESE-ICSI which were divided into clinical pregnancy positive (n=37) and negative (n=7) groups. There was no difference for paternal and maternal age, numbers of oocytes retrieved, baseline FSH, LH and E2 levels of women, and FSH, LH and Testosterone of men. CPR per ET cycle and per couple were similar in CBAVD (40.2% and 84.1%, respectively) and in other obstructive (41.3% and 79.4%, respectively).
Limitations, reasons for caution: There was a lack of accurate term of obstruction with respect to not CBAVD OA patients. Some other obstructive patients could be congenital but not acquired. Additionally, the safety and screening for congenital malformations among these children has not been fully investigated.
Wider implications of the findings: Long-term obstruction is not related to a sperm retrieval by conventional TESE and clinical pregnancy, however, embryonic development were not similar as the other OAs. In CBAVD couples, the selection of motile sperm from testicular tissue could be a critical key to succeed and rationale for good embryonic development.
Trial registration number: not applicable

P-043 Sperm count affects cumulative live birth rate of assisted reproduction cycles in relation to ovarian response

C. Zaca'[1], G. Coticchio[1], N. Tarozzi[1], M. Nadalini[1], C. Lagalla[1], A. Garolla[2], A. Borini[1]

[1]9.Baby, Family and Fertility Center, Bologna, Italy ; [2]University of Padova, Department of medicine - Unit of andrology and reproductive medicine, Padova, Italy

Study question: Does sperm quality, as assessed by prewash total sperm count (TSC), affect cumulative success rates in assisted reproduction cycles?
Summary answer: Sperm quality impacts on the efficacy of IVF treatments primarily in cases of reduced ovarian response, but not in normal or high responders.
What is known already: The clinical outcome of treatments is influenced by numerous intrinsic and extrinsic factors. The female gamete is recognised as the single most important factor affecting the ability of the preimplantation embryo to implant and develop. For this reason, oocyte legacy has overshadowed the sperm role in embryogenesis. Regardless, TSC has been described as being highly predictive of male health in general and reproduction in particular. Its relative importance in determining the efficacy of IVF treatments remains uncertain and therefore demands thorough assessment, especially in the light of possible interactions between the male and female gametes
Study design, size, duration: Reported data concern a retrospective cohort study carried out between January 2009 to December 2013 involving 765 couples undergoing complete ICSI cycles, i.e. whose all embryos were transferred or disposed. Couples were characterised by male infertility, while female age was less than 36 years to minimise the well-documented maternal age effect on treatment outcome. Couples with a combination of female and male infertility factors were excluded.
Participants/materials, setting, methods: The cohort was grouped according to male partner's TSC into five groups, according to values discussed in the World Health Organization guidelines: **A)**< $0.1x10^6$ (189/765 cycles,24.7%); **B)**$0.1x10^6$ to $1x10^6$(144/756 cycles,18.8%); **C)**$1x10^6$ to $5x10^6$(150/756 cycles,19.6%); **D)**$5x10^6$ up to $10x10^6$ (103/756 cycles,13,5%); **E)**$10x10^6$ to $39x10^6$ TSC(179/756 cycles,23,4%).Groups were also analysed according to the number of oocytes retrieved. Mean age and number of oocyte was comparable among groups.Preimplantation genetic testing treatments and cycles in which spermatozoa were surgically recovered were excluded.
Main results and the role of chance: Mean age and number of retrieved oocyte was comparable among groups. The mean number of embryos across the different TSC groups was also similar (3.0±1.6, 2.8±1.7, 3.4±2.2, 3.1±1.8 and 3.2±1.9, respectively; P=0.066). Cumulative live birth rates (CLBR) were progressively higher with increasing TSC, reaching a plateau in groups with higher TSC (22.2%, 27.1%, 34.7%, 36.9%, 36.9%, respectively; P=0.01). On the contrary, miscarriage rates were comparable ranging from 14.7% to 25% (P=0.5). Furthermore, cumulative outcome rates were comparatively assessed in individual TSC groups in relation to different oocyte yield (1 to 5; 6 to 10, >10). As expected, in the most severe TSC condition (≤$0.1x10^6$) CLBR were progressively higher as the number of retrieved oocytes increased (5.3%, 21.5% and 30.2%, respectively; P=0.008). Similar trends were observed in the outcome of groups with TSC values of >$0.1x10^6$ to $1x10^6$ and >$1x10^6$ to $5x10^6$. On the contrary, in groups characterized by TSC of >$5x10^6$ to $10x10^6$ and >$10x10^6$ to $39x10^6$, CPR and LBR did not increase as a function of the number of retrieved oocytes.
Limitations, reasons for caution: The study design is retrospective and requires further refinement to control for factors that may impact clinical outcome.
Wider implications of the findings: This study highlights the general importance of sperm TSC for the efficacy of assisted reproduction treatments. The consequences of sperm quality on clinical outcome emerge decisively in case of reduced ovarian response, suggesting a relationship between ovarian

response and oocyte ability to compensate for paternal-derived deficiencies.
Trial registration number: Not applicable

P-044 Effect of paternal age on outcomes in ART cycles: A systematic review and meta-analysis

G. Morris[1], D. Mavrelos[1,2], E. Theodorou[1], M. Campbell-Forde[1], D. Cansfield[1], E. Yasmin[1,2], P. Sangster[1,2], W. Saab[1], P. Serhal[1], S. Seshadri[1]

[1]Centre for Reproductive and Genetic Health, Medical, London, United Kingdom ; [2]University College London Hospitals NHS Foundation Trust, Reproductive Medicine Unit, London, United Kingdom

Study question: Could paternal age have an independent effect on the clinical outcomes of ART cycles?
Summary answer: Autologous oocytes studies suggest increased male age reduces live birth and increases miscarriage. Donor oocytes studies found no impact of male age on ART outcome.
What is known already: There is no effect of paternal age on clinical outcomes in donor oocyte studies. However, studies where autologous oocytes were used, have demonstrated conflicting results with some suggesting that increased male age has a deleterious effect.
Study design, size, duration: A systematic review and meta-analysis of ten autologous oocyte cohort studies (including 11004 cycles) and 11 donor oocyte cohort studies (including 10338 cycles).
Participants/materials, setting, methods: The Cochrane Central Citation Index Register of Controlled Trials (CENTRAL), MEDLINE, EMBASE, NHS evidence and conference abstracts were searched for randomized controlled trials (RCT) and observational studies (OBS) that addressed the impact of paternal age on ART published up to December 2018. We searched reference lists of relevant articles and hand-searched relevant conference proceedings/abstracts. Data for women aged 39 years or under were extracted and analysed.
Main results and the role of chance: Clinical pregnancy rates were found to be statistically higher when the paternal age was under 40 years in autologous oocyte studies (OR 1.68, [1.24 – 2.28]; p = 0.0009) however there was no difference in clinical pregnancy in the same age category when donor oocyte studies were analysed (OR 0.95, [0.84 – 1.07]; p = 0.41). Livebirth rate (LBR) was reported in three autologous oocyte studies (2926 cycles) and five donor oocyte studies (7648 cycles). LBR rate was found to be significantly increased when male age was under 40 years in autologous oocyte studies (OR 2.37, [1.15 – 4.85]; p = 0.02) but no difference in LBR was found in donor oocyte studies (OR1.03, [0.80 – 1.32]; p = 0.84). Miscarriage rate was reported in two autologous oocyte studies (970 cycles) and four donor oocyte studies (3741 cycles). Miscarriage was found to be more likely with male age over 40 years in autologous studies (OR 0.57, [0.42 – 0.77]; p = 0.0003). In donor oocyte studies there was a trend towards increased miscarriage when male age was above 50 years however this effect did not reach statistical significance (OR 0.71, [0.48 – 1.04]; p value = 0.08).
Limitations, reasons for caution: The autologous oocyte studies are relatively heterogeneous in populations with varied female ovarian reserve and differing male age group divisions. The analysis was limited to cycles including women under 39 years of age to mitigate this heterogeneity.
Wider implications of the findings: Men over the age of 40 may have a reduced chance of a successful outcome following ART when using autologous oocytes. This effect does not appear to be present when donor oocytes are studied although men over the age of 50 years may still have an increased chance of miscarriage.
Trial registration number: n/a

P-045 Microfluidics is highly effective in selecting a sperm subpopulation with low DNA fragmentation index.

K. Wouters[1], L. Vandenberghe[1], A. Racca[1], D. Jankovic[1], G. Verheyen[1], I. Mateizel[1]

[1]UZ Brussel, Centre for reproductive medicine, Brussel, Belgium

Study question: Is microfluidic sorting of unprocessed semen better in selecting non-DNA fragmented sperm compared with other semen preparation techniques?
Summary answer: The use of microfluidic sperm sorting chip allows the selection of highly motile sperm with very low levels of DNA fragmentation.
What is known already: DNA fragmentation represents the last event of cell apoptosis. The use of sperm cells with DNA fragmentation for oocyte insemination is correlated with a negative paternal effect on embryo development and an increased miscarriage rates.

Both microfluidic sorting (MS) of unprocessed semen and Magnetic activated cell sorting (MACS) performed after density gradient centrifugation were reported to improve the sperm quality by selecting non apoptotic cells. However, it is uncertain which procedure leads to the lowest DNA fragmentation index (DFI).
Study design, size, duration: The study investigates whether microfluidic sorting of unprocessed semen improves sperm selection as compared to standard preparation procedures (sperm washing and density gradient centrifugation) or MACS in split samples after routine diagnostic semen analysis. The primary outcome was sperm DNA fragmentation index and the secondary outcome was sperm motility.
Participants/materials, setting, methods: Sperm samples from 6 different patients were used. Each sample was split and subjected to 4 different sperm selection techniques: 1) sperm washing (SW), 2) density gradient centrifugation (DGC), 3) DGC followed by MACS (Miltenyi Biotec, Germany) and 4) MS (Fertile plus, Koek Biotechnology).
DNA fragmentation was analyzed using the Sperm-Chromatin-Dispersion Assay (GoldCyto sperm kit, Goldcyto Biotech corp.). The DFI was calculated on at least 500 cells by the Sperm Class Analyzer CASA-system (Microptic, Spain).
Main results and the role of chance: The median DFI for the 4 processing techniques were: 18.3% (range 13.9-87.6) for SW; 14.6% (range 6.1-71.7) for DGC; 11.8% (range 3.9-46.9) for MACS, and MS: 0.7% (range 0-34.2) for MS. The samples processed by microfluidics showed a significantly lower DNA fragmentation rate compared to the other techniques (Friedman test, P<0.05).
The median progressive motility for the 4 processing techniques were: 47.5% (range 29-54) for SW; 58% (range 27-61) for DGC; 46% (range 3-78) for MACS and 92.5% (range 82-96) for MS.

The samples processed by microfluidics showed a significantly higher progressive motility (Friedman test, P<0.05).
Limitations, reasons for caution: The major limitation of the study is the low sample size although the advantage of MS is obvious. Consequently, there is a lack of variation between the samples regarding sperm quality. As this observational study was conducted on semen samples for diagnostic analysis, data on clinical outcome are not available.
Wider implications of the findings: Microfluidic sorting of sperm selects a population with significantly lower DNA fragmentation index and higher proportion of progressive motility compared to standard selection methods or MACS. Moreover, MS offers the advantage of using unprocessed semen, as such reducing the negative impact of centrifugation as compared to standard sperm selection methods.
Trial registration number: not apllicable

P-046 Enzymatic digestion by Collagenase-IV improves quality of testicular sperm retrieved in Non-Obstructive Azoospermic (NOA) patients

E. Piatti[1,2], E.M. Colpi[3], G. Caminiti[2], F. Castiglioni[2,4], E. Bernasconi[5], P. Testa[5], V. Monti[5], M. Bellavia[4], G. Momi[6], G.M. Colpi[2,4]

[1]ProCrea, Andrology, Lugano, Switzerland ; [2]Clinica San Carlo, Andrology, Paderno Dugnano, Italy ; [3]Gynecentro Ticino, Gynaecology, Lugano, Switzerland ; [4]ProCrea, Reproductive Unit, Lugano, Switzerland ; [5]Clinica San Carlo, Reproductive Unit, Paderno Dugnano, Italy ; [6]ProCrea, IVF Laboratory, Lugano, Switzerland

Study question: Does Enzymatic Digestion alone have positive effects on isolation of human sperm from surgical testicular samples, compared to standard mechanical treatment?
Summary answer: Enzymatic Digestion alone by Collagenase-IV seems a valid method to increase the total surgically retrieved viable sperm count suitable for ICSI.

What is known already: When available, surgically-retrieved testicular-sperm (Testi-Sperm) used with ICSI offer an opportunity to father children even to NOA patients. The treatment of testicular fragments is crucial, both for a positive retrieval and for the total Testi-Sperm number obtained and storable for ICSI. Enzymatic treatment following mechanical mincing of testis fragments was reported to increase retrieval success rate and final Testi-Sperm count. Collagenase-IV, a Sertolian protease, was shown to provide higher yelds of Testi-Sperm cells. However, a critical factor for ICSI success is sperm motility, as a proof of sperm viability, especially after cryopreservation.
Study design, size, duration: A prospective blind observational study was performed on 24 NOA patients. In each, the testicular microfragments from microdissection-TESE were divided into two same-weight parts: the first underwent mechanical mincing, the second was treated by Collagenase-IV solution alone (never previously reported). Viability was assessed by Eosin-Y test (WHO 2010), applied to small cell suspension aliquots; and concentration by a counting chamber. All samples were prepared by one biologist and then blind-evaluated by another.
Participants/materials, setting, methods: The surgical samples were placed in Petri dishes containing HAM's F10 medium: the first half, mechanically minced to obtain a homogeneous cell suspension, and the second half, immersed in 1 ml Collagenase IV solution. Both were incubated at 37°C for 120'; then, both treatments were stopped by adding 5 ml HSA 0.5% medium, the tubes centrifuged for 10' at 500g for washing, the pellets re-suspended with fresh medium and analyzed.
Main results and the role of chance: For each treatment, we measured the Total Count of the Testi-Sperm retrieved, the percentage of Viable Testi-Sperm (by Eosin-Y test on over 100 cells), and consequently the Total Count of Viable Testi-Sperm actually available for cryopreservation or ICSI. Statistical analysis was performed by Wilcoxon-paired rank test.

Viable Testi-Sperm were [X±SD; (range)]: 31.9±9.7% (19-63%) and 67.2±8.1% (52-80%) for mechanically and Collagenase-IV treated samples, respectively ($p<0.01$).

Total Testi-Sperm retrieved were [M (range)] $0.49 \cdot 10^6$ ($0.06\text{-}2.78 \cdot 10^6$) and $0.77 \cdot 10^6$ ($0.14\text{-}2.3 \cdot 10^6$)($p<0.01$), and Total Viable Testi-Sperm retrieved were $0.16 \cdot 10^6$ ($0.01\text{-}1.0 \cdot 10^6$) and $0.54 \cdot 10^6$($0.08\text{-}1.59 \cdot 10^6$) ($p<0.01$) for mechanically and Collagenase-IV treated samples, respectively.

Therefore, Collagenase-IV treatment alone gives a Total Count of Viable Testi-Sperm useful for cryopreservation or ICSI significantly higher than that of the standard mechanical treatment.
Limitations, reasons for caution: Our results on the higher Viable Total Testi-Sperm Count retrieved by Collagenase-IV alone versus mechanical treatment invite future studies on microdissection-TESE samples, especially to confirm the maintained functional competence of Testi-Sperm in ICSI.
Wider implications of the findings: The enzymatic-only method in processing Testi-Sperm during microdissection-TESE can offer higher positive Testi-Sperm retrieval rates and higher number of viable cells available for cryopreservation or ICSI in NOA patients, especially in those with the poorer prognosis.
Trial registration number: None

P-047 Multiparametric comparative analysis of the effectiveness of conventional ICSI and physiological ICSI (PICSI) among couples with male infertility factor

D. Rusakov[1], O. Shurygina[2], A. Petrova[3], T. Bykova[3], A. Baizarova[3]

[1]Samara state medical University- IDK medical company, Department of histology and embryology- ART Department, Samara, Russia C.I.S. ;
[2]Samara state medical University- IDK medical company, Department of histology and embryology - Department of reproductive medicine clinical embryology and genetics - ART Department, Samara, Russia C.I.S. ;
[3]IDK medical company, ART Department, Samara, Russia C.I.S.

Study question: Multiparametric comparative analysis of the effectiveness of conventional ICSI and physiological ICSI (PICSI) in couples with male infertility factor performed.
Summary answer: PICSI compared to ICSI reduces the number of embryo losses at the laboratory stage and increases cumulative pregnancy rate and cumulative live-birth rate.
What is known already: According to the Russian Association of human reproduction data after the transfer of embryos obtained by ICSI pregnancy occurs in 36.2 % of cases and perinatal miscarriage reaches 78.1 %. The use of hyaluronate for the study of male germ cells in the ICSI procedure allows selecting of sperm without DNA damage and abnormalities in the chromosomal set, thereby increasing the chances of successful fertilization and meanwhile according to a large systematic review devoted to comparing the effectiveness of ICSI and PICSI in male infertility factor, which included 2918 studies, there are no statistically significant differences between these two methods.
Study design, size, duration: Retrospective multiparametric comparative analysis of 284 ICSI procedures and 200 PICSI procedures performed from 2015 to 2019 in the ART Department of "IDK Medical company", (Samara, Russia) was performed.
Participants/materials, setting, methods: The following performance parameters were evaluated: fertilization rate, blastocyst formation rate, embryo freezing rate, embryo utilization rate, implantation frequency rate, pregnancy rate, live-birth rate, cumulative pregnancy rate, cumulative live-birth rate.
Main results and the role of chance: The fertilization rate in ICSI was 86%, in PICSI - 82%. The embryo freezing rate and blastocyst formation rate in ICSI were 28% and 47% respectively, in PICSI - 33% and 51%. The differences between two methods are statistically insignificant ($p>0,05$). The embryo utilization rate in ICSI was 48%, in PICSI - 58%. The differences in these indicators are statistically significant ($p=0,043$). While assessing the implantation frequency rate it was found that in ICSI it has become 44.6%, in PICSI it has become 45%. The pregnancy rate and the live-birth rate after ICSI were 47% and 33% respectively, and the pregnancy rate and the live-birth after PICSI were 48.5% and 35% respectively. The differences in these indicators are statistically insignificant ($p>0,05$). While analyzing the cumulative pregnancy rate and the cumulative live-birth rate the following data was provided: in ICSI these indicators were 53% and 34%, respectively, in PICSI - 81.5% and 56.5% respectively. The differences in these indicators are statistically significant ($p=0,038$).
Limitations, reasons for caution: Absent.
Wider implications of the findings: Multiparametric analysis makes it possible to evaluate the effectiveness of ART programs with great confidence. There are no significant differences between ICSI and PICSI for most of the analyzed indicators, which is consistent with the literature data. But cumulative performance indicators demonstrate the advantage of PICSI over conventional ICSI.
Trial registration number: not applicable

P-048 Which is better for sperm incubation before IVF: lower or higher oxygen?

E. Yalcinkaya[1], B. Alyuruk[2], F. Martinez Pastor[3]

[1]Adatip Hospital, Assisted Reproduction Unit, İstanbul, Turkey ;
[2]Kocaeli University, IVF Unit, Kocaeli, Turkey ;
[3]INDEGSAL, University of Leon, Leon, Spain

Study question: Do lower levels of oxygen result in less oxidative stress on sperm cells before fertilization in bull?
Summary answer: This pilot study reported a higher oxidative stress due to increased mitochondrial activity under high oxygen during incubation.
What is known already: Fertilization of bovine oocytes is still carried out under high oxygen levels in most of the laboratories although embryo culture is performed under lower oxygen tension due to the solid evidence supporting higher blastocyst development rates. However, incubation of sperm cells under lower oxygen concentration might be crucial in terms of sperm function considering that these cells are susceptible to oxidative stress due to their inadequate cell repair system against excessive production of reactive oxygen species (ROS).
Study design, size, duration: This was a pilot study for comparing the effects of two different levels of O_2 on sperm cells during capacitation. The sample of the study included 10 cryopreserved bull semen samples from different breeders. Treatment groups were named as LO (low oxygen; 5% O_2) and HO (high oxygen; 20% O_2).
Participants/materials, setting, methods: Two straws were thawed per each bull and sperm cells were left to swim up for 1 hour. Then, swam sperm cells were divided equally into two; and aliquots were assigned to both treatment goups to incubate for 5-6 hours. Variables of motility, progressive motility, mitochondrial activity, capacitation status and intracellular ROS were measured by flow cytometry at 0 h and 5-6 h.

Main results and the role of chance: Compared to starting levels, both groups showed significantly decreased total and progessive motility, nonsignificant increase in capacitation status, significant decrease in the percentage of active mitochondria and statistically significant decreases in intracellular ROS. The decrease in total and progressive motility was found to be significantly higher in LO compared to HO (22.6% vs 32.8% and 24.4% vs 18.6%; $p<0.05$, respectively). Moreover, the percentage of capacitated cells were found to be higher in HO compared to LO; but the difference was not statistically significant ($p>0.05$). At the end of incubation, mitochondrial activity was observed to be slightly higher in HO than LO; but the difference was not again statistically significant ($p>0.05$). Interestingly, intracellular ROS was found to be decreased following incubation; and it was found to be statistically lower in LO group compared to HO ($p<0.05$).
Limitations, reasons for caution: The main limitation of our study was bull variability and the limited size of the study sample.
Wider implications of the findings: Considering that ROS may lead to problems in reproductive processes when present in excess amounts, use of lower oxygen also during capacitation was found to keep intracellular ROS levels significantly lower as desired. Any further effects on the quality of spermatozoa need to be evaluated by fertilization and IVF outcomes.
Trial registration number: not applicable

P-049 In vitro myo-inositol treatment significantly ameliorates motility, mitochondrial respiratory efficiency and DNA integrity of human sperm

P. Piomboni[1], R. Ponchia[1], B. Semplici[1], L. Governini[1], P. Artini[2], E. Casarosa[2], I. Marzi[2], A. Luddi[1]

[1]Siena University, Molecular and Developmental Medicine, Siena, Italy ; [2]University of Pisa, Experimental and Clinical Medicine, Pisa, Italy

Study question: Does the *in vitro* treatment with myo-inositol affects the mitochondrial function and DNA integrity of human sperm in both basal and capacitated condition?
Summary answer: The *in vitro* treatment with myo-inositol of normozoospermic samples, before and after swim-up capacitation, leads to a significant amelioration of sperm motility and DNA integrity
What is known already: Mammalian fertilization is a multifaceted and complex process because the site of semen deposition is far from the site of fertilization and sperm need to have an adequate motility to reach the oocyte. Sperm motility, as well as capacitation, hyperactivation and acrosome reaction, requires energy and, to this regard, mitochondria play a pivotal role in the aerobic production of energy in comparison with the glycolytic pathway. At same time, DNA integrity must be preserved during sperm capacitation and related processes. These features may be affected by in vitro procedure for sperm selection and capacitation in assisted reproductive techniques.
Study design, size, duration: Human ejaculated sperm were analyzed according to WHO guidelines between September 2019 - January 2020; a total of 40 normozoospermic samples were selected in order to evaluate the effect of an *in vitro* treatment with myo-inositol, before and after swim up selection. Isolated sperm from all specimens were used to measure the respiratory control ratio (RCR) and the DNA oxidation; Sperm ultrastructure was analysed. All patients had given their informed consent.
Participants/materials, setting, methods: Normozoospermic human semen samples (n=40) collected at the Siena University Hospital were processed for the oxygraphic analysis, before and after swim up selection, with or without treatment myo-inositol (2 or 20 µg/µl). To this end, sperm cells were demembranated by hypotonic swelling and the RCR was calculated. DNA sperm oxidation measurement by 8-OHdG and ultrastructural evaluation by transmission electron microscopy were performed in myo-inositol treated and untreated sperm samples.
Main results and the role of chance: Our data highlight that myo-inositol treatment significantly increased sperm progressive motility, in a dose dependent manner ($p<0.05$), both in basal and swim-up selected samples. Moreover, the consumption of O_2 measured by oxigraphic analysis was significantly raised by increasing doses of myo-inositol *in vitro* treatment.The concentration of 8-OHdG, an early marker of DNA oxidation, in untreated sperm was significantly higher than those of sperm supplemented with myo-inositol, confirming its protective role against DNA oxidative damage during the *in vitro* manipulation/incubation of human sperm. To evaluate any possible ultrastructural modifications, semen samples treated with myo-inositol or untreated were analysed by transmission electron microscopy. Despite the treatment seems to not induce appreciable ultrastructural changes, it may be highlighted that sperm surface as well as the observed environment are clearly free from any amorphous fibrous material, which instead appears as background in untreated sperm samples. This finding may confirm the ability of myo-inositol to disrupt the mucoid masses of the seminal fluid, usually able to entrap sperm and any other seminal fluid components, thus reducing sperm motility and capacitation efficiency.
Limitations, reasons for caution: Large-scale studies should be required to assess whether an addition of myo-inositol improves sperm motility, also in oligoasthenozoospermic men. Moreover, the mechanism by which myo-inositol ameliorates mitochondrial activity should be further evaluated.
Wider implications of the findings: These data, if confirmed in future larger studies, will disclose that myo-inositol ameliorates key feature of human sperm (motility, mitochondrial functions, DNA integrity).
Trial registration number: None

P-050 Impact of sperm quality to achieve pregnancies in oocyte donation cycles

M. Cozzolino[1], I. Hervás[1], R. Rivera-Egea[1], A. Pellicer[1], N. Garrido[1]

[1]Fundacion IVI, Valencia, Valencia, Spain

Study question: When should be considered sperm replacement in case of the first failure of oocyte donation?
Summary answer: Replacement patients by donors sperm significantly increase live birth rate and cumulative live birth rate (CLBR) either in oligo-asthenoteratozoospermia or in suboptimal/normal sperm.
What is known already: Oocyte donation is an extremely successful treatment in assisted reproductive technology (ART), unfortunately, any couples remain still barren despite normal sperm and regular uterus morphology. The use of ICSI in clinical practice has modified the indications of sperm donation use, currently, the ESHRE suggests the donation of sperm after at least three failed cycles of ICSI with the sperm of the couple. A repetitive clinical question that remains unsolved so far, concerns to when a couple should be recommended to change patient's by donor sperm after oocyte donation failed treatments
Study design, size, duration: A retrospective study in university-affiliated ART centers was conducted between January 2000 and April 2019. 6065 cycles of oocyte donation were included in the study, with a total of 7757 embryo transfers and 14119 embryos transferred.
Participants/materials, setting, methods: Couples in which male partners have oligoasthenoteratospermia or suboptimal/normal sperm were scheduled for oocyte donation cycles after the failed first attempt, using patients or donors sperm.Oligoasthenoteratospermia was defined as the presence of less than 5 million total progressive motile spermatozoa in the ejaculate. Obstructive azoospermia was excluded. Live birth rates per embryos transferred and embryo transfers, and cumulative live birth rates (CLBR) considering oocyte consumed in the previous donation cycles using patient or donor sperm.
Main results and the role of chance: After the first failure of the oocyte donation cycle our results confirm that in patients with oligoasthenoteratospermia or suboptimal/normal sperm, replacement patient's sperm by donor sperm as soon as increased live birth per embryo transfers or the number of embryos transferred. The live birth rate in couples with oligoasthenoteratospermia showed that replacement patient by donor sperm OR 2.18 CI95% (1.7-2.8) $p<0.001$ when considered for embryo transfers and OR 2.46, CI95% (1.9-3.2) $p<0.001$ considering for embryos transferred. In couples with suboptimal/normal sperm replacement of patient sperm with donor showed an increase live birth for embryo transfers OR 2.21, 95%CI (1.7-2.8), $p<0.001$ and for embryos transferred OR 2.43, CI 95%(1.9-3.1), $p<0.001$. The same results were reached in the third cycles of donation with improving live birth rate for embryo transfers OR 1.51, CI95% (1.0-2.2), $p=0.033$ and embryos transferred OR 1.77, CI 95% (1.2-2.6), $p=0.004$ in oligoasthenoteratospermia, in case of suboptimal/normal sperm was OR 1.40, CI95%(1.0-2.0), $p=0.039$ for embryo transfer and OR 1.53, CI 95%(1.0-2.4), $p=0.013$ for embryo transferred.The survival curves of CLBR with the patient and donor sperm considering oocyte by oocyte showed a statistically significant difference ($p<0.001$), replacing sperm patients after fifteen in oligoasthenoteratospermia and twenty oocytes donated, in suboptimal/normal sperm.

Limitations, reasons for caution: The principal limitation of our study was the lack of andrological studies at the molecular level, such as the sperm DNA fragmentation test or sperm FISH test, which could have identified a clearer indication for the gamete change for each patient and the retrospective nature of the study.
Wider implications of the findings: Prospective studies taking into account an andrological study should confirm the possibility of changing the patient's semen after the first failed donation.
Trial registration number: not applicable

P-051 Distinct expression levels of spermatogenic markers and growth factors in testicular tissue of Klinefelter patients with negative sperm retrieval

E. Lunenfeld[1], M. Azab[2], S. Kleiman[3], R.R. Hauser[4], M. Huleihel.[2]

[1]The Center of Advanced Research and Education in Reproduction CARER-Faculty of Health Sciences Ben-Gurion University of the Negev- Beer-Sheva- Israel. and Soroka Medical Center, Department of Obstetrics and Gynecology, Beer - Sheva, Israel ;
[2]The Center of Advanced Research and Education in Reproduction CARER- Faculty of Health Sciences- Ben Gurion University of the Negev, The Shraga Segal Departement. of Microbiology- Immunology and Genetics-, Beer Sheva, Israel ;
[3]Male Fertility Clinic and Sperm Bank- Lis Maternity Hospital- Tel Aviv Sourasky Medical Center School of Medicine Tel Aviv University, Obstetrics and Gynecology, Tel Aviv, Israel ;
[4]Male Fertility Clinic and Sperm Bank- Lis Maternity Hospital- Tel Aviv Sourasky Medical Center- School of Medicine Tel Aviv University, Obstetrics and Gynecology, Tel Aviv, Israel

Study question: Can we use spermatogenic markers and testicular growth factors to predict spermatogenesis in testicular biopsies of Klinefelter patients without sperm?
Summary answer: The expression of oct4 and CSF-1 were high and in a positive correlation with the expression of crem-1 and protamine, in the examined biopsies.
What is known already: Klinefelter syndrome (KS) is the most prevalent genetic disorder, occurring at about 0.2% of males and 11% of the azoospermic patients. At birth, KS patients have normal amount of testicular germ cells. Until age 10, spermatogonial cells (SCs) are present in the testes, but can be found in 40-50% of the adult patients. The presence of SCs (OCT4 and MAGE-A4) was reported. It is suggested that spermatogenic arrest occurs at the spermatogonium or primary spermatocyte level in KS boys, which undergo apoptosis instead of differentiation. The expression of growth factors in testicular biopsies of Klinefelter patients is not yet clear.
Study design, size, duration: The expression levels of the pre-meiotic (oct4, cd9, gfr-a1, a-6-integrin, sall4, c-kit), meiotic (crem-1) and post-meiotic (protamine) markers as well as the colony stimulating factor-1 (CSF-1) (growth factor) were examined in testicular biopsies of 17 Klinefelter patients (28-40 years old), with no sperm in their testicular tissue.
Participants/materials, setting, methods: 17 Klinefelter patients underwent conventional TESE and no sperm was retrieved. qPCR analysis was used to quantify the expression levels of the extracted RNA from the 17 examined biopsies in whom sperm was not retrieved. The levels of the markers were expressed as fold of increase compared to GAPDH in the same tissue sample.
Main results and the role of chance: Our results show that in 14 biopsies, we examined low expression levels of oct4 - a pre-miotic marker (fold of increase was less than 5), CREM - a miotic marker (fold of increase was less than 6) and CSF-1 (fold of increase were less than 18) but no expression of protamine. However, in three biopsies that highly expressed oct4 (29, 39 and 61 fold) and CSF-1 (162, 86 and 88 fold, respectively), the expression levels of crem-1 were high (50, 21 and 28 fold, respectively) and also protamine (1364, 20 and 466, respectively). No such correlation was found between the expression levels of the pre-meiotic markers cd9, gfr-a1, a-6-integrin, sall4, c-kit and the expression levels of the meiotic marker crem-1 and the post-meiotic marker protamine.
Limitations, reasons for caution: The number of the patients need to be increased and the expression levels of the markers need to be confirmed by immunostaining.
Wider implications of the findings: We would recommend to verify pathological results using those markers in order to increase precision diagnosis among NOA patient in whom sperm was not retrieved. These results may be used for considering re-TESE or re-microTESE.
Trial registration number: not required

P-052 Outcome of IVF/ICSI procedures in male cancer patients: retrospective analysis of procedures performed between 2004 – 2018

T. Papler[1], M. Štimpfel[2], E. Vrtacnik Bokal[3], S. Drobnič[2]

[1]University Medical Center Ljubljana, Department of Human Reproduction, Ljubljana, Slovenia ;
[2]University Medical Centre Ljubljana, Department of Human Reproduction, Ljubljana, Slovenia ;
[3]Univeristy Medical Centre Ljubljana, Department of Human Reproduction, Ljubljana, Slovenia

Study question: Study question: Is the clinical outcome of IVF/ICSI cycles comparable when fresh or cryopreserved semen from male cancer patients is used for fertilization?
Summary answer: There are no statistically significant differences in clinical outcomes of IVF/ICSI procedures when fresh or frozen semen is being used
What is known already: Due to improved survival of men after oncological treatment it has become important to enable them a quality life after the treatment is finished. Fertility preservation and a chance to have biological children represent an important aspect of quality of life. In men we can preserve fertility by cryopreserving semen prior to the start of oncological treatment. Outcomes of IVF procedures are comparable when we use fresh or frozen semen in healthy infertile couples. Data on the use of fresh or frozen semen from oncological patients and the outcomes of IVF procedures however, are scarce.
Study design, size, duration: We retrospectively analysed the outcome of IVF/ICSI cycles where cryopreserved or fresh semen from male oncological patients was used for oocyte fertilization. Analysis included 226 IVF/ICSI cycles performed between 2004 and 2018, 138 with cryopreserved semen and 88 with fresh semen, respectively. We had no exclusion criteria with regard to female age (aged 23-43 years) or female causes of infertility.
Participants/materials, setting, methods: Groups (cryopreserved versus fresh semen) were compared in terms of fertilization rate, number of embryos, blastocysts and cryopreserved embryos. Pregnancy, live birth and miscarriage rates were determined to determine which type of semen used yields better clinical outcomes. To determine the differences between the two groups, Pearson's chi-square test and two-tailed t-test were used. Statistical significance was set at $p < 0.05$.
Main results and the role of chance: The cryopreserved semen and fresh semen group of patients were comparable for mean female age (31.7 ± 4.7 vs. 32.5 ± 4.3; p=0.65), mean number of retrieved oocytes per aspiration (10.2 ± 5.6 vs. 10.1 ± 6.6; p=0.71), fertilization rate (56.9% vs. 59.1%; p=0.35) and number of embryos (629 vs. 423; p=0.34). There was however, statistically significant higher number of blastocysts (211 vs 116; **p=0.018**) and cryopreserved embryos (124 vs 51; **p=0.001**) in the group where cryopreserved semen was used. In terms of clinical IVF outcomes, there were no differences in pregnancy (34.2% vs. 28.6%; p=0.43), live birth (24.8% vs. 24.3%; p=0.92) and miscarriage (27.5% vs. 10%; p=0.18) rates between cryopreserved and fresh semen group.
Limitations, reasons for caution: In the fresh semen group, timing from finished oncological treatment to IVF procedure should be taken into account to get a clearer perspective about semen quality. Also, the type of cancer and oncological treatment should be considered to get a clearer picture.
Wider implications of the findings: Semen cryopreservation prior to oncological treatment represents an efficient way for fertility preservation in men with cancer. Furthermore, it seems that the use of cryopreserved semen is better in terms of number of blastocysts obtained and number of embryos cryopreserved after IVF procedure.
Trial registration number: Retrospective analysis.

P-053 Impact of slow freezing on sperm nuclear quality and telomere length

C. Gouhier[1], H. Pons-Rejraji[1,2], S. Carlet-Dollet[2], B. Pereira[3], A. Tchirkov[4], F. Brugnon[1,2]

[1]CHU Clermont-Ferrand- Hôpital Estaing-, Laboratoire de Biologie du Développement et de la Reproduction- AMP- CECOS, Clermont-Ferrand, France ; [2]Faculté de Médecine, Université Clermont Auvergne- Inserm 1240- IMoST, Clermont-Ferrand, France ; [3]CHU Clermont-Ferrand, DRCI- Délégation Recherche Clinique et Innovation, Clermont-Ferrand, France ; [4]CHU Clermont-Ferrand- Hôpital Estaing-, Service de Cytogénétique Médicale, Clermont-Ferrand, France

Study question: Does slow freezing affect human sperm telomere length?
Summary answer: Slow freezing of human sperm does not alter telomere length despite of increasing DNA oxidation and fragmentation.
What is known already: Sperm telomere length (STL) is a potential interesting biological marker to assess male fertility. While its relationship with standard sperm parameters is still controversial, recent studies have shown correlations between STL and DNA alterations, notably DNA fragmentation and oxidation. Likewise, STL is positively related with pregnancy rate. As STL is transmitted to offspring, its alteration could lead to pathologies that may worsen from generation to generation. Human sperm freezing is an indispensable tool for male fertility preservation despite of inducing nuclear spermatic alterations. Nevertheless, nothing is known about its impact on STL.
Study design, size, duration: This prospective study was conducted between January and December 2018 and approved by the "Germethèque" Scientific Committee and the Ethical Committee under the French IRB CPP Sud-Est6. Samples were surplus semen obtained from 63 men undergoing routine semen analysis at the Center for Reproductive Medicine. STL measurement was carried out on all the 63 fresh samples, and for 30 of those also after cryopreservation. In addition, nuclear quality was measured before and after freezing-thawing cycle.
Participants/materials, setting, methods: The 63 subjects (35 normozoospermic) had a mean age of 34±0.6 years and a BMI of 27.4±0.8. Spermatozoa were slowly frozen in high security straws using freezing medium and programmable freezer. STL was measured for all fresh and frozen-thawed samples by qPCR. For 10 samples, STL before and after freezing-thawing was additionally assessed by qFISH. For another 10, sperm DNA oxidation (8-OHdG residues immuno-detection) and fragmentation (TUNEL assay) were measured by flow cytometry.
Main results and the role of chance: We did not measure any significant impact of freezing on the mean telomere length of sperm samples, whether it was analyzed by qPCR (3.25 ± 0.15 arbitrary unit (a.u.) *vs.* 3.46 ± 0.2 a.u., n = 30) or by qFISH (0.84 ± 0.1 a.u *vs.* 0.84 ± 0.04 a.u, n=10). qFISH method highlighted STL heterogeneity within each sperm sample. The cryopreservation tended to modify STL distribution (segmented by intervals of 0.25 a.u.) even if it was not statistically significant.

In addition, slow freezing-thawing cycle decreased sperm motility and vitality ($p < 0.05$ for both, n=10), and increased DNA oxidation (average oxidation intensity 839 ± 210 a.u. *vs.* 1445.2 ± 202 a.u., $p < 0.05$, n=10) and fragmentation (23.1 ± 5.4 % *vs.* 39 ± 6 %, $p < 0.005$, n=10). Finally, we did not measure any significant correlations between STL and the analyzed spermatic nuclear markers.
Limitations, reasons for caution: Standard parameters of analyzed samples were normal or slightly altered because the different measurements required a high number of spermatozoa. Nevertheless, fertility preservation is proposed to men with potentially altered sperm parameters, therefore it would be essential to measure cryopreservation impact on semen of oligo-astheno-teratozoospermic patients.
Wider implications of the findings: Although slow freezing increased DNA oxidation and fragmentation, it did not alter STL. To our knowledge, this was the first study to assess the impact of cryopreservation on STL. Compared to qPCR that only gives a mean STL, qFISH provides the distribution of STL within a semen sample.
Trial registration number: not applicable

P-054 Relationship between the degree of sperm-autoimmunization with natural and intra-uterine insemination-assisted live births

S. D'Andrea[1], C. Castellini[1], E. Minaldi[1], M. Totaro[1], G. Cordeschi[1], S. Francavilla[1], F. Francavilla[1], A. Barbonetti[1]

[1]University of L'Aquila, Pubblic Health- Clinical- Life and Envirenomnental Science, L'Aquila, Italy

Study question: What is the relationship between the degree of sperm-autoimmunization, assessed by IgG-mixed antiglobulin reaction (MAR) test, with natural and intra-uterine insemination (IUI)-assisted live births?
Summary answer: Infertile couples with 100%-positive MAR-test, where natural live births were much less than at lower degree of positivity (50%-99%), could be successfully treated with IUI.
What is known already: Although the World Health Organization (WHO) has recommended the IgG-MAR test as an integral part of semen analysis, considering 50% antibody-coated motile spermatozoa as the clinically-relevant threshold, the predictive value of the degree of positivity of the MAR test above such a cut-off on the occurrence of natural pregnancies still remains largely undetermined. Furthermore, the effectiveness of IUI in cases of strong sperm-autoimmunization is not yet well-established.
Study design, size, duration: This was a historical cohort study on 108 infertile couples with ≥50% positive MAR test in men, who had attended a university/hospital's andrology/infertility clinic for the management of couple infertility from March 1994 to September 2017.
Participants/materials, setting, methods: The IgG-MAR was carried out as an integral part of semen analysis. The patients were divided into two groups: 100%– and 50%–99%-positive MAR test. Post-coital test (PCT) was performed in all the couples and IUI was offered as the first-line treatment. Laboratory and other clinical data were retrieved from the computerized database. Data on subsequent pregnancies were obtained by contacting patients over the telephone.
Main results and the role of chance: Eighty-four men (77.8%) were successfully contacted by telephone and agreed to participate. Forty-four men belonged to the group of 100%-positive MAR test, while 40 showed lower MAR test positivity. The couples with a 100%-positive MAR test showed a natural live birth rate per couple (LBRcouple), that was considerably lower than that observed at a lower degree of positivity (4.5% vs. 30.0%; $p = 0.00001$). Among the clinical variables, a significant difference was observed only for the PCT outcome, which was poorer in the 100%-positive MAR test group. Better PCT outcomes (categorized as negative, subnormal and good) were positively correlated to the occurrence of natural live births (6.3%, 21.7%, and 46.2%, respectively; $p = 0.0005$ for trend), for which the sole independent negative predictor was the degree of sperm-autoimmunization. IUI was performed as the first line treatment in 38 out of 44 couples with 100%-positive MAR test, yielding 14 live births (LBRcouple = 36.8%). In couples with lower MAR test positivity, the LBRcouple after IUI was similar to the natural LBRcouple (26.9%).
Limitations, reasons for caution: We cannot exclude uncontrolled variables that may have affected natural pregnancies during the follow-up, or a selection bias in the comparison of outcomes, due to the lack of randomization even though the clinical variables were not different in couples that had or had not undergone IUI.
Wider implications of the findings: While 100%-positive IgG-MAR test can represent the sole cause of a couple's infertility, which could be successfully treated with IUI, a lower degree of positivity may only represent a contributing factor to be considered in addition to conventional prognostic factors, including the PCT outcome, in decision making "treat or wait".
Trial registration number: not applicable

P-055 Cell-free seminal mRNA as a marker of complete obstruction in azoospermic men

M. Jeseta[1], P. Ventruba[1], W. Kranc[2], K. Jopek[3], J. Žáková[1], I. Crha[1,4], B. Kempisty[2,3]

[1]Faculty of Medicine- Masaryk University Brno and University Hospital Brno, Department of Gynecology and Obstetrics, Brno, Czech Republic ; [2]Poznan University of Medical Sciences, Department of Anatomy, Poznan, Poland ; [3]Poznan University of Medical Sciences, Department of Histology and Embryology, Poznan, Poland ; [4]Faculty of Medicine- Masaryk University Brno and University Hospital Brno, Department of Nursing and Midwifery, Brno, Czech Republic

Study question: Is it possible to use cell-free mRNA (cfs-mRNA) in seminal plasma as a diagnostic biomarker of obstruction in azoospermic patients?
Summary answer: Our results showed that the seminal plasma samples from non-obstructive azoospermic donors differed significantly in contents of cell-free mRNA when compared to obstructive azoospermic men.
What is known already: Extracellular cell-free mRNA has been detected in various body fluids including seminal plasma. This mRNA is actively released from living cells or can be released from dying cells. Cell-free seminal mRNA (cfs-mRNA) can be used as a biomarker in many non-invasive diagnostic applications as it contains tissue-specific and stable mRNA. In azoospermic males, it is very important to know if there is an obstructive problem or not. However, to the best of our knowledge there is no existing model that can accurately predict successful sperm retrieval by MESA or TESE. Analysis of cfs-mRNA is a promising tool for such prediction.
Study design, size, duration: In this study we evaluated cfs-mRNA composition in samples of seminal plasmas from men with non-obstructive azoospermia (NOA) and obstructive azoospermia (OA). A total of 8 patients (4-NOA and 4-OA) aged 28 to 40 years were included in this prospective study from spring to autumn 2019. The seminal plasma samples were collected after centrifugation of ejaculate. The cfs-mRNA content was determined by the microarray analyses.
Participants/materials, setting, methods: The non-obstructive azoospermia group included men who were cryptozoospermic in previous years and azoospermic in this analysis, the obstructive azoospermia group included men after vasectomy. RNA was isolated from a total of 8 samples. Two samples (with the highest concentration and quality) were selected for each group. Further analyses were performed using GeneChip ™ Human Gene 2.1 ST Array Strip microarrays. The statistical analysis was performed in the R programming language with the Bioconductor package.
Main results and the role of chance: Statistical analysis consisted of comparing cfs-mRNA content from men with non-obstructive azoospermia (NOA) and men with obstructive azoospermia (OA). In the next step, a total of 762 upregulated genes in NOA (fold above 2) were selected. Most of the upregulated genes belong to processes such as: cellular component organization or biogenesis (GO:0071840), cellular metabolic process (GO:0044237), cellular component organization (GO:0016043), organelle organization (GO:0006996). These processes belong to the GO BP (Gene Ontology Biological Process). The genes that showed the largest change in expression (largest fold) are these: *VTRNA1-1 (Vault RNA1-1), MT-TS1 (Mitochondrially Encoded tRNA Serine 1), MT-TV (Mitochondrially Encoded tRNA Valine), RNU6-441P (RNA, U6 Small Nuclear 441, Pseudogene), MT-TC (Transfer RNA Mitochondrial Cysteine), RNU1-83P (RNA, U1A Small Nuclear), PCGEM1(Prostate-specific gene), SEMG2 (Semenogelin 2), ND1 (NADH dehydrogenase, subunit 1), MT-TF (mitochondrially encoded tRNA phenylalanine)* and *PIP (prolactin induced protein)* which was previously considered as a specific protein marker of non-obstructive azoospermia.
Limitations, reasons for caution: A limitation is the number of samples included and analysed in this study which slightly reduced the power of statistical analysis. The obtained result will be validated on more samples using the quantitative RT-qPCR method.
Wider implications of the findings: These results suggest that the analysis of cell-free seminal mRNA is a very promising tool and that the cfs-mRNA could be used as a non-invasive biomarker for identifying the complete obstruction in case of azoospermia.
Trial registration number: Supported by MH CZ – DRO (FNBr, 65269705) and Ministry of Health, Czech Republic projects no. NV18-08-00291 and NV-18-08-00412.

P-056 Spermatogenesis in advanced-stage Hodgkin's lymphoma patients treated with escalated BEACOPP: a retrospective study of impaired fertility and recovery

E. Williams[1], V. Jayadev[1]

[1]*Concord Repatriation General Hospital, Andrology, Sydney, Australia*

Study question: To determine the effect of escalated-BEACOPP on spermatogenesis in Hodgkin's lymphoma patients and to investigate both the potential for spermatogenesis recovery and factors predicting recovery.
Summary answer: Escalated-BEACOPP causes significant spermatogenesis impairment in Hodgkin's lymphoma patients, with spermatogenesis recovery occurring only in a minority of individuals. No factors predicting recovery were elucidated.
What is known already: Escalated BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, prednisone), a multiagent chemotherapy regimen, was introduced in the 1990s for the treatment of advanced-stage Hodgkin's lymphoma. It demonstrates superior prognostic outcomes in progression-free survival, overall survival and complete remission when compared to the preceding first-line protocol, ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine). These benefits over ABVD appear to come at the cost of increased germinal toxicity and impaired spermatogenesis in male patients. The degree of impairment and the recovery of this fertility post-treatment remains in question, and considering the youth of many Hodgkin's lymphoma survivors, is clinically significant.
Study design, size, duration: A retrospective longitudinal study examining semen and hormonal analysis of 28 male patients with advanced-stage Hodgkin's lymphoma (Ann Arbor stage IIB, III or IV) treated with escalated BEACOPP. Pre- (n=28) and post-treatment data (n=19) was evaluated. 19 patients engaged in post-escalated BEACOPP analysis which occurred at no uniform time, between one and six years post-treatment. The number of post-treatment analyses undertaken by each patient varied from one to four with a median of two.
Participants/materials, setting, methods: Included patients were those with histologically-confirmed advanced-stage Hodgkin's lymphoma who presented to Concord Repatriation General Hospital's (CRGH) Andrology Department between January 2009 and June 2017 for semen cryopreservation and analysis prior to commencing escalated-BEACOPP therapy, without age limits. As a retrospective study, data was obtained from medical records (stage, treatment) and semen cryopreservation data of the CRGH Andrology department. Each analysis involved seminal fluid analysis, hormonal analysis (testosterone, LH, FSH, SHBG) and testicular volume measurement.
Main results and the role of chance: In pre-treatment analysis, gonadal dysfunction was present in one in three patients with 68% of patients having normospermia and 32% having azoospermia or other dyspermia. In the identification of factors which may affect baseline sperm quality, only the presence of B symptoms (weight loss ≥ 10%, night sweats or fevers ≥ 38°C) was found to have significant effect on pre-treatment semen quality ($P<0.05$).

All 19 patients undergoing post-treatment follow-up were azoospermic at first analysis after escalated BEACOPP. Serum LH ($P<0.01$) and FSH ($P<0.001$) were significantly increased, while testosterone and SHBG concentrations were not significantly changed.

Three patients (15.8%) recovered spermatogenesis with a mean recovery time of 44 months. Spermatogenesis recovery in these three patients occurred at 36.5 months (Patient A), 44.6 months (Patient B) and 50.8 months (Patient C) post-treatment.

To ascertain whether potential predictors of spermatogenesis recovery exist, a binary logistic regression was performed on patient age (P=0.414), the presence of B symptoms (P=0.715), pre-treatment total sperm count (P=0.126) and the number of escalated-BEACOPP cycles received (P=0.261). None of these factors were found to contribute to the likelihood of spermatogenesis recovery.
Limitations, reasons for caution: Primary limitations are 1) the small sample-size, which limited statistical power and subgroup analysis, and 2) the retrospective nature, culminating in significant loss to follow-up and no schedule of analysis. Records also contained limited data on other possible risk factors for impaired spermatogenesis including radiotherapy, pre-treatment ESR, and bulky/mediastinal disease.
Wider implications of the findings: These results suggest that, while impaired spermatogenesis is initially universal after escalated-BEACOPP, spermatogenesis recovery is evidenced in a proportion of patients in the years following. This research will allow appropriate evidence-based risk-counselling of advanced-stage Hodgkin's lymphoma patients considering escalated-BEACOPP and facilitate more informed patient decision-making.
Trial registration number: Not applicable

P-057 Immunohistochemical Investigation of CatSper Ca2 + Channel Proteins in Normozoospermia and OAT patient groups in Progesterone Applied Culture Media.

N. Köprülü[1], T. Irez[2]

[1]Biruni University, Institute of Health Sciences- Department of Clinical Embryology, Istanbul, Turkey ;
[2]Istanbul Yeni Yuzyıl University, Medical Faculty- Clinical Embryology, İstanbul, Turkey

Study question: To investigate effect of progesterone, which is a strong chemoattractant candidate, on sperm tail motions that evaluate hyperactivation and CatSper expression in fertile and infertile cases.
Summary answer: Progesterone-treated sperms effected Catsper Channels and caused hyperactivation in infertile and fertile cases.
What is known already: Sperm chemotaxis causes intracellular calcium increase and hyperactivation motility as a result of Ca2 + flow into the cell with the activation of odor receptors. CatSper channels are cation channels necessary for fertility in rodents. Chemoattractants provide CatSper cation channel protein expression in the sperm principal peace region. Rabbit studies have shown that progesterone produces CatSper expression.
Study design, size, duration: Sperm chemotaxis causes intracellular calcium increase and hyperactivation motility as a result of Ca2 + flow into the cell with the activation of odor receptors. CatSper channels are cation channels necessary for fertility in rodents. Chemoattractants provide CatSper cation channel protein expression in the sperm principal peace region. Rabbit studies have shown that progesterone produces CatSper expression.
Participants/materials, setting, methods: After standard semen analysis, sperm prepared in two groups by the swim-up method was kept at 37 ° C for 45 minutes in culture medium containing progesterone. Motility and CatSper IHC were evaluated before and after incubation.
Main results and the role of chance: Progesterone was found to have important chemoattraction ability for hyperactivation effect on the sperm tail movement on normospermic and oligoasthenoteratospermic sperm that integrity in luteal phase doses. Infertile group showed less progressive motility, less hyperactivation and less CatSper expression than fertile Normospermia group. (p<0,05). Progesterone administration caused higher rate of hyperactivation and CatSper positivity in normospermic cases than OAT group (p <0.05).
Limitations, reasons for caution: We conducted our study in 56 cases. It is beneficial to conduct the study in larger groups.
Wider implications of the findings: The results of our study may be the pioneer of studies investigating the relationship between CatSper expression and sperm hyperactivation. A new research project is planned to examine IVF results in terms of infertility and unexplained infertility in men.
Trial registration number: 0

P-058 Combined treatment with myo-inositol and alpha-lipoic acid of sub-fertile men significantly improves semen competence in IVF cycles

F. Sozzi[1], P. Canepa[1], E. Maccarini[1], C. Massarotti[1], C. Rizzo[1], D.L. Alessandro[2], M. Gallo[2], E. Licata[2], P. Anserini[1], R. Rago[2], P. Scaruffi[1]

[1]IRCCS Ospedale Policlinico San Martino, UOS Fisiopatologia della Riproduzione Umana, Genova, Italy ;
[2]Ospedale Sandro Pertini - ASL Roma 2, UOSD Fisiopatologia della Riproduzione e Andrologia, Roma, Italy

Study question: Does combined treatment with myo-inositol and alpha-lipoic acid of sub-fertile patients improve semen competence in IVF cycles?
Summary answer: Sub-fertile men's diet oral supplementation with combined myo-inositol and alpha-lipoic acid improved sperm parameters and semen reproductive competence in IVF cycles.
What is known already: Human infertility affects 15% of couples in childbearing age, of which 40% is due to male factors. Alterations of sperm number, motility and morphology are mostly associated with male infertility. Some 30% to 80% of sub-fertile men may be associated to oxidative stress (OS) that damage spermatozoa. Furthermore, negative relations between OS and low success of IVF techniques has been observed. Antioxidant oral supplements are widely used in sub-fertile patients. We previously reported that a combination of nutraceuticals (myo-inositol, alpha-lipoic acid, folic acid, betaine, and vitamins) significantly improves sperm parameters in sub-fertile men.
Study design, size, duration: This pilot, multi-centric study was performed in 2018-2019 including 124 idiopathic, sub-fertile, 26-53 years aged men. Semen analysis was performed before (T0) and after 90 days (T90) of treatment and results were compared. A subset of 62 patients who underwent an IVF cycle at T0 with unexplained <70% fertilization rate (sperm count >1x10^6/ml, woman age <38 years, inseminated oocytes >6) took the antioxidant supplements. Outcomes of the paired T0 and T90 IVF cycles were compared.
Participants/materials, setting, methods: Patients' diet was supplemented with myo-inositol (1000 mg), alpha-lipoic acid (800 mg), coenzyme Q10 (200 mg), selenium (83 mcg), zinc (15 mg), vitamin B2 (2.8 mg), B6 (2.8 mg), B12 (5 mcg). Sperm analysis was assessed according to WHO manual. Semen OS was measured by MioxSIS® (Aytu BioScience). The IVF cycles were performed according to conventional procedures using fresh gametes of each couple. Wilcoxon and chi-square tests compared data before and after the antioxidant treatment.
Main results and the role of chance: Statistical analyses showed a significant increase of sperm concentration (P=0.0307) and motility (P=0.0003) after 90 days of treatment. After therapy with antioxidants it was observed a decreasing trend of OS levels in semen (normalized oxidation-reduction potential (mV/10^6 ml sperm). T0: 8.9+8.6; T90: 6.1+7.7). As regard as the outcomes of the IVF cycles, the fertilization rate was significantly higher in the T90 cycles with respect to T0 ones (P<0.0001). Moreover, results demonstrated a significant improvement in the embryo quality in the cycles performed at T90, in terms of higher embryo top quality rate (P=0.0001) and blastulation rate (P<0.0001). Any T0 IVF cycle did not result in a successful pregnancy. Conversely, in the T90 cycles we obtained 11/62 clinical pregnancies (30%) with an implantation rate of 19%.
Limitations, reasons for caution: These data will be confirmed in a larger sample size to correct primary endpoints for putative confounders. We also foresee to deeply investigate the effect of the antioxidant treatment on semen OS status and ultimately on sperm DNA integrity. Lastly, a prospective study will determine true clinical value and limitations.
Wider implications of the findings: The outcomes of this pilot study suggest that treatment of sub-fertile men with combined myo-inositol and alpha-lipoic acid may have beneficial effect on sperm quality and pregnancy rates. Therefore, such a "nutraceutical" diet supplementation may become an additional tool to reduce the semen OS, thus improving the success of IVF.
Trial registration number: not applicable

P-059 Improvement in mitochondrial integrity and fertility potential in men with Rheumatoid arthritis by yoga based lifestyle intervention

S. Gautam[1], R. Kumar[2], U. Kumar[3], R. Dada[1]

[1]All India Institute of Medical Sciences, Anatomy, New Delhi, India ;
[2]All India Institute of Medical Sciences, Urology, New Delhi, India ;
[3]All India Institute of Medical Sciences, Rheumatology, New Delhi, India

Study question: Can a yoga based lifestyle intervention bring about alterations in mitochondrial integrity and fertility potential in men with Rheumatoid arthritis?
Summary answer: Yoga not only reduces disease severity, minimizes usage of drugs but also increases mitochondrial copy number and improves mitochondrial integrity.
What is known already: The complex mechanism of Rheumatoid arthritis with infertility in men involves interactions between endocrine, immune, and reproductive systems. Association of autoimmunity with dysregulated androgen (hypogonadism) levels may cause transient infertility in men. Furthermore, usage of disease-modifying antirheumatic drugs (DMARDs) like cyclophosphamide, methotrexate, sulphasalazine etc. may result into decreased quantity and quality of sperm, mitochondrial dysfunctions, reduced fertility potential and ultimately permanent infertility. These drugs can cross blood-testis-barrier and induce changes in sperm impairing spermatogenesis. Complementary and alternative medicine like yoga reduces seminal oxidative stress and its consequences like DNA fragmentation in sperm nuclear/mitochondrial genome.
Study design, size, duration: Sixty males with RA were enrolled in this 12-week prospective, open-label, single-arm exploratory study, designed to explore the impact of yoga based lifestyle intervention (YBLI) on mitochondrial integrity and fertility potential in men with Rheumatoid arthritis.
Participants/materials, setting, methods: The participants were evaluated for pre (day 0) and post (12th week) levels of inflammatory markers: IL-6, IL-17A

and soluble HLA-G. Mitochondrial health was assessed by calculation of mitochondrial copy number variation and transcripts associated with mitochondrial integrity: *AMPK, PRC-1, TFAM, SIRT-1*. Sperm parameters as per WHO 2010 guidelines and reactive oxygen species (ROS), DNA fragmentation index (DFI), 8-hydroxy-2'-deoxy guanosine (8-OHdG) were estimated.
Main results and the role of chance: The mean levels of ROS ($p<0.05$***), DFI ($p<0.05$**) and 8-OH2dG ($p<0.05$**) levels were significantly reduced after 12 weeks of yoga intervention. We observed reduction in mean levels of CRP ($p<0.05$***), IL-6 ($p<0.05$**), IL-17A ($p<0.05$**) and soluble HLA-G ($p<0.05$**) at 12 weeks compared to baseline level (day 0). There was a significant increase in mitochondrial copy number and increased expression of transcripts that maintain mitochondrial integrity after 12 weeks with respect to the baseline levels (day 0).
Limitations, reasons for caution: Compliance of patients for Yoga based lifestyle intervention was poor, hence we enrolled large number of patients to achieve the desirable sample size.
Wider implications of the findings: Adoption of yoga based lifestyle intervention as an integral part of our lifestyle may hold the key to increase mitochondrial copy number, increase the expression levels of transcripts that maintain mitochondrial integrity and its associated consequences on physical, mental and reproductive health.
Trial registration number: N/A

P-060 TDG involves in the key maintenance pathways of neonatal spermatogonial cells

T.L. Lee[1]

[1]*The Chinese University of Hong Kong, School of Biomedical Sciences, Sha Tin, Hong Kong*

Study question: The role of TDG in spermatogonial cell development during neonatal stage
Summary answer: TDG involves in key pathways associated with spermatogonial cell maintenance at neonatal stage.
What is known already: Active DNA demethylation through 5-formylcytosine (5fC) and 5-carboxylcytosine (5caC) by TDG is essential for mouse embryonic and stem cell development, but its role remains elusive in SSC biology. Therefore, we examined the functional role of TDG in male germ cell development using our recent established germline-specific TDG knockout animal.
Study design, size, duration: 6-day old balb/c mouse with TDG KO (KO) were compared against the wild type and hemizygous controls.
Participants/materials, setting, methods: 6-day old balb/c mouse strain was used. Isolation of neonatal spermatogonial population was performed by OCT4 GFP signal.
Main results and the role of chance: Using KO TDG animal model, we found that TDG knockout males expressed a progressive loss of fertility. Transcriptome analysis by RNA-seq revealed altered gene expression of a subset of retinoic acid target genes, including Stra8 and Cyp26a1. Furthermore, we found that the demethylation of Stra8 during the KIT transition was impaired after depletion of TDG in Oct4-GFP+ undifferentiated spermatogonia. These results indicate that TDGmediated active demethylation regulates the differentiation of undifferentiated spermatogonia through the coupling of the retinoic acid signaling pathway.
Limitations, reasons for caution: The role of TDG in adult SSC stage was not studied.
Wider implications of the findings: A key question in SSC biology is whether and how epigenetic programs contribute to the cellular identity of SSC and specific gene expression programs. The study provides details about the molecular regulation of TDG in neonatal spermatogonial cell development and will allow the development of future male infertility treatment.
Trial registration number: not applicable

P-061 The presence of high risk human papilloma viruses in semen affects seminal parameters and sperm DNA quality in infertile men

E. Mastora[1], **A. Zikopoulos**[1], **E. Hatzi**[1], **I. Mpoumpa**[1], **I. Georgiou**[1], **K. Zikopoulos**[1]

[1]*University of Ioannina, Department of Medicine, Ioannina, Greece*

Study question: The aim of the present study was to assess the impact of high risk HPV infection on semen parameters and sperm DNA fragmentation index in infertile men.
Summary answer: High risk HPV seminal infection is probably responsible of lower sperm motility and higher DNA fragmentation index (DFI).
What is known already: HPV infection is a common sexually transmitted disease, related to genital warts and cancer. In males, human papilloma virus DNA has been found in the seminal fluids. HPV is commonly present in sperm samples. However, whether the prevalence of high risk HPV in semen is associated with modified semen parameters and sperm DNA fragmentation index has yet to be elucidated.
Study design, size, duration: From January to December 2018, about 505 infertile couples were analysed at the Human Reproduction Unit of Ioannina University Hospital. A total of 335 clinical and laboratory data from male partners were included in the study. Semen parameters and sperm DNA fragmentation index were compared among those with or without HPV in spermatozoa.
Participants/materials, setting, methods: A real time polymerase chain reaction assay was performed to detect the presence of HPV. All patients underwent a semen analysis. The amount of DNA fragmented sperm, expressed in DFI, was valuated using the sperm chromatin dispersion test. Semen parameters and sperm DNA fragmentation index were compared among high risk HPV positive and HPV negative men.
Main results and the role of chance: 49 (14,6%) of the total semen samples were HPV positive. Overall, 38/335 (11,3%) and 11/335 (3,3%) patients had high risk HPV and low risk HPV, respectively. HPV31 was the prevalent type. The amount of DNA fragmented sperm between high risk HPV positive and negative males was different. Sperm motility was lower (P=0.007) and SDF values were higher (P=0.003) in infected men compared to those without HPV.
Limitations, reasons for caution: Main limitation is the relatively small sample size.
Wider implications of the findings: The results suggest that high risk HPV infection probably impairs sperm DNA quality. These observations point out the importance of testing seminal HPV presence in everyday clinical practice.
Trial registration number: None

P-062 Permanent testicular metabolomic and lipidomic signatures induced by the adoption of a high-fat diet in childhood and sperm quality in adulthood

Study question: Can a diet intervention in young mice fed high fat diet improve sperm quality in adulthood?
Summary answer: The adoption of high-fat diets from childhood to early adulthood causes irreversible metabolic and lipidomic changes in testis, reflected in poorer sperm quality.
What is known already: The prevalence of overweight and obesity has soared worldwide in recent decades, fueled by poor dietary habits as the adoption of high-fat diets (HFD). Besides, the adoption of HFD often occurs in childhood, triggering the onset for these conditions and associated comorbidities, such as diabetes, at increasingly younger age. Thus, men can spend most of their sexual development suffering from a metabolic disease, with unknown consequences for future sperm quality. A change in diet habits may prevent the progression of the disease, but it is not known whether it can rescue potential negative effects of HFD to male fertility.
Study design, size, duration: Hereby, we used a rodent model to study diet intervention during early adulthood, after childhood obesity, to correct HFD and how it affects the metabolic and reproductive health later in life. For that, after weaning (day 21 after birth), 3 groups of 12 mice each were fed with different diet regimen during 200 days: CTRL – standard mucedola; HFD – high-fat diet; HFDt – high-fat diet for 60 days, then replaced by standard mucedola.

Participants/materials, setting, methods: Animals were then sacrificed, and tissues collected and weighed. Epididymal sperm parameters (sperm counts, motility, viability and morphology) were evaluated. Animals biometric, metabolic (fasting glucose, ipGTT, ipITT, HOMA2) and endocrine (serum insulin, testosterone, estrogen, gonadotrophins) parameters were studied. Testicular metabolites were extracted and characterized by 1H-NMR and LC-MS. Testicular mitochondrial (citrate synthase, complex I, II and IV) and antioxidant activity (CAT, SOD, GSR, GPx) were also evaluated by colorimetric and fluorometric methods.

Main results and the role of chance: Our results showed an induction of a pre-diabetic state due to consumption of a HFD. Based on HOMA2, diet intervention in early adulthood prevents the development of metabolic syndrome in adulthood, although insulin resistance is maintained. No changes were observed in endocrine function. Importantly, sperm parameters were not recovered after diet intervention. Spermatozoa motility and viability were still affected in mice fed HFD during childhood, even after a dietary intervention, particularly head defects. HFD, even if transient, promoted changes in testicular metabolome and lipidome. Notably, it affected the glutamate, pyruvate, ethanol and ammonia metabolism, and promoted the storage of unsaturated fats. Interestingly, no differences were found in mitochondrial and antioxidant enzyme activities. The progression of metabolic syndrome due to HFD was found to be correlated with the changes in testicular metabolism. In turn, testicular metabolic remodeling was strongly correlated with sperm parameters. Therefore, a causal relation between the adoption of HFD in childhood and poorer sperm quality in adulthood is not just a stochastic event.

Limitations, reasons for caution: Despite using this mouse model, we are unable to state whether normal sperm quality could be achieved even later in life, or if the adoption of HFD in adulthood triggers the same deleterious effects in sperm parameters.

Wider implications of the findings: Diet intervention reverses some of the detected changes but cannot overcome the long-term consequences of HFD to sperm quality. Our conclusions must raise awareness about tackling childhood obesity, to avoid irreversible damage for the reproductive health of the future fathers, with unpredicted effects to their progeny.

P-063 Blood plasma miR-20a-5p expression as a potential non-invasive diagnostic biomarker in patients with non-obstructive azoospermia

G. Cito[1], P. Pinzani[2], R. Fucci[3], R. Picone[3], F. Salvianti[2], C. Giachini[3], P. Falcone[3], E. Micelli[3], A. Cocci[1], P. Verrienti[1], A. Minervini[1], M. Carini[1], A. Natali[1], M.E. Coccia[3]

[1]Careggi Hospital- University of Florence, Dept. of Urology, Florence, Italy ;
[2]Careggi Hospital- University of Florence, Molecular and Clinical Biochemistry Unit, Florence, Italy ;
[3]Careggi Hospital- University of Florence, ARTs Center, Florence, Italy

Study question: To evaluate the blood plasma miR-20a-5p expression in infertile patients with non-obstructive azoospermia (NOA) compared to healthy normozoospermic men.

Summary answer: The overexpression of blood plasma miR-20a-5p seems to be directly related to damaged spermatogenesis, including conditions of NOA.

What is known already: Recently, alterations in the expression of specific microRNAs (miRNAs) in semen have been linked to altered spermatogenesis suggesting their expression could be used as potential infertility biomarkers and explain the molecular mechanisms underlying the altered spermatogenesis. In previous animal studies dysregulation of miR-20a-5p was found to be under-expressed in the low motile sperm and potentially target genes associated with cell apoptosis and spermatogenesis alteration. Considering previous findings with miRNAs in human plasma, serum and urine, we believe that the expression of miR-20a-5p might represent a new source of non-invasive diagnostic biomarkers for idiopathic male infertility.

Study design, size, duration: From January 2018 to December 2019, 24 infertile couples who referred to our ARTs Centre were prospectively enrolled. All the patients were included into two groups: Group 1 comprised infertile men with NOA, Group 2 involved healthy normozoospermic men belonging to couples with female infertility tubal factor who achieved pregnancy using IVF or ICSI.

Participants/materials, setting, methods: The expression of circulating miR-20a-5p was assessed by RT qPCR in plasma samples. A relative quantification strategy was adopted using the $2^{-\Delta Cq}$method to calculate the target miR-20a-5p expression with respect to miR-16-5p as an endogenous control. Total cell-free RNA extracted from 0.5 ml plasma using the mirVana PARIS kit (ThermoFisher Scientific, USA) was submitted to RT-qPCR using TaqMan Advanced miRNA cDNA Synthesis Kit and TaqMan® Advanced miRNA Assays (ThermoFisher Scientific) according to the manufacturer's instructions.

Main results and the role of chance: Group 1 included 14 patients, Group 2 comprised 10 men. No genetic abnormalities and significant comorbidities were detected in all the patients enrolled. Mean male age was 35.6 ± 4.2 years. Considering the Group 1, mean FSH value was 19.4 ± 7.8 IU/l, mean LH value was 8.5 ± 3.4 IU/l, mean TT was 12.5 ± 3.9 nmol/l, mean TSH was 2.0 ± 1.1 mIU/l and mean PRL was 10.5 ± 3.2 ng/ml. Mean right testicular volume was 8.9 ± 5.2 ml, mean left testicular volume was 8.2 ± 4.5 ml. All NOA patients underwent testicular sperm extraction (TESE). Successful sperm retrieval (SR) with cryopreservation was found in 8/14 patients (overall SR rate: 57.1%). Mean sperm concentration was 0.001 ± 0.0001 x 10^6/ ml. Mean non progressive motility was 0.2 ± 0.6 %. Mean number of biosystem straws collected was 3.2 ± 2.0. All healthy normozoospermic men showed serum hormonal levels and testicular volume in the normal range. Mean miR-20a-5p value was 0.25 ± 0.20 and 0.06 ± 0.02 in the Group 1 and Group 2, respectively. Thus, the relative expression of miR-20a-5p was significantly higher in patients affected by NOA than in healthy normozoospermic control subjects (p=0,026).

Limitations, reasons for caution: Further larger studies are needed to evaluate the correlation between this marker and testicular histopathological findings in order to increase its usefulness as a predictor in the clinical practice.

Wider implications of the findings: Blood plasma miR-20a-5p could represent a potential non-invasive diagnostic biomarker in infertile patients with non-obstructive azoospermia who undergo TESE. A possible correlation of this marker with testicular histopathological findings could allow the clinician to correctly counsel the azoospermic patients in performing surgery for fertility purpose.

P-065 Novel PMFBP1, TSGA10 and SUN5 variants in acephalic spermatozoa syndrome and the overcoming this male infertility

L. Weina[1], W. Ni[2], Z. Huan[3], Y. Silu[1], L. Ge[3], L. Guangxiu[3], L. Gang[1]

[1]Reproductive and Genetic Hospital of CITIC-Xiangya, Andrology Laboratory, Changsha, China ;
[2]Central South University, Institute of Reproduction and Stem Cell Engineering, Changsha, China ;
[3]Reproductive and Genetic Hospital of CITIC-Xiangya, Reproductive center, Changsha, China

Study question: What are the genetic diagnosis and effective therapeutic strategies to overcome infertility in acephalic spermatozoa syndrome?

Summary answer: We identified four novel mutations in *PMFBP1*, *TSGA10*, and *SUN5* in three out of eleven patients. These male infertility could be overcome by ICSI.

What is known already: Acephalic spermatozoa are a rare teratozoospermia which leads to male infertility. The vast majority of acephalic spermatozoa cases are idiopathic, and 52.63% (51.22%, 21/41 SUN51-5; 50%, 7/14 PMFBP16 7; 100%, 1/1 TSGA108; 100%, 1/1 BRDT9) have been associated with definitive genetic etiology. Considering that negative/negative results are rarely published,

the previous study population mainly covers Hefei and Xiamen, and the contribution of these genes to acephalic spermatozoa might not be as high as described previously.

Study design, size, duration: This genetic study used whole-exome and Sanger sequencing to discover and identify related-genes mutations, and was followed by a series of studies to certificate potentially damaging.

Participants/materials, setting, methods: 11 patients with acephalic spermatozoa were recruited from our hospital in China in the first half of year 2019. Genomic DNA samples from the individuals were extracted from peripheral blood. All samples were subjected to whole-exome sequencing and variant filtering, using Sanger sequencing to identify mutations. Identified mutations were further investigated using bioinformatics, papanicolaou staining, CASA, transmission electron microscopy(TEM), scanning electron microscopy (SEM) and RT-PCR.We evaluated their available clinical data and pregnancy outcomes.

Main results and the role of chance: We identified one compound heterozygous variant (c.361C>T[p.Gln121Ter],c.2089-1G>T) in *PMFBP1*, one homozygous mutation (c.1739A>C[p.Gln580Pro]) in *TSGA10*, and one homozygous variant (c.772C>T[p.Arg258Cys]) in *SUN5* in three unrelated infertile men.The remaining were new gene results that should be further validated by animal models. RT-PCR in blood revealed that mutation causes loss of the wild-type splice site, which leads to aberrant splicing of *PMFBP1* mRNA and consecutive formation of the *PMFBP1* alternative transcript (p.Ile697Leufs*257). All of these mutations cause protein truncations or lead to point mutations and have a recessive inheritance pattern. All patients with acephalic spermatozoa had different phenotypes and proportions caused by their different ultrastructure. Patients with p.Arg258Cys in *SUN5* showed 70% acephalic spermatozoa and 25% microcephalic spermatozoa but no so-called round-headed like spermatozoon,which suggest that a variant in *SUN5* does not result in microcephalic spermatozoa in patient 3. There are other pathogenic genes for his multiple malformations in spermatozoa, which need to be further explored. *PMFBP1*, *TSGA10* and *SUN5* may associate with the centrosome and basal body and participate in completing the coupling apparatus, ultimately resulting in acephalic spermatozoa but not delayed or stagnated embryonic development. *PMFBP1*, *TSGA10* and *SUN5* mutation-associated male infertility could be successfully overcome by ICSI in humans.

Limitations, reasons for caution: Our pilot study was intended as proof of principle, and the number of patients is low. Although these patient defects could be resolved by microinjection of the tailless sperm head into the oocyte, further studies are needed to validate the safety of offsprings.

Wider implications of the findings: We summarized known data on the genetic contribution of genes to acephalic spermatozoa, expanded the mutation spectrum, and analyzed the variety of phenotypes for each type of mutation. This work lays the foundation for the genetic diagnosis, genetic counseling and treatment of acephalic spermatozoa syndrome in China,for reproductive options.

Trial registration number: Not applicable.

P-066 Effect of high fat diet induced paternal obesity and micronutrient intervention on offspring testicular antioxidant capacity

M.M. Billah[1], S. Khatiwada[1], V. Lecomte[1], M.J. Morris[1], C.A. Maloney[1]

[1]UNSW Sydney, School of Medical Sciences, Sydney, Australia

Study question: Does paternal obesity perturb testicular antioxidant capacity in father and offspring? If so, can we mitigate this transgenerational effect by micronutrient intervention in father?

Summary answer: Obesity-related reductions in testicular SOD and glutathione peroxidase activity in fathers and increased SOD activity in offspring were ameliorated by micronutrient intervention in obese fathers.

What is known already: Obesity has tripled in males of reproductive age since 1970. As well as affecting individuals, obese people can produce offspring that are predisposed to metabolic and reproductive complications. One possible mechanism is oxidative stress which increases sperm DNA damage, alters sperm epigenetic profile thus affecting future generations. It is known that obesity is associated with higher levels of oxidative stress. We sought to reduce this effect by providing a micronutrient supplement (consisting of metabolites of one-carbon metabolism) targeting oxidative stress to prospective rat fathers.

Study design, size, duration: Founder (F0) male Sprague Dawley rats (12 per group, 48 total) were weaned (Day21) onto control (C) or HFD (H), or micronutrient supplemented versions of these (CS; HS). At 19 weeks of age, they were mated with CD females. 48 F1 offspring (one from each F0 pairing) were weaned onto chow diet, generating four F1 groups. At cull (30 weeks for F0, 23 weeks for F1), right testis was harvested and stored at -80°.

Participants/materials, setting, methods: Testis was assayed for the level of lipid peroxidation (MDA), glutathione and the activity of superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPx) in F0 founders and MDA, SOD, CAT in F1 offspring according to kit protocols. Susceptibility index of prooxidative damage was calculated in F0 testis from the ratio SOD:CAT+GPx. Statistical analyses were performed using IBM SPSS v23.0 software. Data were presented as mean±SEM and analysed by two-way ANOVA followed by post hoc LSD.

Main results and the role of chance: In founders, HFD significantly increased body weight (H: 765.1±16.5 vs C: 632.5±15.1 g; p= 0.0001) which was normalized by supplementation (HS: 601.9±11.8 g vs H; p=0.0001). Supplemented HFD fed fathers had reduced testicular lipid peroxidation (HS: 7.5±2.1 vs H: 12.8±1.7 nmol/g testis; p=0.01). No significant effect of HFD was observed in testicular lipid peroxidation. HFD fed fathers had reduced testicular enzymatic antioxidant activity (SOD & GPx: H vs C; p=0.002) while supplementation restored these activities (HS vs H; p=0.002). Moreover, supplementation increased a major cellular antioxidant, glutathione (HS: 4179.7±197.1 vs H: 3421.2±194.8 nmol/g testis; p=0.004). No significant effect of HFD was observed on testicular glutathione levels. Susceptibility index of prooxidative damage was significantly increased by chronic HFD intake (H: 1.7±0.2 vs C: 1.1±0.1; p=0.002) and normalized by supplementation (HS: 1.2±0.1 vs H; p=0.004). No effect of HFD and supplementation was observed in F0 testicular catalase activity. In F1 testis, offspring from HFD fed fathers had increased testicular SOD activity (H: 67.2±6.5 vs C: 49.6±6.1 U/mg protein; p=0.04) whereas, offspring from HS fathers had decreased SOD activity (HS vs H; p=0.02). No effects of paternal diet and supplementation were observed in offspring testicular lipid peroxidation level and catalase activity.

Limitations, reasons for caution: F0 testis was harvested at 30 weeks rather than at mating (19 weeks). As we have no measurement of sperm DNA damage in F0 and F1 males, it is difficult to comment on underlying mechanisms of transgenerational effects of paternal obesity at this stage.

Wider implications of the findings: HFD induced paternal obesity may affect offspring testicular antioxidant capacity which might relate to metabolic and reproductive complications in future generations. Our micronutrient supplementation might be a novel intervention to restore antioxidant capacity in obese father and their offspring. Supplementation of non-obese individual may have deleterious effects in next generation.

Trial registration number: Not applicable

P-067 Seminal oxidative stress and sperm DNA fragmentation in men from couples with idiopathic recurrent pregnancy loss or infertility

J.M. Kold[1], M.R. Dalgaard[1], F. Dardmeh[2], H. Alipour[2], O.B. Christiansen[1]

[1]Aalborg University Hospital, Department of Obstetrics and Gynaecology, Aalborg, Denmark ;

[2]Aalborg University, Department of Health Science and Technology, Aalborg, Denmark

Study question: Are seminal oxidative stress (OS) and sperm DNA fragmentation (SDF) correlated, and can they explain idiopathic infertility or recurrent pregnancy loss (RPL)?

Summary answer: OS and SDF levels are not different between case groups and fertile controls and OS correlates to SDF in infertile but not in RPL cases.

What is known already: Around 15% of all couples experience infertility while 1-2% experience RPL. Approximately 25% of infertility and 40% of RPL cases are considered idiopathic. Studies have reported that seminal OS and SDF appear frequently in men from couples with infertility or RPL. Furthermore, the use of sperm with a high level of SDF has been associated with poor artificial reproductive technology outcome. However, there is no consensus on the impact of and whether to test for seminal OS or SDF in cases of idiopathic RPL or infertility.

Study design, size, duration: This clinical case-control study aimed to include 30 men in each of the two case groups and 30 fertile controls. The data collection and assessments were according to the protocol planned between June 2019 and July 2020 at a tertiary university centre for infertility and RPL treatment.
Participants/materials, setting, methods: Semen samples from male partners of couples with idiopathic infertility (n=23), idiopathic RPL without concomitant infertility (n=20), and fertile men (n=29) were assessed for SDF using sperm chromatin dispersion test, concentration, motility and morphology by the Sperm Class Analyzer (Microptic S.L., Spain) computer aided sperm analysis (CASA) system. Seminal OS was measured as static oxidation-reduction potential (sORP) using Male Infertility Oxidative System (MiOXSYS, Aytu BioScience Inc, USA). sORP were normalised to semen concentration.
Main results and the role of chance: The infertile and RPL groups, showed no significant difference in the levels of OS (p=0.59 and p=0.67, respectively) or SDF (p=0.85 and p=0.11 respectively) when compared to fertile controls. There was a significant correlation between OS and SDF in the infertile group (R=0.404, p=0.028) but not in RPL group (R=0.225, p=0.18). Additionally, in the infertile group 84.6 % of men with a high level of OS (normed sORP >1.38mV/106 sperm mL) had a high level of SDF (> 15 %), whereas 60 % with low OS had a low level of SDF. The infertile men were from couples diagnosed with idiopathic infertility based on traditional (manual) semen analysis, but nevertheless analysed by CASA 78.3% had a motility below the World Health Organisation (WHO) reference values.
Limitations, reasons for caution: Several of the men diagnosed with idiopathic infertility had a motility below the WHO reference values. Thus, this study had not only examined men from couples with idiopathic infertility as intended but also men who may have occult male factor infertility.
Wider implications of the findings: OS determined as normed sORP may be useful to evaluate the risk of SDF in men with infertility. Several men diagnosed with idiopathic infertility had low motility when samples were assessed using CASA, indicating that these men had been misdiagnosed with idiopathic infertility instead of male factor infertility.
Trial registration number: Ethical committee approval no. N-20190023

P-068 A new oral treatment based on the ATM/ATR DNA repair pathways enhancement reduce sperm DNA damage and improve semen parameters

J. Franco[1], S. Lara-Cerrillo[2], Á. Vives-Suñé[3], M. Ballester-Ferrer[3], T. Lacruz-Ruiz[2], C. Rosado-Iglesias[2], M. Velasco-Álvarez[4], E. Rodríguez-Ferradas[4], A. Jiménez-Macedo[5], J. Carrera-Rotllan[5], A. García-Peiró[2]

[1]Hospital Ruber Internacional, Human Reproduction, Madrid, Spain ;
[2]CIMAB- Barcelona Male Infertility Centre, Research & Development, Sant Quirze del Vallés - Barcelona, Spain ;
[3]Hostpital Universitari Dexeus, Reproducció Assistida, Barcelona, Spain ;
[4]Instituto Vasco de Fertilidad - Grupo IVF Life, Reproducción asistida, San Sebastián, Spain ;
[5]Unitat d'Endocrinologia Ginecològica, Reproducció assistida, Vic, Spain

Study question: Can double-strand sperm DNA breaks and semen parameters be improved by oral administration of antioxidants and ATM/ATR-enhancers?
Summary answer: A new treatment based on ATM/ATR-repair-pathways enhancement significantly reduced double-strand sperm DNA breaks and improved semen parameters.
What is known already: Double-strand breaks (DSB) take place during male meiosis to enable DNA recombination and packaging. These breaks must be repaired later to ensure sperm genome integrity. However, defective chromatin condensation, incomplete apoptosis and oxidative stress can increase both DSB and single-strand breaks (SSB). Several studies demonstrated that DSB are a major source of chromosome abnormalities causing miscarriage. The ATM/ATR kinases play an essential role in genomic maintenance through the repair of DSB and the activation of cell-cycle checkpoints. Moreover, seminal parameters are improved by oral treatments including antioxidants. The enhancement of ATM/ATR-repair-pathways could be a new strategy to improve sperm quality.
Study design, size, duration: This prospective and multicentric study included 71 infertile patients that were randomly divided into three groups, receiving a different treatment: Control group (Androferti, n = 21); Experimental formula 1 (high concentration of ATM/ATR-enhancer, n = 25); Experimental formula 2 (low concentration of ATM/ATR-enhancer, n = 25). Semen parameters and sperm DNA fragmentation were determined before and after 13 weeks of treatments.
Participants/materials, setting, methods: All patients included presented high values of DSB. Patients receiving medication or other fertility treatments before the start of the study were excluded. DSB and SSB were analysed through the Neutral and Alkaline CometFertility assay (CIMAB, Spain), respectively. Semen parameters including concentration, total sperm count and progressive motility were determined according to the last World Health Organization guideline.
Main results and the role of chance: DSB values were significantly reduced by all three treatments (p=0.042). The greatest reduction was observed in Formula 1, which reduced 27.1%. Formula 2 and the Control group reduced 19.9% and 15.8%, respectively. SSB was reduced by all three treatments. Formula 1 significantly reduced SSB 19.5% (p=0.040). Even not statistically significant, Formula 2 and the Control group reduced SSB 6.8% and 8.6%, respectively.
Regarding seminal parameters, Formulas 1 and 2 increased sperm concentration 2.11% (p=0.046) and 53.55% (p=0.200) respectively. The Control treatment reduced 20.14% this parameter (p=0.160). Total sperm count was improved by experimental treatments with an increase of 17.41% (p=0.135) and 113.13% (p=0.012) for Formulas 1 and 2, respectively. The Control group reduced 23.64% this parameter (p=0.001). Formulas 1 and 2 showed a moderate improvement in progressive sperm motility (9.10% and 1.08%, respectively) despite not being statistically significant (p=0.072 and 0.067, respectively). Not significantly, the Control treatment reduced 14.14% the progressive motility (p=0.200).

None of the experimental ATM/ATR-enhancement-based treatments showed any adverse effects on sperm genome integrity or other semen parameters. Formula 1 proved to be the most effective treatment to reduce sperm DNA fragmentation. On the other hand, Formula 2 proved to be the best treatment improving seminal parameters.
Limitations, reasons for caution: Patients compliance with treatment cannot be guaranteed. For this reason, patients were excluded from the study when there was a suspicion that the intake of the treatment did not follow the protocol instructions.
Wider implications of the findings: DSB are a major cause of chromosomal abnormalities in a zygote, cause a delay in embryo development and impair embryo implantation. Prevention of sperm DNA fragmentation through effective oral treatments focused on improving DNA damage repair and/or activating apoptosis systems would be of great interest to patients affected by DSB.
Trial registration number: Does not apply.

P-069 Association of serum metabolomic profile by nuclear magnetic resonance spectroscopy with semen parameters.

A. Taylor[1], K. Al Rashid[2], M.A. Lumsden[2], N. Goulding[1], D. Lawlor[1], S. Nelson[2]

[1]UNiversity of Bristol, Bristol Medical School, Bristol, United Kingdom ;
[2]Universiy of Glasgow, School of MEdicine, Glasgow, United Kingdom

Study question: To assess the association of 155 circulating metabolic measures relevant to lifestyle and metabolic health with sperm parameters (as measured by concentration, motility and total motile sperm count (TMSC)).
Summary answer: An extensive range of metabolites were not associated with semen parameters, highlighting the potential limited contribution of lifestyle modification to improve sperm count or motility.
What is known already: Several observational studies and small randomised controlled trials (RCTs) have investigated the association between metabolic health, nutritional supplements and lifestyle modification on sperm parameters with some, but not all studies, suggesting that improved metabolic health may be associated with improved semen parameters. However, these studies have been limited to a range of metabolic measures with limited adjustment for confounders, and recent large well-conducted RCTs of supplementation have not observed an improvement in sperm parameters.
Study design, size, duration: Cross-sectional study of 325 men prospectively recruited between 1 April 2017 and 31 March 2019.
Participants/materials, setting, methods: Men intending to undergo assisted conception at a University Hospital, had a detailed demographic, lifestyle, fertility and medical history and semen analysis. Non-fasting serum lipids, lipoprotein subclasses, and low-molecular weight metabolites (including amino

acids, glycolysis and inflammatory markers) were quantified by NMR spectroscopy. Multivariable linear and logistic regression was used to examine the associations of serum metabolic profiles (exposures), with functional sperm concentration, motility and TMSC (outcomes) with adjustment for confounders.
Main results and the role of chance: Participants were mean 37.2 (SD 5.7) years and had a median sperm concentration of 35 million/ml (IQR 15, 69 million/ml) and median motility of 53% (IQR 42,67). 76% of men had a TMSC >15 Million, 10% 5-15 Million and 14% <5 Million. In both univariate and adjusted analyses an extensive range of lipids and lipoproteins, acetate, beta-hydroxybutyrate, creatinine, albumin, glucose and the amino acids; alanine, glutamine, glycine, histidine, isoleucine, leucine, valine, phenylalanine and tyrosine did not show strong statistical evidence of associated with sperm concentration, motility, or the odds of having a reduced or low TMSC (all $_P_{Bonferroni} > 0.0029$).
Limitations, reasons for caution: Residual confounding may have resulted from crude questionnaire measurements, though we cannot think of masking confounders. Sperm parameters were measured on a single sample, in accordance with recent WHO guidance, and by non-automated techniques which may have introduced random measurement error that could have attenuated to the null.
Wider implications of the findings: We did not find any robust associations between a range of established and novel metabolic measures with semen parameters. Replication of our observed null results is critical given current interest in improving semen parameters through lifestyle modification.
Trial registration number: Not applicable

P-070 The effect of sperm DNA fragmentation index on the outcome of intrauterine insemination

D. Gunasheela[1], R. Nayak[1], B.S. Indrani[1], L. Sasikala[1], P. Ajitha[1], W.Y. Son[2]

[1]Gunasheela Surgical & Maternity Hospital, Obst & Gyne, Bangalore, India ; [2]McGill University Health Centre MUHC- Royal Victoria Hospital- Canada, Embryology, Montreal, Canada

Study question: Can sperm DNA fragmentation affect reproductive outcomes of intrauterine insemination?
Summary answer: High sperm DNA fragmentation (DFI: > 30%) is associated with poor reproductive outcomes in couples undergoing IUI.
What is known already: The pregnancy outcome after IUI procedures was unpredictable because several possible factors were involved in the process. A number of studies concerning the association between DFI and pregnancy outcome after IUI have been performed. Some studies showed that high DFI was positively correlated with low pregnancy rate after IUI. However, several other reports have found that DFI is not correlated with pregnancy outcome in IUI. The predictive value of DFI in reproductive outcome of IUI remains controversial.
Study design, size, duration: This prospective observational study included 413 women who underwent IUI cycle from October 2017 to October 2019. The male partners of the infertile couple underwent sperm-DFI by TUNEL or SCD assay. Depending on DFI, they were divided into three groups; Group 1 (DFI-negative:<15%), Group 2 (DFI-fair positive:15-30%) and Group 3 (DFI-high positive: > 30%). The clinical & ongoing/live birth rates were compared among the three groups. P < 0.05 was considered statistically significant
Participants/materials, setting, methods: This study was conducted in infertile couples attending our ART center, who planned for IUI and tested DFI ((n= 413), with also signed the consent form. The exclusion criteria were men not consenting to undergo the DFI test, those with oligozoospermia (< 15 million/ml) and cases of donor semen. Ovulation induction in IUI cycles was performed by clomiphene citrate 50–100 mg or Letrozole 5 mg with or without human menopausal gonadotropin (hMG), or hMG alone.
Main results and the role of chance: Out of 413 men who had tested DFI, 80 (19.3 %), 247 (59.8%) and 86 (20.8%) men were Group 1, 2 and 3, respectively. The clinical pregnancy and ongoing/live rates in Group 3 (11.6%, 10/86; 8.1%, 7/86) was significantly lower than those of Group 1 (17. 5% 14/80; 15.0%, 12/80) and Group 2 (16.6%, 41/247; 14.2%, 35/247) ($P < 0.05$). However, there was no statistically significantly difference in the reproductive potential between Group 1 and Group 2.
Limitations, reasons for caution: Sample size is still low even after collecting data for 2 years and more patients are required to better address this issue**.**
Wider implications of the findings: Sperm DNA fragmentation may be a potential predictor of reproductive outcomes of IUI.
Trial registration number: Not applicable

P-071 The impact of physical activity on semen analysis parameters in healthy males undergoing fertility investigation

N. Vlahos[1], A. Philippou[2], E. Maziotis[1], E. Alexopoulou[1], P. Giannelou[2], A. Rapani[1], S. Grigoriadis[1], A. Gryparis[1], P. Bakas[1], C. Siristatidis[1], D. Tzanakaki[1], M. Koutsilieris[2], M. Simopoulou[1]

[1]Aretaieio Hospital- National and Kapodistrian University of Athens, Second Department of Obstetrics and Gynecology, Athens, Greece ; [2]National and Kapodistrian University of Athens- Medical School, Physiology, Athens, Greece

Study question: Do levels of physical activity (PA) and metabolic equivalent (METs) correlate to parameters of semen analysis in healthy males?
Summary answer: Men reporting with moderate levels of PA present with higher sperm concentration, progressive and total motility, compared to men presenting with low levels of PA.
What is known already: The potential association between semen analysis parameters and environmental as well as lifestyle factors-including physical activity-has been extensively investigated in literature. Recent studies demonstrate that moderate physical activity may improve semen analysis parameters. However, discordant conclusions are reported on this topic. Furthermore, existing evidence is of poor quality as evident in recent systematic reviews and meta-analyses. This underlines the requirement for conducting large well-designed studies. The aim of this study was to investigate the possible effect of physical activity on semen parameters, evaluating the metabolic equivalent, in healthy males undergoing fertility investigation.
Study design, size, duration: A total of 223 men were recruited for this present prospective observational single-center study from November 2015 to October 2017. Participants were 18-40 years old, with a Body Mass Index (BMI) of 18.5-29.9 kg/m2. Men subjected to medication administration as part of a therapeutic regime, with current or previous diagnosis of cancer, endocrinological or genetic disorders, with a history of diseases that may affect the reproductive system and azoospermic men were excluded from the study.
Participants/materials, setting, methods: The participants were interviewed according to the Global Physical Activity Questionnaire (GPAQ). They were divided into 3 groups -namely, low, moderate and high PA- according to their physical activity levels as suggested by the World Health Organization (WHO). Semen analysis was performed according to WHO 2010 guidelines.
Main results and the role of chance: Forty men were categorized in the Low PA group, 117 in the moderate PA group and 66 in the high PA group. No statistically significant difference between the three groups was observed regarding the age, BMI, smoking status and the number of days of abstinence. No correlation was observed between the levels of METs and sperm concentration, total motility or the percentage of normal morphologically spermatozoa. The level of METs were negatively correlated with progressive motility (p=0.01). The Kruskal-Wallis test revealed differences between the groups regarding progressive (p=0.001) and total motility (p=0.04). In the post-hoc analysis, the moderate PA group presented with higher total motility (43.08±18.34 vs 36.43±16.01; p=0.01) and progressive motility (31.86±17.69 vs 25.75±16.50; p=0.04) when compared to the low PA group. The three groups-low, moderate and high PA-did not differ statistically significantly regarding neither sperm concentration (26.04±21.04 vs 55.53±37.16 vs 47.86±32.83; p=0.25), nor normal morphologically spermatozoa (12.35±6.69 vs 10.64±7.65 vs 10.82±7.13; p=0.80). The moderate PA group presented less risk for abnormal semen analysis compared to the low PA group (RR:0.65;95%CI:0.52-0.81;p=0.01). The high PA group presented with similar risk for abnormal semen analysis compared to either the low (RR:0.82;95%CI:0.66-1.03;p=0.10) or the moderate PA group (RR:1.26;95%CI:1.00-1.60;p=0.06), albeit marginally.
Limitations, reasons for caution: The present study corresponds to a single time-frame regarding semen analysis, as a second evaluation was not performed. Furthermore, the small sample size and the single-center nature of this study present as limitations.

Wider implications of the findings: The moderate PA group presented with a higher total and progressive motility, as well as with a lesser risk regarding abnormal semen analysis compared with the low PA group. To conclude, results presented herein demonstrate that moderate PA may improve semen quality, especially spermatozoa motility, buttressing existing published data.
Trial registration number: not applicable

P-072 Zona pellucida selects spermatozoa with good DNA fragmentation

R. Ganeva[1], D. Parvanov[1], D. Vaneva[2], M. Vasileva[3], G. Stamenov[4]

[1]Nadezhda Woman's Health Hospital, Research and development, Sofia, Bulgaria ; [2]Nadezhda Woman's Health Hospital, Andrology, Sofia, Bulgaria ; [3]Nadezhda Woman's Health Hospital, Embryology, Sofia, Bulgaria ; [4]Nadezhda Woman's Health Hospital, Obstetrics and gynecology, Sofia, Bulgaria

Study question: To evaluate and compare the sperm DNA fragmentation in normozoospermic patients after swim up preparation and zona pellucida binding sperm isolation.
Summary answer: Zona pellucida selected spermatozoa from normozoospermic patients have significantly lower DNA fragmentation than native semen and those prepared only by swim up.
What is known already: Sperm DNA fragmentation is associated with fertilisation and implantation success. It was suggested that routinely applied methods, such as swim up, lead to selection of spermatozoa with low DNA fragmentation. Another technique for sperm selection is based on sperm zona pellucida binding. The sperm zona adhesion abilities were suggested as a predictor for the fertilisation ability of the semen. Recent study has shown that using sperm bound to zona pellucida proteins for ICSI leads to higher pregnancy rates and fewer miscarriages than conventional sperm selection. However, data about sperm DNA fragmentation after zona pellucida selection is still absent.
Study design, size, duration: This observational study involved 29 normozoospermic patients of MHAT "Nadezhda", Sofia, Bulgaria, between December 2019 and January 2020. Semen samples were analysis performed according to WHO 2010. Native semen was liquefied and was subjected to swim up. The isolated motile spermatozoa were allowed to adhere on acid solubilized zona pellucida coated petri dishes. Sperm DNA fragmentation (SDF) was analysed in each patient's native semen, swim up prepared samples and zona bound spermatozoa.
Participants/materials, setting, methods: SDF of fresh semen, swim up prepared samples and zona bound spermatozoa was done using Halosperm G2 test kit (Halotech DNA SL, Madrid, Spain). Data was checked for normal distribution using Kolmogorov-Smirnov test. Spearman correlation analysis was used for comparison of the SDF and semen analysis parameters. Differences between the groups were *analyzed by Wilcoxon* paired test. Statistical analysis was performed using IBM SPSS ver.21. P<0.05 was considered significant.
Main results and the role of chance: The percentage of SDF of fresh semen, swim up prepared samples and zona bound spermatozoa did not correlate to the conventional semen analysis parameters (sperm concentration, motility and morphology) of the studied normozoospermic patients (p>0.05). However, the SDF values of the fresh semen were found to be 32±5%, which is slightly above the previously estimated cut off for good DNA fragmentation (30%).

Following sperm preparation by swim up and zona binding the SDF values were reduced significantly (p=0.018, p=0.017 respectively). Moreover, the median SDF percentage in the swim up prepared samples and zona bound spermatozoa were found to differ significantly (Median: 15% vs. 10%; p=0.01). In addition, zona bound spermatozoa from all patients had DNA damage 3-4 times lower than the estimated cut off value for good SDF.**Limitations, reasons for caution:** Results from this study need to be confirmed by larger group of samples.
Wider implications of the findings: Sperm zona selection provides spermatozoa with good DNA fragmentation. Zona selection technique may be used to improve the impact of abnormal SDF on the reproductive outcomes even in normozoospermic patients.
Trial registration number: not applicable

P-073 Effect of Unilateral Microsurgical Varicocelectomy on fertility outcome and treatment plans of patients with severe oligospermia

H. Elbardisi[1], K. Khalafalla[1], A. Majzoub[1], S. Alsaid[1], M. Arafa[1]

[1]Hamad Medical Corporation, Urology, Doha, Qatar

Study question: Does unilateral microsurgical subinguinal varicocelectomy have a favorable effect on the fertility potential of patients with severe oligospermia?
Summary answer: Microsurgical sub inguinal varicocelectomy improves semen parameters of patients with severe oligospermia improving their fertility outcome.
What is known already: Severe oligospermia or a sperm concentration below 5 million/ml, is an extreme derangement of male fertility potential that is often managed with assisted reproductive therapy. Intracytoplasmic sperm injection (ICSI) is usually preferred in such type of patients in order to maintain a higher success rate during the invitro fertilization (IVF) cycle. The effect of Varicocelectomy on patients with oligoasthenoteratospermia has been extensively investigated with proven improvement, however its impact on patients with severe oligospermia remains to be elucidated.
Study design, size, duration: This was a retrospective study of 114 patients diagnosed with severe oligospermia between January 2016 till January 2018, who underwent unilateral microsurgical sub inguinal varicocelectomy. Patients with genetic abnormalities, history of varicocelectomy, or those who received any infertility related therapy before surgery were excluded from the study.
Participants/materials, setting, methods: Patients were evaluated pre-operatively and 6 months following surgery. Data regarding age, testicular size, serum hormones (Testosterone, LH, FSH) and semen analysis results were collected. Categorical data was presented as numbers (percentages) while numerical data was presented as mean ± SEM. Data was compared using Wilcoxon Signed Ranked Test. A p value <0.05 was considered significant.
Main results and the role of chance: The patients' mean age was 36.8 ± 5.2 years. A statistically significant improvement in sperm concentration (p<0.001), total motility (p<0.001) and progressive motility (p=0.003) was observed after surgery. The pre-surgical total motile sperm count (TMSC) was 1.5±0.34 million sperm and was significantly increased following surgery to 10.5±2.0 million sperm (p< 0.001). No significant differences were noted in hormonal levels following surgery.

Six months following varicocelectomy, the sperm concentration improved in 79 patients (69.3%); 16/114 (14%) patients showed normal sperm concentration while 26/116 (22.8%) patients improved to the oligospermia category. The TMSC increased to above 5 million in 28 patients (24.5%).
Limitations, reasons for caution: The main limitation is the retrospective design of the study.
Wider implications of the findings: Documenting an improvement in the fertility potential of patients with severe oligospermia is important as it would change their management plans. A good percentage of patients may become candidates for intrauterine insemination or even natural conception instead of intracytoplasmic sperm injection.
Trial registration number: NA

P-074 Effect of Abstinence Period on Seminal Oxidative Stress in Infertile men

M. Arafa[1], K. Khalafalla[1], A. Majzoub[1], A. Agarwal[2], S. Alsaid[1], H. Elbardisi[1]

[1]Hamad Medical Corporation, Urology, Doha, Qatar ; [2]Cleveland clinic, American Center for Reproductive Medicine, Cleveland-, U.S.A.

Study question: Does the duration of abstinence period affect seminal oxidative stress in infertile men?
Summary answer: Shorter abstinence period significantly decreases seminal oxidative stress with subsequent improvement of motility, progressive motility and normal morphology.
What is known already: The duration of abstinence may affect the semen quality. While longer abstinence is associated with more semen volume and sperm concentration, it negatively affects total and progressive motility. WHO guideline stated that abstinence should be 2-7 days. Different studies have sought to determine the optimal time frame for ejaculatory abstinence, however the results are often found to be contradictory. Also, there are no studies discussing the effect of abstinence on seminal oxidative stress measured by oxidation reduction potential.

Study design, size, duration: This retrospective study included 255 patients presenting with male factor infertility to a tertiary medical center over a period of 2 months. The inclusion criteria were patients who did semen analysis with an abstinence of less than 2 days or more than 5 days.
Participants/materials, setting, methods: Patients were grouped into group A (76 patients) with abstinence < 2 days and group B (177 patients) with abstinence > 5 days. Semen analysis was done according to the 5th edition WHO guidelines. ORP was determined using the MiOXSYS system (Aytu BioScience, Englewood, CO). SDF was measured by sperm dispersion method (Halosperm). The results were compared by Wilcoxon rank sum test and paired T test. p value < 0.05 was considered significant.
Main results and the role of chance: The patients' mean age was 35.9±7.6 years. ORP was significantly lower in group A than in group B (2.5±3.0 vs 5.3±10.5mV/10^6 sperm). Sperm concentration was lower in group A than group B but the difference was non-significant (32.9±25.7 vs 37.7±28.6millions/ml). Total and progressive motility were also better in group A than group B (53.6±18.1% vs 49.2±18.8%, 12.5±10.9% vs 11.6±11.5% respectively) but again the differences were insignificant. Abnormal form was slightly and insignificantly less in group A than group B (93.7±9.8% vs 93.8±9.0%). Sperm DNA fragmentation was less in group A than group B (28.8±21.2% vs 31±15.9%) but the difference was not significant.
Limitations, reasons for caution: The main limitation is the retrospective design of the study.
Wider implications of the findings: The significant improvement in seminal oxidative stress with the short abstinence may introduce a new treatment technique in infertile men were couples can be counseled to engage in frequent sexual intercourses hoping to benefit from the improvement in semen parameters.
Trial registration number: NA

P-075 Threshold-dependent effects of energy restriction as a novel potential therapy to increase sperm concentration in men with obesity: A Randomised Controlled Study

"Abstract withdrawn by the authors"

P-076 Does the presence of varicocele Influence microsurgical testicular sperm retrieval in men with non-obstructive azoospermia (NOA)?

K. Khalafalla[1], M. Arafa[1], H. Elbardisi[1], S. Alsaid[1], A. Majzoub[1]

[1]Hamad Medical Corporation, Urology, Doha, Qatar

Study question: Can the outcome of sperm retrieval in patients with non-obstructive azoospermia be affected by an untreated clinical varicocele?
Summary answer: The presence of clinical varicocele did not influence the sperm retrieval rate in this population of NOA patients.
What is known already: Varicocele is prevalent in approximately 5% of men with NOA, the pathophysiology of azoospermia and its relation to varicocele is still under investigation. It is still debatable whether varicocele contributes to spermatogenesis disruption and affects sperm retrieval rates in NOA. Recent studies have reported a significant influence for varicocele on patients with non-obstructive azoospermia (NOA) suggesting varicocelectomy prior to testicular sperm extraction (TESE) procedures.
Study design, size, duration: The charts of 448 patients who presented to the Male infertility clinic from 2011 – 2016 with Non-obstructive azoospermia and underwent microsurgical TESE were included and retrospectively studied. Exclusion criteria for this study were prior varicocelectomy, TESE, chemotherapy or radiation therapy, patients with abnormal genetics or chromosomal deletions.
Participants/materials, setting, methods: Patients demographics, clinical and laboratory data (age, BMI, estradiol, FSH, LH, Prolactin, Testosterone) as well as the sperm retrieval outcome were compared between non-obstructive azoospermic patients with and without varicocele. Data was compared using Wilcoxon Signed Ranked Test. A p value <0.05 was considered significant.
Main results and the role of chance: Varicocele data was available in 222 charts, 157 patients had a clinical varicocele and 70 had no varicocele. Sperm were retrieved from 57% of patient with Varicocele (n=89) compared with 45.3% of patients (n=38) with No-Varicocele. The difference in sperm retrieval between both groups was not statistically significant (p=0.09). Patients with varicocele were significantly older than patients with No-varicocele (p=0.006). No significant differences between the 2 groups with regards to testicular size (right, left), reproductive hormones (Testosterone, LH, FSH, Estradiol) and BMI were observed.

Parameters	Non Varicocele group	Varicocele group	P Value
Age (years)	35.3±0.74	38.2±0.623	0.006
BMI (Kg/m²)	31.5±1.6	30.4±0.8	0.12
Testosterone (nmol/L)	14.8±1.06	15.8±0.62	0.38
LH (IU/L)	7.23±0.62	7.03±0.43	0.79
FSH (IU/L)	13.85±1.26	13.53±0.78	0.83
E2 (pg/ml)	110.15±5.8	122.5±7.4	0.296
Left Testes size (cm³)	7.02±0.54	7.06±0.3	0.94
Right Testes size (cm³)	7.9±0.6	7.0±0.3	0.12

Limitations, reasons for caution: The main limitation is the retrospective design of the study.
Wider implications of the findings: Patients with NOA who have a clinical varicocele should be thoroughly counselled before treatment decisions are made. The expected clinical benefit in face of the invasiveness and the extra cost of the varicocelectomy should be discussed with the patients before undergoing testicular sperm retrieval.
Trial registration number: NA

P-077 Impact of the assessment of sperm DNA damage on IVF and ICSI outcome: role of intra-individual variation

P. Christensen[1], E. Parner[2], A. Birck[3]

[1]SPZ Lab A/S, Clinical Research, Copenhagen, Denmark ;
[2]Aarhus University, Department of Public Health- Section for Biostatistics, Aarhus C, Denmark ;
[3]SPZ Lab, Clinical Research, Copenhagen OE, Denmark

Study question: How does intra-individual variation in the assessment of sperm DNA damage affect the outcome of IVF and ICSI treatments?
Summary answer: Intra-individual variation in assessment of sperm DNA damage plays a very important role for the outcome of IVF and ICSI treatments.
What is known already: The impact of sperm DNA damage on the outcome of assisted reproduction remains controversial. The lack of agreement in the literature is partially due to a diversity of test methods as well as poorly standardized protocols. Methods based on flow cytometry have the potential of being very robust and precise. However, large differences in intra-individual variation have been reported for different laboratories assessing sperm DNA damage based on the SCSA protocol. Some of this variation may have a biological background, but can to a large extend be due to differences in laboratory performance and quality control procedures.
Study design, size, duration: Simulated power calculations using 10,000 replications were based on our previous retrospective analysis of the impact of sperm DNA damage on 406 clinical cases for IVF and ICSI (Christensen et al., Hum Reprod. 2013;28:i128-P-026). Intra-individual variation (CV within male: CV_w) for assessment of sperm DNA damage in our laboratory was calculated to 16.5% using data from a previous randomized and double-blind controlled trial (Blomberg-Jensen et al., J Clin Endocrinol Metab 2018;103:870-81).
Participants/materials, setting, methods: The median percentage of sperm with damaged DNA (DFI) was 15.9% with a total CV of 60.2%. Calculations of true pregnancy rates for IVF and ICSI were estimated using a CV_w of 0.0%. The true pregnancy rates were then used in calculations of statistical power. We considered scenarios of CV_w of 16.5% plus increases of CV_w with 50% and 100%. A 2-sided chi2-test was used for comparison of pregnancy rates (significance level 0.05, power 80%).

Main results and the role of chance: For IVF treatments, true pregnancy rates (CV_w = 0) were calculated to 47.7% (DFI≤15) and 22.2% (DFI 15 to 25). For ICSI treatments, true pregnancy rates were calculated to 49.5% (DFI<25) and 24.7% (DFI≥25). Using our laboratory's CV_w of 16.5%, the sample size needed for comparison of pregnancy rates was estimated to n=169 for an IVF study. A study with ICSI-treatments would require a sample size of n=336. When CV_w was increased with 50%, the required sample sizes increased to n=207 (IVF) and n=437 (ICSI). A 100% increase in CV_w gave corresponding sample sizes of n=260 (IVF) and n=569 (ICSI). A small intra-individual variation in the assessment of sperm DNA damage is essential for correct diagnosis and treatment. In contrast, a high variation may lead to misclassification of patients and potentially suboptimal treatment. When the impact of sperm DNA damage on assisted reproduction outcomes is to be studied, a high degree of intra-individual variation increases the required sample size markedly. Without a sufficient sample size, the true biological relationship may remain concealed. To produce reliable and valuable results having low intra-individual variation, laboratories performing tests of sperm DNA damage should ensure good quality control to minimize potential laboratory errors.
Limitations, reasons for caution: None.
Wider implications of the findings: Laboratories performing test of sperm DNA damage should declare the level of uncertainty of the test used. Differences in quality control procedures between laboratories are likely to play a significant role in interpretation of results even when the same method is used and may impact assisted reproduction treatment outcome.
Trial registration number: Not applicable

P-078 Is there an effect of artificial oocyte activation on euploidy of embryo in patients with male factor infertility?

H. Jeong[1], K.Y. Kang[1], H.S. Choi[1], E.H. Moon[1], Y.R. Park[1], S.H. Lee[1], E.A. Park[1], J.Y. Lee[1], H.S. Kim[1], K.A. Lee[2], J.J. Ko[2], I.S. Kang[1], M.K. Koong[1], Y.S. Kim[1], M.J. Kim[1]

[1]CHA Fertility Center Seoul Station, Fertility laboratory, Seoul, Korea- South ; [2]CHA University, Department of Biomedical Science- College of Life Science, Pocheon, Korea- South

Study question: The purpose of this study is to identify euploidy rate in severe male factor patients treated with artificial oocyte activation(AOA) after ICSI.
Summary answer: There was an insignificant difference of euploidy in severe male factor groups treated AOA after ICSI with preimplantation genetic testing-aneuploidy(PGT-A).
What is known already: In many studies, it is known that sperm abnormalities result in abnormal sperm decondensation, aberrant pronuclear development, migration, apposition and first mitosis. It has been reported that treatment of AOA in patients with male factors improves these problems. Also, AOA leads to a cascade of events including extrusion of the second polar body, decondensation of a haploid set of chromosomes and initiation of embryonic development. Thus, sperm abnormalities and oocyte activation are important in fertilization. Generally, AOA is used for low quality oocytes and sperm, and the low fertilization rate and frequent fertilization failure.
Study design, size, duration: 25,427 IVF-ICSI cycles were performed at our center from January 2016 to December 2019. From those studies, only 2,285 cycles were performed with preimplantation genentic testing and 750 cycles were performed with PGT-A. Among them, the cycles with artificial activation after ICSI were only 103 cases. The embryo euploidy rate was evaluated in cases of blastocyst PGT-A. Statistical analysis was performed using the chi-squared test. P values p<0.05 were considered significant.
Participants/materials, setting, methods: IVF-ICSI cycles that performed blastocyst biopsies were sorted from cycles performed with PGT-A and these were divided into four groups depending on the concentration of the sperm; Group 1: severe oligozoospermia(<1xml), Group 2: oligozoospermia(1≤~<15xml), Group 3: normal(≥15xml), Group 4: TESE sperm(sperm retrieved from azoospermia patients). Each group was additionally divided into two groups; with or without activation. We used 10μM/L calcium ionophore(A23187; Sigma-Aldrich) in culture medium for the AOA for 5min at 30min after ICSI.
Main results and the role of chance: Euploidy rates of PGT-A blastocyst with AOA and without AOA after ICSI were compared in each group. Maternal and paternal age had no significant differences between two groups, with AOA and without AOA. Euploidy rates of each group are below. (Groups with AOA- Group 1: 34.88%(43/15), Group 2: 33.33%(78/26), Group 3: 32.46%(228/74), Group 4: 38.71%(31/12), Groups without AOA- Group 1: 30.77%(13/4), Group 2: 33.33%(48/16), Group 3: 34.36%(2363/812), Group 4: 30.77%(26/8)). In severe male factor group, Group 1 and Group 4, cases with AOA had higher euploidy rate than cases without AOA. However, there was no significant difference stastistically in Group 1(34.88% vs. 30.77%, *p>0.05*) and Group 4(38.71% vs. 30.77%, *p>0.05*). In oligozoospermia group, Group 2, euploidy rate of cases with AOA was no different from cases without AOA(33.33% vs. 33.33%, *p>0.05*). Also, there was no significant difference in normal sperm group, Group 3(32.46% vs. 34.36%, *p>0.05*). This study showed no significant differences in euploidy rate between cases with and without AOA.
Limitations, reasons for caution: Even though there were numerous cases in our center, we had limits in analyzing significant differences among cases. It is because there were a few PGT-A cases with AOA in male factor infertility patients. Furthermore, we only concerned cases treated with calcium ionophore among various AOA in this study.
Wider implications of the findings: Although our study needs to be supported by further study, this study revealed that AOA contributes to increasing euploidy rates in severe male factor infertility patients. Consequently, it is expected that AOA could increase clinical pregnancy rates by increasing euploidy rates in severe male factor infertility patients.
Trial registration number: not applicable

P-079 Very low concentration of aged cerium dioxide nanoparticles (CeO2NPs) induce DNA damage in human and rat gametes after in vitro exposure

M. Cotena[1], M. Auffan[2], V. Tassistro[1], C. Uboldi[1], J. Rose[2], J. Perrin[3]

[1]Faculty of Medecine- Aix Marseille Université- Equipe Biomarqueurs-Environnement- Santé - Institut Méditerranéen de Biodiversité et d'Ecologie UMR 7263- IRD 237, Faculty of Medicine, Marseille, France ; [2]European Centre Research And Teaching In Geosciences of the Environment CEREGE - CNRs- IRD- Collège de France- INRA- Aix-en-Provence- France, ED-Environnement Durable, Marseille, France ; [3]Aix Marseille University- AP-HM La Conception- Centre Clinico-Biologique d'Assistance Médicale à la Procréation - CECOS- 13385 Marseille Cedex 5- France, Faculty of Medicine, Marseille, France

Study question: Do aged CeO_2NPs induce DNA damage in human and rat gametes after *in vitro* exposure?
Summary answer: *In vitro* gametes exposure to the lowest concentration of CeO_2NPs tested induces a significant increase in DNA damage compared to the highest doses.
What is known already: Cerium dioxide nanoparticles (CeO_2NPs) are an active catalyst and are widely used as diesel additive to increase fuel economy. They are released in the atmosphere after engine combustion. The Organization for Economic Cooperation and Development included CeO_2NPs in the priority list of nanomaterials requiring urgent evaluation. CeO_2NPs can transfer to the testicles and epididymis after inhalation in rats. *In vitro* exposure of human and mouse sperm and cumulus oocyte complexes (COC) to low concentrations of pristine CeO_2NPs (10 $\mu g.l^{-1}$) induce significant DNA damage. Nevertheless, pristine CeO_2NPs are altered by combustion and the potential hazard of aged CeO_2NPs exposure remains unexplored.
Study design, size, duration: Pristine CeO_2NPs were extracted from Envirox™ diesel additive, combusted at 850°C, (average combustion temperature in a diesel engine) and physically characterized. Chemical (un)stability in Ferticult™ embryo culture medium was assessed by Inductively coupled plasma mass spectrometry (ICP-MS). Rat gametes were collected in epididymis and oviducts after cervical dislocation euthanasia of 60 days old males and 26 days old females (after ovarian stimulation). Human frozen sperm from fertile donors were purchased from Germetheque biobank (France).
Participants/materials, setting, methods: Human and rat gametes were exposed *in vitro* to CeO_2NPs [1 to 1.10^3 $\mu g.l^{-1}$] during 1 hour at 37°C, 5%CO_2. DNA damage was analysed by alkaline comet assay (ACA) and quantified by Olive Tail Moment (OTM) in COC and by %Tail DNA in sperm. CeO_2NPs-cells

interaction was assessed in human sperm by Transmission Electron Microscopy (TEM). Oxidative stress was evaluated using 2,7-dichlorodihydrofluorescein (H_2DCF) probe detected by Flow Cytometry and expressed as Mean Fluorescence Intensity (MFI).

Main results and the role of chance: In human sperm, exposure to 1 µg.l^{-1} CeO_2NPs induced a significant increase of DNA damage (mean %Tail DNA±SEM = 32.06 ± 0.54) compared to the unexposed control (11.96 ± 0.30) ($p < 0.0001$). TEM analysis showed big CeO_2NPs aggregates at 100 µg.l^{-1} but close proximity between cells and NPs at 1 µg.l^{-1}. Oxidative production was increased in human sperm exposed to 1 µg.l^{-1} CeO_2NPs (MFI±SEM = 16.9% ± 1.5), compared to the negative control (2.7% ± 1.4).

In rat oocytes and follicle cells, exposure to 1 µg.l^{-1} CeO_2NPs induced significantly higher DNA damage (mean±SEM OTM = 10.26±0.36 and 4.91±0.29, respectively) compared to the unexposed controls (2.21±0.18 and 0.72±0.05, respectively) and to higher CeO_2NPs concentrations ($p < 0.0001$). In rat sperm, exposure to 1 µg.l^{-1} CeO_2NPs induced significantly higher DNA damage (mean %Tail DNA±SEM = 21.23±0.37) compared to unexposed control (11.06±0.24) and to higher CeO_2NPs concentrations ($p < 0.0001$).

DNA damage was inversely proportional to the CeO_2NPs concentration; we might hypothesize that our results are related to the aggregation states. At high concentration, nanoparticles tend to aggregate between them, reducing the surface of interaction with cells. Conversely, at low concentration they can easily come into contact with cells.

Limitations, reasons for caution: These results cannot be extrapolated to *in vivo* toxicity of CeO_2NPs after inhalation, but demonstrate that interactions between CeO_2NPs and germ cells induce significant DNA damage and oxidative stress. Additional data should be needed to better understand the mechanism of interaction between cells and NPs by using nano-tomography imaging analysis.

Wider implications of the findings: The results obtained give some light on the complex cellular mechanisms by which ROS generation could exert their biological effects on human spermatozoa after CeO_2NPs *in vitro* exposure. Potential impacts of diesel exhaust exposure in couples are a major concern for public health, highlighting the need for *in vivo* studies.

P-080 Air pollution and seminal parameters in subfertile men

"Abstract withdrawn by the authors"

P-081 Correlation between teratozoospermia index (TZI) and sperm aneuploidy in infertile men

M. Benincasa[1], A. Crippa[1], M.C. Magli[1], F. Coppola[2], G.B. La Sala[1], L. Gianaroli[1]

[1]*S.I.S.Me.R, Reproductive Medicine, Bologna, Italy ;*
[2]*Centro Medico Spallanzani, Clinical Center, Parma, Italy*

Study question: Does the teratozoospermia index (TZI) correlate with the frequency of sperm aneuploidy in a manner that is dependent on the severity of the male factor condition?

Summary answer: TZI correlates with the frequency of sperm aneuploidy and increases with the severity of the male factor condition.

What is known already: The contribution of sperm aneuploidy to the embryo chromosome status is generally perceived to be clinically irrelevant in comparison with the oocyte counterpart. However, increases in sperm aneuploidy have been reported to have an effect on male infertility and on IVF cycle outcomes especially in cases of repeated implantation failure and recurrent miscarriages. Infertile men typically have significantly higher levels of sperm aneuploidy compared with fertile or normozoospermic males and the level of aneuploidy correlates to the severity of the male factor. Sperm aneuploidy is routinely evaluated by FISH (Fluorescence in Situ Hybridization).

Study design, size, duration: Since January 2018, 139 sperm samples from patients with a normal karyotype undergoing assisted conception cycles were analysed for semen parameters according to WHO 2010. In addition to the morphology evaluation, TZI (representing the number of abnormalities per abnormal spermatozoon) was also determined. The same sperm samples were also analyzed by FISH to evaluate possible correlations between TZI, aneuploidy and the severity of the male factor.

Participants/materials, setting, methods: All patients had a history of reproductive implantation failures and/or miscarriages. When classified according to WHO criteria, 29 samples were normozoospermic, 82 were moderate oligoasthenoteratozoospermic (OAT) (sperm count ≥5 million and < 15 million spermatozoa/ml) and 28 were severe OAT (sperm count <5 million spermatozoa/ml). The FISH analysis was performed for nine chromosomes using probes specific for the chromosomes X, Y, 13, 15, 16, 17, 18, 21 and 22.

Main results and the role of chance: TZI was significantly higher in severe OAT samples (2.1±0.2, range 1.5-2.4) when compare with normal (1.7±0.1, range 1.4-1.9) (P= 1.11E-8) and moderate OAT samples (1.9±0.2 range 1.5-2.5) (P= 2.20E-5). TZI was also significantly higher in moderate OAT compared with normal samples (P= 1.19E-6).

The frequency of total sperm aneuploidy was in inverse correlation with sperm concentration (R= -0.38, P= 5.36E-6), progressive motility (R= -0.41, P= 4.57E-7), total motility (R= -0.25, P= 0.0026) and morphology (R= -0.36, P= 1.04E-5. When considering the sperm typology, the frequency of total aneuploidy was significantly higher in severe OAT (5.01±1.82%, range 2.62-9.04%) when compared with normal (2.24±0.79%, range 0.63-4.22%) (P= 9.31E-9) and moderate OAT samples (3.04±1.12%, range 1.47-7.82%) (P= 2.50E-6). It was also significantly higher in moderate when compared with normal samples (P=0.00067). The combined analysis of TZI and aneuploidy in the different sperm typologies showed a significant positive correlation between the frequency of total aneuploidy and TZI (R= 0.47, P= 6.72E-9).

Limitations, reasons for caution: This study included a restricted number of samples. Additional data are necessary to corroborate our findings.

Wider implications of the findings: Morphologically abnormal spermatozoa often have multiple defects. A detailed assessment of their incidence would refine the relevance of morphological defects, single or multiple, on the capacity of a sperm cell to support fertilization and embryo development, contributing to the evaluation of the extent of damage occurring during human spermatogenesis.

Trial registration number: Not Applicable

P-082 Identification of novel mutations in DPY19L2 responsible for human fertilization failure and have a favorable clinical outcomes by artificial oocyte activation

X.J. Zhuang[1], P. Liu[1]

[1]*Reproductive Medical Center- Peking University Third Hospital, Department of Obstetrics and Gynecology, Beijing, China*

Study question: Does artificial oocyte activation (AOA) together with intracytoplasmic sperm injection (ICSI) improve clinical outcomes for human fertilization failure of globozoospermia linked to DPY19L2 mutations patients?

Summary answer: Novel DPY19L2 deletions were revealed by whole-exome sequencing. AOA together with ICSI improved cycles of DPY19L2 mutations by increasing the fertilization and transferable embryo rates.

What is known already: In clinical, some infertile couples suffer from recurrent fertilization failure. Globozoospermia is a rare form of male infertility characterised by round-headed sperm and malformation of the acrosome. Although the fertilization rate was improved by ICSI, about 1–5% of ICSI cycles still display fertilization failure. The genetic reasons for fertilization failure are largely unknown. Although pathogenic variants in DPY19L2 are known causes of globozoospermia, novel DPY19L2-mutated in infertile patients should be revealed and the treatment of these DPY19L2 deleted globozoospermic patients by AOA together with ICSI should be evaluate.

Study design, size, duration: Globozoospermic patients were recruited from the Reproductive Medical Center of Peking University Third Hospital (Beijing China) between January 2016 and June 2019. Informed consent was obtained from all individual participants included in the study. All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and national research committees of Peking University Third Hospital and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.

Participants/materials, setting, methods: DPY19L2 were analyzed with blood and sperm samples from globozoospermic patients. DPY19L2 levels in human testes were investigated using RT-PCR, western blotting and Immunofluorescent analysis, respectively. And its novel mutations using

whole-exome sequencing and sanger sequencing was explored. Human sperm samples from globozoospermic donors with DPY19L2 mutations are subjected to ICSI and AOA. The fertilization rates, cleavage rates and transferable embryo rates of DPY19L2-mutated patients were compared with its previous ART cycles.

Main results and the role of chance: DPY19L2 mRNA and protein were abundantly transcribed in male testis in human. Immunohistochemical results revealed DPY19L2 was localized in the cytoplasm of spermatids and round spermatids. Through whole-exome sequencing and sanger sequencing, we identified that five patients carried DPY19L2 deletions and six patients contained novel DPY19L2 point mutations in couples diagnosed with fertilization failure. Expression of these mutations in human testis significantly reduced the levels of DPY19L2 expression. In addition, the fertilization rate, embryo cleavage rate and transferable embryo rate were significantly higher in the AOA group than its previous cycle of group (fertilization rate 50.38% versus 13.86%, respectively, $P < 0.001$; embryo cleavage rate 59.16% versus 19.04%, respectively, $P < 0.001$; transferable embryo rate 43.51% versus 16.69%, respectively, $P < 0.001$). Five live-birth babies were born by AOA together with ICSI.

Limitations, reasons for caution: Analysis was performed in testicular biopsy samples from only a small number of patients with DPY19L2 mutations. In future investigations, a larger sample size should be used and the role of the other genes involved in the globozoospermic should be analyzed.

Wider implications of the findings: DPY19L2 variants are highly related to globozoospermia and fertilization failure. AOA could rescue the phenotype of fertilization failure and help establish pregnancy and lead to live birth. These findings bring us closer to a complete molecular diagnosis for globozoospermia patients which would help to predict the success of reproductive treatments.

Trial registration number: This study was supported by the National Natural Science Foundation of China (NO.81671513) and Beijing Natural Science Foundation (NO.7172236).

P-083 Does sperm origin - either ejaculated or testicular – affect early and late embryonic morphkinetic parameters

G. Karavani[1], N. Schachter - Safrai[1], I. Har-Vardi[2], A. Buxboim[3], Y. Kantor[4], S. Zeev[4], O. Yuval[4], S. Yoel[5], A. Ben-Meir[1]

[1]Hebrew University-Hadassah Medical center, Obstetrics and Gynecologyresident, jerusalem, Israel ;

[3]Hebrew University-Hadassah Medical center, Alexander Grass Center for Bioengineering- School of Computer Science and Engineering- The Hebrew University of Jerusalem- Jerusalem- Israel, jerusalem, Israel ;
[4]The Hebrew University of Jerusalem- Jerusalem- Israel., Alexander Grass Center for Bioengineering- School of Computer Science and Engineering, Jerusalem, Israel ;
[5]Infertility and IVF Unit, Helen Schneider Hospital for Women, Rabin Medical Center

Study question: Is there an effect of sperm origin on embryo morphokinetics in couples diagnosed with male factor infertility (MFI)?

Summary answer: Testicular sperm impacted early developmental stages, while ejaculated sperm was associated with faster late cell division, faster compaction and higher implantation rate.

What is known already: Time-lapse imaging provides a non-invasive technique that enables assessment of embryo quality by morphokinetic parameters. While embryonic morphokinetic milestones are known to reflect the developmental and implantation potential, it is unclear whether sperm origin, either ejaculated or testicular, in MFI has an early or late effect with influence on cleavage, blastulation and implantation potential. There is only scarce data regarding the paternal effect on embryo development, with regard to sperm origin, using TLI.

Study design, size, duration: The study included a retrospective analysis of morphokinetic parameters performed by TLI from five medical centers between January 2013 and December 2017.The developmental process and kinetics of 424 embryos obtained from ejaculated sperm from couples with MFI attributed to Oligoasthenoteratozoospermia (OAT) were compared to 160 embryos derived from surgically extracted testicular sperm from couples diagnosed with azoospermia (AS)

Participants/materials, setting, methods: The study included women younger than 38 years who underwent controlled ovarian stimulation and fertilization using either ejaculated abnormal sperm (OAT) or surgically extracted testicular sperm (AS). A comparison between the morphokinetic parameters, implantation and clinical pregnancy rates of the two groups was made with additional subgroup analysis according to the implantation status. Logistic regression was conducted to assess the association between sperm origin and embryonic morphokinetic parameters and implantation.

Main results and the role of chance: Implantation rate was significantly higher in the ejaculated sperm group compared to the testicular sperm group (45.8% vs. 33.6%, p=0.02). Embryos from the OAT group reached the later morphokinetic milestones - embryonal third cell cycle (ECC3), synchronous division (S3) and Morula compaction- faster than embryos obtained from azoospermic patients. Implanted embryos developed in similar rate in both group. In a multivariate analysis for the entire study population, ejaculated sperm (OR=5.88 (CI 95% 2.56-12.50), p<0.001) and time to 8 cell stage (OR=0.90 (CI 95% 0.82-0.98), p=0.013) were positively associated with successful implantation.

Limitations, reasons for caution: The two patients' groups were not homogeneous in their basic characteristics. A higher rate of nulliparity and increased fragmentation was demonstrated in the AS couples. Information regarding the maximal dose of GT obtained, previous IVF response and ovarian reserve testing was lacking.

Wider implications of the findings: Ejaculated sperm impact on late preimplantation development, especially the third cell cycle and compaction, may highlight another pathophysiology by which sperm origin effects embryo developmental kinetics. Morphokinetic parameters, with regard to sperm source, may assist in predicting implantation.

Trial registration number: Kamin fund

P-084 Sperm fatty acid profile in infertile men.

A. Stendardi[1], S.E. Pizzasegale[1], F.L. Vellucci[1], G. Collodel[2], E. Moretti[2], C. Signorini[2], L. Gambera[1]

[1]A.G.I. Medica, Reproductive Medicine, Siena, Italy ;
[2]Università degli Studi di Siena, Dipartimento di Medicina molecolare e dello sviluppo, Siena, Italy

Study question: Are the sperm characteristics correlated with sperm fatty acid composition?

Summary answer: Our results show a relationship between sperm fatty acid composition and sperm characteristics evaluated by light and electron microscopy

What is known already: In sperm membrane and semen plasma, lipids and fatty acid (FA) composition are relevant to spermatozoa function and spermatogenesis. Mammalian spermatozoa are characterized by a high proportion of polyunsaturated fatty acids (PUFA) which play a crucial role in sperm maturation and motility, in acrosome reaction and fertilization. Due to the high presence of PUFA, sperm are susceptible to lipid peroxidation. It is known that men with altered seminal parameters had shown different FA composition and different omega-6/omega-3 PUFA ratio.

Study design, size, duration: The proposed investigation is a retrospective study. Twenty-three infertile men (aged 27-38) referred to *AGI Medica* lab (Siena, Italy) for semen analysis were enrolled from January 2019 to June 2019.

Participants/materials, setting, methods: Semen characteristics were evaluated by light and transmission electron microscopy (TEM). TEM data was quantified with a mathematical formula which provides numerical scores as the percentage of apoptosis, necrosis and immaturity and a fertility index. Sperm FA composition was evaluated by a gas chromatography instrumentation (Lipinutragen, Bologna, Italy). The content of FA and the value of the ratios between different FA were correlated with sperm characteristics (Spearman's Rank Correlation Coefficient).

Main results and the role of chance: Semen analysis showed an impaired semen quality. By TEM investigation, sperm pathologies were increased and fertility index reduced as compared to normal values. A positive correlation was detected between docosahexaenoic acid (DHA), an omega-3 PUFA, and sperm concentration, vitality and fertility index. Necrosis was positively correlated with oleic, vaccenic, palmitoleic acid content, and negatively with DHA and saturated fatty acid/monounsaturated fatty acid ratio. The omega-6/omega-3 ratio negatively correlated with sperm concentration, motility and morphology and

positively with sperm necrosis. Sperm immaturity positively correlated with eicosatrienic acid.

With a view to the role of FA in sperm characteristics, these preliminary data show that, i) DHA content appears strictly related to sperm quality, in particular to sperm vitality; ii) the omega6/omega3 ratio increases in presence of necrosis, as well as eicosapentaenoic acid/arachidonic acid ratio.

These results may be implemented by further studies on the relationship between FA composition and sperm characteristics since a dietary FA supplementation should improve semen quality.

Limitations, reasons for caution: The study group is small and selected groups of patients with different reproductive pathological conditions will to be compared

Wider implications of the findings: A deeper knowledge on sperm FA profile and its correlation with sperm pathology indicate the potential role of personalized nutraceutical treatments to modulate sperm FA composition improving male reproductive efficiency.

Trial registration number: none

P-085 A novel homozygous CEP112 mutation in humans causes male infertility with azoospermia

X. Zhang[1], G. Huang[2], G. Zhang[2], W. Xu[2]

[1]Department of Obstetrics/Gynecology- Joint Laboratory of Reproductive Medicine SCU-CUHK- Key Laboratory of Obstetric- Gynecologic and Pediatric Diseases and Birth Defects of Ministry of Education- West China Second University Hospital-Sichuan Universi ;

[2]Department of Obstetrics/Gynecology- Joint Laboratory of Reproductive Medicine SCU-CUHK- Key Laboratory of Obstetric- Gynecologic and Pediatric Diseases and Birth Defects of Ministry of Education- West China Second University Hospital-Sichuan Universi

Study question: To date, several gene mutations have been identified in azoospermia, which can explain the genetic causes of a small number of azoospermia cases. Here, we report anovel gene mutations

Summary answer: Our experimental observations on human subjects suggested that CEP112 is involved in sperm flagellum structure and that loss-of-function mutations could lead to male infertility

What is known already: Nearly half of male infertility cases are thought to be linked to genetic defects. And 20% of infertile men are diagnosed with azoospermia. Nonobstructive azoospermia is defined as spermatogenic failure, and are often be discovered during the semen analysis showing the absence of sperm in semen. Azoospermia is a heterogeneous disease with many histological phenotypes. To date, several gene mutations, including TEX11, SYCP3, have been identified in azoospermia, which can explain the genetic causes of a small number of azoospermia cases.

Study design, size, duration: Whole-exome sequencing (WES) was performed with patient DNA. In Brief, genomic DNA was isolated from peripheral blood samples, and utilized for exon capture using the Agilent SureSelect Human All Exon V6 Kit and sequenced on the Illumina HiSeq X system. Candidate pathogenic variant on the patient was validated by Sanger sequencing in the patients' parents as well as the normal controls. Then Knockout mice were used to observe phenotypes.

Participants/materials, setting, methods: A-30-year-old Han Chinese man from a consanguineous family was diagnosed with infertility for 2 years, and no fertility-related diseases were detected in his wife. The parents of the patient were also recruited. Whole-exome sequencing (WES) was performed with patient DNA. Immunofluorescence staining, Scanning electron microscopy (SEM) assay and transmission electron microscopy (TEM) assay were performed according to a protocol described previously. The flow cytometric analysis and cell sorting were performed as previously described.

Main results and the role of chance: To illuminate the genetic cause of the azoospermia in this study, we performed Whole-exome sequencing (WES) was performed on the patient and a homozygous mutation (g.17:64125864_64125941cnv, c.NA, p.NA) was identified in centrosomal protein 112kDa gene named CEP112, which is primarily expressed in the testis and belongs to the cell division control protein 42 effector protein family. The protein encoded by this gene has putative coiled-coil domains and plays a role in spermatogenesis. Our experimental observations on human subjects and mice suggested that CEP112 is involved in sperm flagellum structure and assembly. Loss-of- function mutations could lead to male infertility in humans and mice by damaging spermatogenesis and making abnormal sperm

Limitations, reasons for caution: Considering the relationship between CEP112 and primary ciliarym, we wanted to performed CT and MRI scans on the patient that can assess clinical signs of PCD. Unfortunately, the patient refused further examination, therefore we did not assess ciliary beat in the patient.

Wider implications of the findings: The screening of the deleterious mutations of *CEP112* could be important for clinical molecular diagnosis of male infertility. Further study is required to elucidate the molecular mechanism of *CFAP65* in sperm flagellar development.

Trial registration number: 81771642

P-086 Microfluidic sperm sorter versus sperm slow prior to ICSI in oligoasthenozoospermia samples with poor DNA Fragmentation Index (DFI) scores in SCSA testing

P. Selvaraj[1], K. Selvaraj[1], V. Srinivasan[2], M. Sivakumar[1], V. Harikrishnan[1], S. Balakrishnan[1], S. Sudan[1]

[1]Fertility Research and Women's Speciality Hospital, G.G. Hospital, Chennai, India ; [2]The Tamilnadu Dr.MGR Medical University, Biostatistics, Chennai, India

Study question: Compare the outcomes of sperm preparation by Microfluidics and Sperm slow in oligoasthenozoospermia samples with poor DFI and high DNA stainability scores in sperm chromatin structural assay(SCSA) prior to ICSI.

Summary answer: The use of Microfluidics and Sperm slow had no statistically significant differences on primary outcomes.

What is known already: Ideal sperm preparation methods for oligoasthenozoospermia samples have long been debated especially if additional testing such as DFI and high DNA stainability (HDS) scores have been added using SCSA. Micorfluidics has emerged as an atraumatic method of sperm selection, enabling enhanced retrieval of motile sperm with normal morphology, mimicking nature and proving a non static restricted environment. Spermslow on the other hand has the advantage of replacing Polyvinylpyrrolidone and providing hyaluronan and important components for pre-fertilization event of zona-binding and penetration. This hyaluronan enriched semi viscous medium enhances selection of low DNA fragmented sperm with better embryo formation rates.

Study design, size, duration: A prospective study was conducted from June 2016 to December 2018 with the sample size of 109 couples undergoing assisted reproduction. The mean age of women was 32.26±4.26 years. The mean age of men was 36.62±4.5 years. The oligoasthenozoospermic sample had a mean count of 48.71±13.45 million/ml with motility of 35.13±16.86. The definition for poor SCSA score was a DFI of >50% and HDS of >25 %. The outcomes were interpreted .

Participants/materials, setting, methods: The study participants were divided into two groups. Group A (n=56) comprised of sample prepared by Microfludics and Group B comprised of sample prepared by Sperm slow (n=53). The stimulation protocols were short protocol with antagonist and recombinant hCG for trigger. All patients underwent ICSI. The outcomes in both groups were compared as mentioned for Clinical pregnancy, miscarriage rates and live birth rates.

Main results and the role of chance: There were no statistically significant difference between Group A and Group B in patients who have low DFI value in SCSA test with respect to clinical pregnancy (p=0.112) and miscarriage rates (p=0.61), live birth (p=0.611), fertilization rates (p=0.185), and implantation rates (p=0.623). This signifies that the MFSS and Spermslow gives better normal embryos fertilization and delivery rates equal as per primary study outcomes.

Limitations, reasons for caution: A larger sample size would add more value to the study.

Wider implications of the findings: MFSS and SS have proven clinical efficacy in oligoasthenozoospermic males with poor SCSA scoring. We have achieved better clinical outcomes when compared to our retrospective results using conventional sperm preparation methods in similar groups.

Trial registration number: NA

P-087 Comparison between the sperm retrieval rate by micro-dissection testicular sperm extraction (mTESE) versus convention TESE (mTESE) combined with stereoscopic dissection

A. AlAhwany[1], T. Alglely[2], M. Ragab[1], H. AlAhwany[3]

[1]Cairo University, Department of Andrology, Cairo, Egypt ;

[2]Nile IVF Center, Department of Embryology, Cairo, Egypt ;
[3]Nile IVF Center, Department of Gynaecology, Cairo, Egypt

Study question: Can conventional TESE (cTESE) combined with stereoscopic dissection achieve a sperm retrieval rate similar to Micro-dissection Testicular Sperm Extraction (mTESE)?
Summary answer: Our study suggests that micro-TESE still has the highest recovery rate of sufficient sperms and good quality diatoms for immediate or potential cryopreservation for ICSI.
What is known already: Infertile patients with non-obstructive azoospermia are treated by testicular sperm harvesting combined with ICSI. Micro-dissection Testicular Sperm Extraction (mTESE) is considered the gold standard procedure with the highest sperm retrieval rate compared with the conventional TESE. But mTESE cannot be widely offered in most infertility centres because of its high cost, should be done by an expert well-trained surgeon and requires expensive equipment. Laboratory stereoscopic testicular tissue dissection helps in identifying the dilated seminiferous tubules. In this study, we tested whether cTESE combined by stereoscopic dissection can identify dilated seminiferous tubule and subsequent high sperm retrieval rate.
Study design, size, duration: This is a prospective comparative study, comparing the difference in sperm retrieval rate between Micro-dissection Testicular Sperm Extraction (mTESE) (n=100) and Convention TESE (cTESE) using Stereomicroscope (n=100), where Two hundred patients with NOA undergoing ICSI and TESE were recruited between 2018 and 2019.
Participants/materials, setting, methods: Two hundred patients with NOA undergoing ICSI and TESE were recruited. Patients were counselled, consented and randomly randomised. Convention TESE with additional stereomicroscope dissection was applied to the first group (n=100), while micro-TESE was applied to the second group (n=100). Parameters such as patient's average age, testicle size, follicle-stimulating hormone (FSH), luteinizing hormone (LH), testosterone levels, were analysed as predictors of sperm recovery rate.
Main results and the role of chance: The average age of 100 men in the micro TESE was 35.74 ± 37.7, the size of the right testicle was 10.5 ± 4.5, the size of the left testicle was 10.5 ± 4.3, the level of the hormone FSH recorded 19.3 ± 13.9, and the hormone LH concentration was 17.1 ± 23.8, and the testosterone hormone level was 3.4 ± 2.3. In conventional TESE group the average age of 100 men 35.17 ± 7.83 and the size of the right testicle 10.9 ± 4.6 and the size of the left testicle 11.1 ± 4.9 and the level of the hormone FSH 18.3 ± 10.4 and the hormone LH concentration 21.4 ± 44.1 and testosterone level 2.7 ± 0.7. Micro-TESE was successful in obtaining sperm from the testicle in 43% (43/100) of cases. While patients with sperm retrieval in a conventional TESE manner the success rate was 36% (36/100) showing a statistically significant difference (P<0.05).
Limitations, reasons for caution: 1) Larger (n) number of patients were needed. 2) Some of the patients already undergone a partial or conventional TESE screening elsewhere. 3) This study was single-blinded and subjective to the surgeon decision during the operation.
Wider implications of the findings: Even though mTESE shows a higher recovery rate of sufficient sperms for immediate or potential cryopreservation for ICSI, still, conventional TESE combined with stereoscopic dissection could be the method of choice of clinics because of its low cost and also giviving better results than partial or conventional TESE screening.
Trial registration number: N/A

P-088 Does oral antioxidant supplementation for the male partner improve clinical pregnancy rate in couples undergoing ICSI treatment for male factor infertility? A randomized controlled trial

T. Joseph[1], M. Mascarenhas[2], R. Karuppusami[3], M. Karthikeyan[4], A.T. Kunjummen[4], M.S. Kamath[4]

[1]Christian Medical College, Reproductive Medicine, Vellore, India ;
[2]Leeds Fertility -Leeds Teaching Hospitals NHS Trust-, Leeds Fertility-, Leeds-, United Kingdom ;
[3]Christian Medical College and Hospital, Biostatistics, Vellore, India ;
[4]Christian Medical College and Hospital, Reproductive Medicine, Vellore, India

Study question: Does oral antioxidant supplementation for the male partner improve clinical pregnancy rate in couples undergoing intracytoplasmic sperm injection (ICSI) for male factor infertility?
Summary answer: Oral antioxidant supplementation for the male partner resulted in significantly increased clinical pregnancy rate in couples undergoing ICSI for male factor infertility versus no supplementation
What is known already: Reactive oxygen species (ROS)-mediated damage to sperm contributes significantly to male factor infertility. ROS related injury reduces fertilization potential and adversely affects sperm DNA integrity. Antioxidants act as free radical scavengers to protect spermatozoa against ROS induced damage. During ICSI, use of sperms which have been exposed to ROS mediated damage may affect the treatment outcome. Pre-treatment with anti-oxidants may reduce ROS mediated sperm DNA damage. Currently, there is ambiguity regarding role of anti-oxidants before ICSI in male factor infertility due to conflicting results from earlier studies.
Study design, size, duration: This was an open label randomized trial conducted at a tertiary level infertility clinic between Feb 2013-Jan 2019. The trial included 200 subfertile couples who were undergoing ICSI treatment for male factor infertility
Participants/materials, setting, methods: Couples were randomized into treatment arm (n = 100) and control arm (n = 100). In the treatment arm, the male partner received oral anti-oxidants (vitamin C, vitamin E and zinc) for three months just prior to ICSI cycle. In the control arm, no antioxidant was given to the male partner. The primary outcome was clinical pregnancy rate and live birth and miscarriage rates were the secondary outcomes
Main results and the role of chance: A total of 200 randomized women were available for analysis**.** The clinical pregnancy per transfer was significantly higher following anti-oxidant therapy (54.7% vs.36.2% Odds ratio, OR: 2.1, 95% Confidence Interval, CI 1.06-4.26) compared to no therapy. There was no significant difference in live birth rate per transfer (39.1%, vs. 30.4 %; OR: 1.5, 95% CI 0.71-3.00) or miscarriage rate per pregnancy (25.7% vs. 8.0%; OR: 3.9, 95% CI 0.78-20.3) following antioxidant therapy compared to no therapy. However, the intention to treat analysis did not show any significant difference in live birth rate per woman randomized (25.0% vs.21.0%; OR: 1.3, CI: 0.65-2.43). The semen parameters of sperm concentration (18.2 (8.7,37.5) vs. 20.5 (8.1,52.5) million; *P*= 0.86) , motility (34 (20,45) vs. 32.0 (18,45) %; *P* = 0.55) and morphology (2.0 (1.39) vs. 2.2 (1.48); *P* = 0.63) did not show any significant improvement before and after anti-oxidant therapy.
Limitations, reasons for caution: Objective assessment of sperm DNA damage was not done before and after the anti-oxidant supplementation. The study duration got prolonged from two to five years due to slow recruitment. However, no major protocol changes were introduced during the study period
Wider implications of the findings: The preliminary result of the current study suggests that while there is an increase in clinical pregnancy rate following anti-oxidant supplementation for the male partner in couples undergoing ICSI for male factor infertility compared to no supplementation, there is no improvement in live birth rate
Trial registration number: CTRI/2013/02/003431

P-089 Effort to ameliorate sperm profile by folic acid-antioxidant combination therapy to evade single nucleotide polymorphisms of methylenetetrahydrofolate reductase and methionine synthase in idiopathic male infertility

R. Chattopadhyay[1], S. Parvin[2], S. Kalapahar[2], P. Paladhi[3], S. Dutta[3], S. Ghosh[3], P. Chakraborty[2], B. Chakraborty[2]

[1]Institute of Reproductive Medicine, ART, Calcutta, India ;
[2]Institute of Reproductive Medicine, Department of Assisted Reproduction, Calcutta, India ;
[3]University of Calcutta, Department of Zoology, Kolkata, India

Study question: Does anti-oxidants and folate combination therapy influence the association of single-nucleotide-polymorphisms (SNPs) in methylenetetrahydrofolate reductase (MTHFR) and/or methionine synthase (MS) in hyperhomocysteinemic idiopathic male infertility (IMI)?
Summary answer: MTHFR polymorphism with (1298A>C) SNP is associated with hyperhomocysteinemic IMI. Folate-antioxidant/s combination therapy confers no significant improvement in sperm parameter/s in treated cohort.

What is known already: Abnormal germline DNA methylation has been proposed as possible mechanism compromising spermatogenesis in some men with IMI. Dietary folate influence epigenetic modification/s during spermatogenesis. Recently, associations between four SNPs (MTHFR C677T, MTHFR A1298C, MS A2756G and MTRR A66G) in male infertility are widely studied among several ethnicities; however, results remaining contradictory. Folic acid supplementation usually been given to infertile men, a time when DNA methylation patterns are being actively maintained and remodeled in male germ cells to prepare the epigenome for embryogenesis. It is therefore crucial to understand the possible impact of antioxidant with folic acid supplementation in IMI.

Study design, size, duration: Prospective study; azoospermic/ oligozoospermic men with IMI (n=102; Group A) served as study cohort. Normozoospermic men (WHO criteria, 2010) were treated as controls (n=58; Group B). Patients are supplemented with folic acid (5mg/day) and a combination of antioxidant/s (glutathione: 400 mg/day; vitamin E: 200mg/day) for 3 months. Peripheral blood samples are collected before and after treatment. The study was conducted from October 2018 to September 2019 and approved by Institutional Ethics Committee of the Institute.

Participants/materials, setting, methods: Plasma levels of homocysteine, vitamin B12, folate are determined by chemiluminescence. PCR-RFLP (polymerase chain reaction- restriction fragment length polymorphism) and Sanger sequencing by MiSeq(Illumina) was performed to detect SNPs in homocysteine metabolism (MTHFR 677C>T; MTHFR1298A>C; MS2756A>G). The effect of drug supplementation on sperm parameters and apoptosis status was evaluated by Makler's chamber and flow cytometry respectively. Statistical significance was set at $p < 0.05$ as evaluated by student's T-test.

Main results and the role of chance: In comparison with normozoospermic spermatozoa, there was a significant decrease ($P < 0.03$) in motility and velocity parameters and increase in Caspase+/propidium iodide- (PI-) cells ($P < 0.04$) in oligospermic patients. Increased ($p<0.01$) serum homocysteine levels (mmol/L) was documented in Group A with no other changes in blood profile. MTHFR 1298A>C gene polymorphism was documented in 49/102 (48.03%) in contrast to 11 samples from Group B. 7 participants (14.28%) were homozygous for the MTHFR TT variant while 13 (26.53%) and 10 (20.41%) were CC and CT genotypes, respectively (Group A). 29 cases exhibited MS 2756A>G polymorphism in contrast to Group B (n=11). Serum folate concentrations (nmol/L) increased significantly (28 + 2.72 vs. 42 + 3.81; $p<0.01$) after supplementation with no significant improvements in the three MTHFR genotypes for any of the semen parameters (count, motility). Changes in semen volume, sperm motility and sperm chromatin integrity (assessed by sperm chromatin structure assay or SCSA, and reported as % high DNA stainability) was not significant. Sperm DNA integrity, assessed by SCSA and reported as % DNA fragmentation index (% DFI), demonstrated a trend toward improvement (t-test $P = 0.057$) in oligospermic men after combination regimen.

Limitations, reasons for caution: The global erasure of parental DNA methylation during early stages of embryogenesis is a mechanism for reducing the risk of altered methylation. Thus, recommendations for men with IMI to receive combination of antioxidant-folic acid therapy should be taken with caution..

Wider implications of the findings: A personalized approach to combination of antioxidant-folic acid therapy may be needed, based on factors like genetic background of the recipients. Use of combination treatment did not significantly improve semen quality probably because altered methylation may elude global erasure mechanisms and limit the progress to next stages of mitochondrial development.

Trial registration number: NA

P-090 Sperm selection using microfluidic sorting chips in patients with high DNA fragmentation improves clinical outcomes in egg-donor cycles

A. Farreras Ayestaran[1], A. Munuera[1], B. Freijomil[1], S. Novo[1], À. Garcia-Faura[1], B. Marquès[1], F. Garcia[1], C. Castelló[1], M. Lopez-Teijón[1]

[1]Institut Marques, Reproductive Medicine Service, Barcelona, Spain

Study question: Can sperm selection using microfluidic sorting chips improve reproductive outcomes in patients with high sperm DNA fragmentation (SDF)?

Summary answer: Microfluidics sperm selection significantly increases the number of blastocysts and improves clinical pregnancy rate in egg-donation (ED) cycles and high SDF.

What is known already: Previous studies have described a DNA fragmentation negative effect on early embryo development. Concretely, high levels of DNA fragmentation have been associated with embryo development arrest, as well as low implantation and pregnancy rates. Conventional methods used to select sperm for ICSI, as swim-up or density gradients, require centrifugation. It is well known that centrifugation forces increase Reactive Oxygen Species (ROS), one of the main promoter of SDF. Microfluidic systems don't need centrifugation, consequently avoid ROS formation and could allow us to select sperm with better motility, morphology and lower SDF than conventional sperm selection methods.

Study design, size, duration: Preliminary retrospective cohort study including until now 63 cycles of ICSI-ED and sperm with high SDF (>30%) between January 2017 and October 2019. In all the cycles single fresh blastocyst transfer were performed. SDF was evaluated by SCD (Sperm Chromatin Dispersion) test.

Participants/materials, setting, methods: Two groups of cycles were established according to the sperm selection method used for ICSI: microfluidic chip (G1; n=30) and density gradients (G2; n=33). The groups were homogeneous in terms of the donor age, mean number of mature oocytes collected and embryos transferred. No differences were found between groups in the SCD test using T-student statistics (G1: 45.6±14.5%; G2: 39.0±11.7%; $p=0.05$). The results were analyzed using Fisher test.

Main results and the role of chance: The two considered groups of this study were diagnosed with pathological percentage of sperm DNA fragmentation. Fertilization rate was equivalent ($p=0.07$) between G1 (172/216; 79.6%) and G2 (169/234; 72.2%). However, good quality blastocyst rate (GQB; ≥3BB Gardner score) of G1 (84/172; 48.8%) was significantly higher ($p<0.05$) than in G2 (64/169; 37.9%), as well as pregnancy rate (G1: 90.0%; G2: 54.55%). Additionally, clinical pregnancy rates were higher in G1 (63.3%) than in G2 (48.5%), not being statistically significant. Perhaps, with a higher sample could help to asses if the tendency of this increase keeps on the clinical pregnancy rate. Our results show that processing sperm samples with a microfluidic sperm sorting device could be a more efficient alternative to density gradients in cycles where patients were diagnosed with increased SDF. This method allows the selection of sperm with a low DNA fragmentation promoting the formation of a higher number of GQB to transfer and/or vitrify.

Limitations, reasons for caution: This is a preliminary retrospective study, so the main limitation is the small sample size achieved until now. These results should also be confirmed by further randomized prospective studies.

Wider implications of the findings: Our findings suggest that the application of microfluidic systems could be improving the sperm selection with conserved DNA integrity. In this sense, microfluidic systems increase significantly the number of GQB and therefore could potentially improve the cumulative pregnancy rates and the efficiency of the cycle.

Trial registration number: not applicable

P-091 Fertile®ChiP-ZyMōt improves ICSI clinical outcomes in patients with high values of sperm double-strand breaks using oocytes from both patients and donors.

S. Camacho Fernandez-Pacheco[1], C. Urda-Muñoz[1], S. Lara-Cerrillo[2], T. Lacruz-Ruiz[2], C. Rosado-Iglesias[2], M. De la Casa Heras[1], V. Badajoz-Liébano[1], J. Gijón de la Santa[1], A. García-Peiró[2]

[1]GINEFIV, Assisted Reproduction, Madrid, Spain ;
[2]CIMAB- Barcelona Male Infertility Centre, Research & Development, Sant Quirze del Vallés - Barcelona, Spain

Study question: Are clinical outcomes on ICSI cycles improved by the use of Fertile®ChiP-ZyMōt for sperm selection using oocytes from both patients and donors?

Summary answer: Fertile®ChiP-ZyMōt improved biochemical and clinical pregnancy rates and reduced miscarriage rate in ICSI cycles from patients with altered values of dsSDF.

What is known already: Delays in embryo kinetics, implantation failures in ICSI treatments and recurrent miscarriages have been associated to high values

of double-strand breaks (DSB) in sperm. Moreover, a recent study showed that DSB are not reduced during the sperm selection of an ICSI cycle.

The Fertile®ChiP-ZyMōt is a new method for sperm selection based on microfluidic properties that showed to reduce the presence of DSB in the sperm sample. In this sense, the specific reduction of DSB using Fertile®ChiP-ZyMōt could improve clinical outcomes after ICSI treatments.

Study design, size, duration: This retrospective study included 78 ICSI cycles from January 2018 to March 2019. Three groups were classified attending on the origin of the oocytes and the sperm selection method: Control group = oocytes from patients and density gradients for sperm selection (n=16); Group 1 = oocytes from patients and Fertile®ChiP-ZyMōt for sperm selection (n=22); and Group 2 = oocytes from donors and Fertile®ChiP-ZyMōt for sperm selection (n=11). All male patients presented high values of DSB.

Participants/materials, setting, methods: Patients included in the study presented high values of DSB analyzed though the Neutral CometFertility assay (CIMAB, Spain). Sperm selection was performed using conventional Density Gradients (Sperm Grad, Vitrolife, Sweden) (Control group) or the Fertile®ChiP-ZyMōt (DxNow, USA) (Groups 1 and 2). ICSI cycles were performed using oocytes from patients or donors and clinical outcomes were studied. Results were compared between groups, being the statistical significance $\alpha = 0,05$.

Main results and the role of chance: Women's age was significantly lower in Group 2 (26.7 ± 4.28) compared to the Control group (35.67 ± 3.43) and Group 1 (36.17 ± 3.84), $p<0.01$.

Fecundation rates were slightly higher, even not significantly, in Group 1 (0.53 ± 0.27) and Group 2 (0.63 ± 0.21) compared to the Control group (0.51 ± 0.29), $p=0.80$. Biochemical pregnancy was significantly higher in Group 1 (12/22 (54.5%)) and Group 2 (7/11 (63.6%)), compared to the Control group (3/16 (18.8%), $p=0.03$. Clinical pregnancy was significantly higher in Group 1 (10/22 (45.5%)) and Group 2 (7/11 (63.6%)), compared to the Control group (2/16 (12.5%), $p=0.01$. Miscarriage rates were significantly higher in the Control group (2/2 (100%)) than in Group 1 (2/10 (20%)) and Group 2 (0/7 (0%)), $p=0.02$.

Even Group 2 showed the best results, there were no significant differences compared to Group 1 for biochemical and clinical pregnancies and miscarriage rates ($p=0.618$; $p=0.325$ and $p=0.418$, respectively).

Compared to density gradients, the use of the Fertile®ChiP-ZyMōt in ICSI cycles improved biochemical pregnancy rates x1,65 using oocytes from patients ($p=0,033$) and x2,32 using oocytes from donors ($p=0,054$). Fertile®ChiP-ZyMōt also improved clinical pregnancy rates x1,71 using oocytes from patients and x2,68 oocytes from donors ($p=0,036$).

Limitations, reasons for caution: Despite biochemical and clinical pregnancies presented significant better results using the Fertile®ChiP-ZyMōt, the increase in the fecundation rate was not significant. More studies analysing a larger number of ICSI cycles are needed to confirm these findings.

Wider implications of the findings: The use of the Fertile®ChiP-ZyMōt in ICSI cycles to treat high values of DSB in sperm increase biochemical and clinical pregnancy rates. These increases are even more important when oocytes are from a donor.

Trial registration number: Does not apply.

P-092 Varicocelectomy corrects sperm capacitation functions and enhances sperm genomic integrity

M. Haddad[1], P. Xie[1], A. Parrella[1], Z. Rosenwaks[1], J. Kashanian[2], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A. ;
[2]Weill Cornell Medicine, Department of Urology, New York, U.S.A.

Study question: To determine whether varicocelectomy improves spermatogenesis by enhancing semen parameters, sperm capacitation, sperm genomic integrity, and overall embryo developmental competence of the male gamete.

Summary answer: Correction of grade 2 or higher varicocele enhanced male gamete production, ameliorated sperm chromatin fragmentation (SCF), and amplified male gamete capacitation.

What is known already: Varicocele is known to induce oxidative damage to the male reproductive system, affecting semen parameters, sperm chromatin integrity, and function. Varicocelectomy has been proposed to enhance typical parameters measured in semen analysis, such as concentration and motility, and ameliorate SCF. Because the predictability of overall gamete competence through semen analysis has been debatable, new bioassays have been proposed. By surveying localization patterns of ganglioside M_1, a key regulator of capacitation and acrosomal reaction, we have been able to quantify subtle sperm function and predict probability of generating a pregnancy (PGP).

Study design, size, duration: In the past 12 months, fresh ejaculates were obtained from 6 consenting men who were initially diagnosed with varicocele of grade 2 or higher and then treated by varicocelectomy. Ejaculates were obtained again at least 3 months post-surgery to allow a full cycle of spermatogenesis. Semen parameters, SCF, CaP-Score™, and PGP were determined in a blind fashion and compared among pre- and post-operative specimens.

Participants/materials, setting, methods: Semen analysis was performed on pre-/post-operative ejaculates. Varicocele was evaluated by physical exam in standing position. Capacitation was measured by CaP-Score™ (Androvia LifeSciences) with normal thresholds of >27.6%. A corresponding PGP was previously established by analyzing pregnancy outcomes from fertile and infertile men who completed 3 IUI cycles with a normal threshold of >32.7%. Total capacitated spermatozoa were quantified by volume x concentration x CaP-ScoreÔ. SCF was assessed using TUNEL with normal threshold of <15%.

Main results and the role of chance: Men (n=6) with grade 2 varicocele or higher aiming to procreate underwent microsurgical varicocelectomy without any post-operative complication. Semen parameters such as volume and normal morphology that were assessed before surgery did not improve. For all men, sperm concentration was initially 35.0 ± 28.0 x10^6/ml and became 57.3 ± 29.5 x10^6/ml ($P < 0.05$). Sperm capacitation function, total capacitated spermatozoa, and PGP at baseline were 25.4 ± 3.4%, 18.4 ± 13.3 x10^6, and 29.3 ± 5.1%, respectively. After 3 months of post-operative recovery, sperm capacitation, number of total capacitated spermatozoa, and PGP significantly increased to 32.0 ± 4.1%, 33.2 ± 16.0 x10^6, and 41.0 ± 7.2% ($P < 0.05$), respectively. Genomic integrity as measured by SCF was originally above threshold at 17.9 ± 6.6% and significantly decreased to an average of 11.0 ± 4.8% ($P < 0.01$) after varicocele correction.

Limitations, reasons for caution: These findings support a beneficial effect of varicocele correction. However, the improvement of sperm concentration together with functional assay, as well as the amelioration of genomic integrity, needs to be confirmed by testing the embryonic developmental competence of the male gamete.

Wider implications of the findings: This analysis confirms the beneficial effect of varicocelectomy on at least one semen parameter. The utilization of a functional assay and the determination of genomic integrity by SCF provide information on an individual's ability to spontaneously reproduce or can help guide one toward the preferential method of assisted reproduction.

Trial registration number: not applicable

P-093 Andropenia precedes AML diagnosis and is associated with fatty marrow

K. Shlush[1], N. Zioni[2], N. Kaushansky[3], G. Oron[4], L. Shlush[3]

[1]fertility clinic Rabin Medical center, Obstetric and Gynecology, Herzliy, Israel ;
[2]Wiezmann institute of science, Immunology, Rehovot, Israel ;
[3]Weizmann institute of science, Immunology, Rehovot, Israel ; [4]Rabin medical center, Obgyn, Petah Tikva, Israel

Study question: What are the effects of andropenia on leukemia and bone marrow?

Summary answer: Many years before AML diagnosis testosterone levels are decreasing. Low testosterone levels after castration cause fatty bone marrow in mice.

What is known already: As human age they accumulate somatic mutations. These early mutations preleukemic mutations (pLMs) accumulate and eventually lead to different myeloid malignancies. Specific pLMs are more common among elderly males. Furthermore myeloid malignancies are more common among males. While large proportion of the population carry pLMs only a small proportion will develop myeloid malignancies. Understanding the mechanisms contributing to the progression to leukemia is of great importance. One factor possibly contributing to leukemia evolution might be the accumulation of fat in the bone marrow (BM) with age. A correlation was found between increased BM fat and low testosterone levels.

Study design, size, duration: The electronic health records of 4.5 million Israelis over 15 years were analyzed to identify AML cases (N=987). We identified all individuals in this group (pre-AML) and studied their blood counts and testosterone levels before AML diagnosis and compared it to 500,000 aged match individuals.
Participants/materials, setting, methods: To study the effect of andropenia on BM fat mice were castrated and BM fat was measured after two month by lipitox staining of CD45 negative cells from the BM. in each group 10 mice were used.
Main results and the role of chance: Testosterone levels were available for 76 pre-AML cases on average 4 years before AML diagnosis. Significantly reduced testosterone levels was present already four years before AML diagnosis and remained significantly lower until diagnosis. Low testosterone levels were achived after castration. Two month after castration a significant increase in the BM fat was noticed with 30% more fat in the castrated mice compared to aged matched controls.
Limitations, reasons for caution: It is not clear why fatty marrow is promoting leukemia among males. Also the number of pre-AML cases with testosterone levels was low and a sampling bias is possible.
Wider implications of the findings: The effect of low testosterone levels on the BM and leukemia evolution remains unknown.In the current study we provide evidence that fatty marrow can be induced by castration. Furthermore, low testosterone levels precede AML. Better understanding the mechanisms leading to increased leukemia might help in preventing this devastating disease.
Trial registration number: NA

P-094 The impact of double-stranded DNA breaks in human spermatozoa on embryo implantation

L. Zimmerman[1], D. Keating[1], A. Parrella[1], Z. Rosenwaks[1], G. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Is there a correlation between double-stranded DNA breaks (DSBs) in human spermatozoa and ICSI outcome?
Summary answer: An increased proportion of DSBs in men with normal semen analyses impairs embryo implantation.
What is known already: Total sperm chromatin fragmentation (SCF) in men with normal semen parameters has been linked to a couple's ability to successfully conceive. Recent studies have challenged this, asserting that DSBs, rather than single-stranded breaks (SSBs), lead to compromised embryo development. There are many techniques to assess the genomic integrity of spermatozoa by measuring indistinct SSBs and DSBs, such as the sperm chromatin structure assay, terminal deoxynucleotidyl dUTP transferase nick-end labeling (TUNEL), sperm chromatin dispersion, and alkaline Comet. However, the only method to specifically detect double-stranded DNA integrity is the neutral Comet test.
Study design, size, duration: In the course of 12 months, we carried out a pilot study to assess exclusively DSBs in spermatozoa by neutral Comet assay. There was a linear correlation between Comet and TUNEL (R2=0.96), which allowed us to extrapolate the proportion of DSBs in all men who had been screened by TUNEL assay. This value was correlated with ICSI outcome.
Participants/materials, setting, methods: A total of 523 men with poor assisted reproductive outcomes were screened by TUNEL, with ≥500 spermatozoa assessed per sample and a normal threshold of ≤15%. Neutral comet was performed using a modified in-house protocol with commercially available materials, with ≥200 spermatozoa assessed, and a normal threshold of ≤3%. All men underwent ICSI, performed in the standard fashion, with their female partners. Fertilization, implantation, and pregnancy outcomes were compared according to DSBs.
Main results and the role of chance: The pilot study yielded an average SCF by TUNEL of 11.3±6% and a DSB of 2.2±3% by neutral Comet in a linear relationship (R2=0.96). This allowed us to extrapolate DSB rates in 523 normozoospermic men (2.6±1 mL volume, 42.3±34x106 concentration, 43.1±10% motility, and 4.1±1% normal morphology) who had undergone TUNEL.

A total of 377 couples with normal DSB rates underwent 736 ICSI cycles. The average maternal age was 37.0±4 years, and the paternal age was 38.5±6 years. These cycles had a 72.7% fertilization rate (4935/6789), with a 12.0% implantation rate (112/935) and a 21.7% clinical pregnancy rate (CPR; 92/423). Fourteen of these pregnancies resulted in miscarriage (15.2%).

A total of 146 couples with an abnormal DSB level were treated by 259 ICSI cycles. The maternal age was comparable between the two groups at 37.3±5 years, while male partners were much older at 41.4±8 years of age (P<0.01). This group had a comparable fertilization rate of 70.1% (1739/2481), an implantation rate of 10.8% (49/455), and a CPR of 22.9% (40/175). However, these couples were significantly more likely to experience a miscarriage, which occurred at a rate of 30.0% (12/40; P<0.05).
Limitations, reasons for caution: This is a retrospective observation in couples with a history of compromised outcomes with assisted reproductive techniques. It would be ideal to reproduce these findings in a prospective manner using solely the neutral Comet assay.
Wider implications of the findings: DSBs in human spermatozoa, which have been associated with structural chromosomal abnormalities, may provide information on embryonic developmental potential. Utilizing an assay that screens exclusively for DSBs may be more beneficial than total SCF in terms of predicting a couple's ability to successfully reproduce.
Trial registration number: not applicable

P-095 The male factor – impact of semen quality on the insemination result in women with endometriosis

Z. Kaszás[1], A. Nemes[1], Á. Anikó[1], D. Pócsi[1], Á. Murber[1], J. Urbancsek[1], P. Fancsovits[1]

[1]Division of Assisted Reproduction Semmelweis University, Department of Gynecology and Obstetrics, Budapest, Hungary

Study question: Do we need higher sperm count to achieve a successful insemination cycle with endometriosis patients?
Summary answer: Our results suggest that sperm viability and/or its lifetime is effected by endometriosis.
What is known already: Little is known about the effect of endometriosis on the outcome of insemination (IUI). In the first 6 month after surgery women with minimum to mild endometriosis have the same chance to get pregnant with IUI as couples with unknown infertility. The ESHRE guideline recommend insemination as treatment for infertility with minimum to mild endometriosis, but this statement has never been linked to any study with male fertility factors. We don't know yet whether sperm react to the intrauterine environment effected by endometriosis, but possibly endometriosis may influence the viability of the motile sperm.
Study design, size, duration: This is a retrospective study performed between 2010 January and 2019 May at university settings. Patients treated with endometriosis and infertility were selected from our institute database such as diagnosis of endometriosis, date of previous surgeries, date of insemination and total motile sperm count (M/ml) after density gradient centrifugation.
Participants/materials, setting, methods: Data of IUI treatments were analyzed in two groups. Endometriosis group: cycles with the diagnosis of previously surgically proven endometriosis. Control group: cycles with "unknown infertility".

Endometriosis group was further divided into two subgroups according to the time elapsed between surgery and IUI. Subgroup A: IUI ≤6 months after surgery; Subgroup B: IUI in 7-18 months after surgery.

Total motile sperm count and pregnancy rates were compared in Endometriosis and Control groups.
Main results and the role of chance: The pregnancy rate of insemination cycles of women with endometriosis (23/341; 6,7%) was similar to the Control group (9/171;5,2%) (P=0,513).

Subgroup analysis of endometriosis patients showed similar pregnancy rates in Subgroup A (4/69; 5,8%) and Subgroup B (10/129;7,7%) (P=0,609).

The progressive motile sperm count in the pregnant IUI cycles was 34,9± 18,4 M/ml, in the Endometriosis group, while 25,8±14,6 M/ml in the Control group. The difference was not significant (P=0,304).

The mean of 22,5 ±9,2 M/ml of progressive sperm count was found in pregnancy in Subgroup A. That is similar to the Control group's (25,8± 14,6 M/ml) result.

However, that of Subgroup B higher sperm number was found in pregnancy cycles (37,3 ±11,3 M/ml), but the difference was not significant (P=0,327) compared to the Control group.

It seems that within 6 months following the endometriosis surgery patients need comparable amount of motile sperm to get pregnant by insemination as the patients with unknown infertility. After this half year period, patients need higher sperm count to get pregnant. These differences can be explained with the recurrent appear of endometriosis changing the pelvic environment.
Limitations, reasons for caution: The retrospective study design limits our chance to make a strong conclusion. Our small sample number in the subgroups also limits our chance to find significant differences.
Wider implications of the findings: Our results could also confirm the ESHRE guideline regarding the necessity of insemination during the first 6 months after the endometriosis surgery. We plan to further explore this field, to find out what kind of biochemical milieu could influence the need for higher sperm count to reach pregnancy.
Trial registration number: not applicable

P-096 Increased DNA damage in infertile patients with high grading varicocele

S. Jellad[1], F. Hammami[1], A. Khalbous[2], M. Cbibani[3], R. Rachdi[3]

[1]Miitary Hospital of Tunis- Faculty of Medicine of Tunis, laboratory of Reproductive Biology- Unit of Assisted Medical Procreation, Tunis, Tunisia ;
[2]Miitary Hospital of Tunis, laboratory of Reproductive Biology- Unit of Assisted Medical Procreation, Tunis, Tunisia ;
[3]Miitary Hospital of Tunis- Faculty of Medicine of Tunis, Unit of Assisted Medical Procreation, Tunis, Tunisia

Study question: This study aims' at evaluating the impact of clinical varicocele on sperm nuclear DNA quality and standard semen parameters?
Summary answer: Clinical varicocele generates a significant increase of sperm abnormalities and DNA damage and these changes are positively correlated with varicocele grade.
What is known already: Varicocele is thought to progressively reduce spermatogenesis via elevated intratesticular temperature and altered testicular blood flow. The decreased supply of oxygenated blood and nutrients to the sperm secretion sites reduces sperm quality and quantity, and consequently, their fertility capacity. Although a cause-effect relationship is not established, multiple reviews conclude that there is indeed evident association between varicocele and increased DNA fragmentation
Study design, size, duration: The study included 45 men assessed by our laboratory of reproductive biology of military hospital of Tunis during 6 months. A prospective study was designed involving one control group of men with unknown fertility and normal semen parameters (n = 10) and one group of patients with clinically diagnosed varicocele and infertility (n=30).
Participants/materials, setting, methods: Our prospective study involved 30 infertile patients with clinical varicocele and 15 control patients referred to our laboratory for routine spermiological exploration). Men with azoospermia, severe oligozoospermia or leucocytospermia were excluded from the study. Spermograms were performed and analyzed according to WHO guidelines 2010. The DNA fragmentation was detected by the terminal desoxynucleotidyl transferase-mediated deoxyuridine triphosphate biotin nick-end labeling (TUNEL) assay.
Main results and the role of chance: The average age of the patients at the time of diagnosis was 26 ± 4 years (19-35) and 35 ± 7 years (27-47) for the control group. The DNA fragmentation index was significantly higher in patients with clinical varicocele compared to controls (13.3±3.4 % versus 6.1±2.5%, p=0.0001). In addition, the DFI was positively and significantly correlated with the degree of severity of varicocele thus the DFI was 15.24±1.9% in patients with grade 3 versus 12.92±3.5 % in those with grade 2 (p<0.0001). However, an abnormality of at least one of the semen parameters was found in 90% of varicocele patients, and all semen characteristics such as sperm count, vitality, mobility and typical forms were decreased compared to the controls. Furthermore, statistically significant negative correlations were noted between sperm DNA fragmentation index and sperm concentration (p=0.0001), motility (p=0.03), and normal sperm morphology (p=0.03).
Limitations, reasons for caution: Although considered as referent technique the TUNEL assay has certain limits as it doesn't allow differentiating between normal and pathological DNA ruptures. Further investigations are also needed to reveal the cause and effect relationship between the increase of DNA fragmentation levels and clinical varicocele, as well as the underlying mechanisms.
Wider implications of the findings: Sperm DNA damage independent of its cause, may affect the sperm quality and have implications on patient's fertility potential. Therefore, we recommended the evaluation of sperm DNA status in infertile patients with a high clinical varicocele grade in order to optimize sperm quality and pregnancies rates in this population.
Trial registration number: not applicable

P-097 Male lifestyle and pathological conditions associated with couple infertility in a referral center in Italy: a cross-sectional study of 13452 male patients

M. Dal Canto[1], C. Signorini[2], L. Mura[1], S. Casellato[3], L. Carmignani[2], M.M. Renzini[1], J. Buratini[1,4], S. Maruccia[3]

[1]Biogenesi - Reproductive Medicine Centre, Istituti Clinici Zucchi, Monza, Italy ;
[2]U.O. Urologia IRCSS Policlinico San Donato, Milano, Italy ;
[3]U.O. Urologia Istituti Clinici Zucchi, Monza, Italy ;
[4]Sao Paulo State University, Institute of Biosciences, Department of Physiology

Study question: Is overall male health associated with male fertility as assessed by semen analysis in couples undergoing subfertility treatment?
Summary answer: Oncologic, cardiovascular, metabolic and allergic diseases are more frequent in infertile men with impaired semen analysis than in those with normal semen parameters.
What is known already: Current literature suggests an association between male infertility and a wide range of other comorbid conditions, ranging from oncologic, cardiovascular, autoimmune, and metabolic disorders. The exact nature of this putative association remains somewhat unclear, although hypothesized mechanisms linking men's health and fertility include genetic, developmental, and lifestyle-based factors. The male population seeking for fertility treatment constitutes an extremely valuable opportunity to clarify this issue, but have not been sufficiently explored in previous studies with this aim.
Study design, size, duration: Sociodemographic, health, lifestyle and recreational data from 13452 male patients seeking for couple infertility treatment were collected at a single referral centre between 01/2013 and 12/2019. Frequencies of diseases and lifestyle/recreational habits impacting on health (smoking, use of alcohol and other drugs of abuse) were compared between male patients with different fertility as assessed by semen analysis.
Participants/materials, setting, methods: This is a retrospective study utilizing data collected from 13452 male partners of couples seeking for infertility treatment at our clinic. Treatments included 1091 IUI, 7443 ICSI and 1348 IVF. The WHO 2010 referral criteria were used to categorized semen parameters as pathological or normal. Descriptive statistics was applied to describe the whole cohort. Differences in frequencies were assessed with the Chi Square test.
Main results and the role of chance: The median age was 41.5 years (95% CI ±0,09). 8209 (61.0%) men had pathological semen parameters (any type), while 5243 (39.0%) individuals presented normal semen parameters. Among patients with pathological semen, 3666 (44.6%) had a sperm concentration <15mln/ml, 3689 (44.9%) had a total sperm count <39 mln, 4695 (57.1%) had a motility <32%, and 6764 (82,3%) men had a normal morphology <4%. In terms of health comorbidities, patients with abnormal semen parameters more frequently reported a history of hypertension [941 (11.4%) vs. 234 (4.4%)], diabetes mellitus [804 (9.7%) vs. 178 (3.3%)] and cardiovascular diseases [613 (7.4%) vs. 160 (3.0%)], than those with normal semen analysis (p<0.001). Testis cancer was more frequently found in men with abnormal semen parameters [140 (1.7%) vs. 24 (0,4%), p<0.001]. Men with impaired semen parameters were more frequently active smokers [3336 (40.6%) vs. 764 (14.5%)] and alcohol consumers [208 (2.5%) vs. 15 (0.2%)] than those with normal semen parameters (all p<0.001), while the use of substances of abuse was similar among groups. A history of allergic diseases was more frequently found in men with impaired semen analysis [2031 (24.7%) vs. 477 (9.0%); p<0.001].
Limitations, reasons for caution: The retrospective nature of the study.
Wider implications of the findings: Our data contribute to a better comprehension of the association between men's health and fertility, while favouring early diagnosis of important male diseases and medical counselling during subfertility treatment.
Trial registration number: Not applicable

P-098 Improved classification of testicular histopathology to promote uniform diagnosis and discovery of genetic causes for male infertility

G. Van der Heijden[1], M. Wyrwoll[2], L. Ramos[1], J. Veltman[3], F. Tüttelmann[4]

[1]Radboud University Medical Center, Gynaecology, Nijmegen, The Netherlands ; [2]University of Münster, Department of Clinical and Surgical Andrology- Centre of Reproductive Medicine and Andrology, Münster, Germany ; [3]Newcastle University, Institute of Genetic Medicine, Newcastle, United Kingdom ; [4]University of Münster, Institute of Human Genetics, Münster, Germany

Study question: Can a descriptive framework for testicular histopathology be designed that identifies phenotypically unique cases and facilitates research on the genetic causes of male infertility?

Summary answer: We propose an organized nomenclature for testis histopathology that makes use of clearly defined rules and definitions, describing certain patterns of disruption of spermatogenesis.

What is known already: With the availability of Next Generation Sequencing the genetic causes of male infertility are increasingly being chartered. A genetic diagnosis combined with a clear unambiguous description of accompanying testis histology will hugely benefit interpretation of the function of identified genes. However, a universal ontology for testis histopathology is lacking. The Human Phenotype Ontology (HPO) is a formal ontology, which describes phenotypes encountered in human diseases. The HPO allows phenotype driven differential diagnostics in clinical routine and research. The current hierarchy of terms regarding azoospermia, is not a systematical one. Moreover, the majority of testicular phenotypes are not annotated yet.

Study design, size, duration: We aimed to design a framework that is easy to understand and straightforward in its application but does contain most relevant information to study the impact of an identified mutation on spermatogenesis.

Participants/materials, setting, methods: The ontology classification is based on qualitative and quantitative histology description of testicular samples from azoospermic samples (>1000) in our centers. For the differentiation between the classification of hypospermatogenesis and complete spermatogenesis, n=117 testicular biopsies post vasectomy cases were used.

Main results and the role of chance: Building on what has been published previously we propose a framework for testis histopathology based on the presence/absence of germ cells and/or Sertoli cells. Our framework has five main categories. In addition to Sertoli cell only phenotype we add the classification of tubular shadows, when also Sertoli cells are absent. When germ cells are present, their stage of arrest, numbers and distribution can inform us about the effect of the causal mutation. We therefore propose to distinguish Germ Cell Arrest (GCA), in which no spermatozoa are observed, from hypospermatogenesis (HS). Both categories are sub-divided to obtain information on the timing of the arrest (GCA) or the severity of overall loss of spermatogenesis (HS). To establish a lower threshold for complete spermatogenesis we determined the number of tubules that contain elongating spermatids (ES) in a collection of samples of men with an obstructive azoospermia due to a previous vasectomy (N=117). The majority of samples contained ES in ≥60% of their tubules, suggesting 50% to be a reasonable cut-off to distinguish hypospermatogenesis from complete spermatogenesis. We conclude that once this framework is incorporated in the HPO, the standardized vocabulary will facilitate communication and interpretation in both a clinical routine and research.

Limitations, reasons for caution: Words describing the world are words not the world. Some classifications of histopathology remain arbitrary. Discussions should follow to further improve categories and reach a consensus.

Wider implications of the findings: Histopathology of the testis is just one aspect of the diagnosis, treatment and study of male infertility. The use a uniform ontology for all clinical diagnoses concerning male infertility should be facilitated and stimulated.

Trial registration number: not applicable

P-099 A randomized clinical trial comparing intracervical insemination and intrauterine insemination for donor sperm treatment in the natural cycle.

F. Kop[1], M. Van Wely[1], A. De Melker[1], B.W. Mol[2], R. Bernardus[3], M. De Brucker[4], P. Janssens[5], A. Nap[6], B. Cohlen[7], J. Pieters[8], S. Repping[1], F. Van der Veen[1], M. Mochtar[1]

[1]Amsterdam UMC- University of Amsterdam, Centre for Reproductive Medicine-Amsterdam Reproduction & Development Institute, Amsterdam, The Netherlands ; [2]Monash University, Department of Obstetrics and Gynaecology, Melbourne, Australia ; [3]Nij Barrahûs, Fertility clinic, Wolvega, The Netherlands ; [4]University hospital Brussels, Centre for Reproductive Medicine, Brussels, Belgium ; [5]Rijnstate, Department of Clinical chemistry and haematology, Arnhem, The Netherlands ; [6]Rijnstate, Department of Obstetrics and Gynaecology, Arnhem, The Netherlands ; [7]Isala, Department of Obstetrics and Gynaecology, Zwolle, The Netherlands ; [8]Vivaneo Medisch Centrum Kinderwens, Fertility Clinic, Leiderdorp, The Netherlands

Study question: Are six cycles of ICI non-inferior to six cycles of IUI in donor sperm treatment in the natural cycle in terms of ongoing pregnancy?

Summary answer: In donor sperm treatment in the natural cycle in terms of ongoing pregnancy rate, we could not demonstrate non-inferiority of ICI as compared to IUI.

What is known already: Both ICI and IUI in the natural cycle are performed as first line treatments in women who are eligible for donor sperm treatment. IUI is more costly than ICI, due to the involvement of sperm processing. High quality data on the effectiveness of ICI versus IUI in the natural cycle in terms of ongoing pregnancy are lacking. A large retrospective cohort study performed in the Netherlands suggested that ICI and IUI in the natural cycle in donor sperm treatment resulted in comparable ongoing pregnancy rates of 40% after six cycles.

Study design, size, duration: We performed a multicenter, non-blinded, non-inferiority randomized controlled trial in six fertility clinics in the Netherlands and Belgium. Women were allocated to receive either ICI or IUI in a natural cycle during six cycles. Based on the retrospective cohort study we assumed a live birth rate of 40% after six cycles of IUI. To assess a non-inferiority margin of 12%, we needed to include 416 women.

Participants/materials, setting, methods: All women scheduled for donor sperm treatment were eligible, regardless of the indication for treatment. The primary outcome was ongoing pregnancy within eight months after randomisation leading to a live birth. Secondary outcomes were multiple pregnancy, miscarriage, time to ongoing pregnancy and pregnancy complications.

We calculated relative risks (RR) and risk difference (RD) and 95% CI. We analysed the data both on an intention to treat and per protocol basis.

Main results and the role of chance: Between June 2014 and February 2019, we included 419 women, of whom 211 women were randomly allocated to ICI and 208 to IUI.

Women's age was on average 34 years (SD ± 4) in both groups.

Of the 419 women included, ongoing pregnancy occurred in 52 women (25%) in the ICI group and 77 women (37%) in the IUI group (RR 0.67, 95% CI 0.50 to 0.89 and RD -0.12, 95% CI -0.21 to -0.04). Live birth occurred in 51 women (25%) in the ICI group and 76 women (37%) in the IUI group (RR 0.67, 95% CI 0.50 to 0.91).

In the per protocol analysis we included 193 women in the ICI group and 193 women in the IUI group. We excluded two spontaneous pregnancies. Ongoing pregnancy occurred in 51 women (26%) in the ICI group and 76 women (39%) in the IUI group (RR 0.67,95% CI 0.50 to 0.90 and RD -0.12, 95% CI -0.21 to -0.03). In both the intention to treat and per protocol analysis ICI was inferior to IUI as the left boundary of the 95% confidence interval crossed the pre-set absolute difference of 12%.

Limitations, reasons for caution: We did not perform analyses for factors possibly affecting ongoing pregnancy rate like quality of frozen-thawed donor sperm. These data will be available in July 2020.

Wider implications of the findings: In women undergoing donor sperm treatment in a natural cycle, ICI results in lower ongoing pregnancy rates than IUI. Therefore, IUI should be the preferred treatment.

Trial registration number: NTR4462

P-100 Impact of genotype and phenotype on the spermatogenesis of cystic fibrosis (CF) patients: a cohort study about 57 patients from 1998 to 2019

A. Chargui[1], L. Adjiman[1], D. Hubert[2], C. Jean[1], A.S. Gille[1], E. Girodon Boulandet[3], L. Ferreux[1], C. Chalas[1], K. Pocate[1], J.P. Wolf[1], N. Thiounn[4], T. Bienvenu[3], C. Patrat[1]

[2]Hôpital Cochin - Assistance Publique des Hôpitaux de Paris, Service de Pneumologie - Centre de ressources et de compétences de la mucovisidose, Paris, France ;
[3]Hôpital Cochin - Assistance Publique des Hôpitaux de Paris, Service de Génétique et Biologie moléculaire, Paris, France ;
[4]Hôpital européen Georges Pompidou - Assistance Publique des Hôpitaux de Paris, Service d'Urologie, Paris, France

Study question: Is there an impact of CFTR (cystic fibrosis transmembrane-conductance regulator) gene mutation type and/or general health condition and the quality and yield of spermatogenesis?
Summary answer: Neither genetic severity nor clinical severity seems to have a negative impact on the characteristics of epididymis and testicular spermatozoa ofn cystic fibrosis (CF) patients.
What is known already: CFTR protein regulates electrolyte and fluid transport in many tissues with exocrine function, including male reproductive tract. Mutation of CFTR gene causes CF, which affects the function of several organs, and impairs male fertility. CF is generally associated to an obstructive azoospermia because of bilateral absence of vas deferens and seminal vesicles degeneration. CFTR protein is detected in human fetus at the early developmental stages and highly expressed in both testis and epididymis. CFTR provides establishment of specific fluid environment for germ cell differentiation and maturation. According to literature, it seems likely that CFTR mutations affect the sperm quality.
Study design, size, duration: This cohort study was conducted in the Assisted Reproduction Center of an university hospital on 57 patients, for whom a CF has been diagnosed and monitored at Cystic Fibrosis Resource and Competence Center (CFRCC) in the same hospital. The CF diagnosis was based on CFTR genetic tests and clinical symptoms. All patients were azoospermic and underwent on a microscopic epididymal sperm aspiration (MESA) and/or a testicular sperm extraction (TESE) between 1998 and 2019.
Participants/materials, setting, methods: Clinical data- one year preceding surgical sperm collection - related to the severity of the CF have been collected: respiratory spirometry data, *Pseudomonas aeruginosa* colonization, number of antibiotic treatment, BMI and Pancreatic insufficiency, as well as CFTR mutations. Linear regression tests (fisher and χ^2) were carried out to establish or not correlation between on the one hand the quality of the spermatic sample and on the other hand genotype and/ or each clinical parameter
Main results and the role of chance: The mean age of patients at sperm retrieval was 31.3 years [21-55]. The mean BMI was 21.3 Patients with severe genotype represented 67.8% and likely (67.3%) an external pancreatic deficiency. *P.aeroginosa* colonization was revealed in 30% of cases and 45.6% patients received at least one IV antibiotic treatment a year before MESA and/or TESE. Respiratory function has been impaired in 18 cases (31.6%) with a maximal expiratory volume per second (MAVS) < 40%.

Spermatozoa were founded for all patients and frozen after 58 surgical sperm collections (one patient has benefited of 2 TESE): 20 MESA, 32 MESA + TESE and 6 only TESE. Spermatic parameters results were: presence of epididymal spermatozoa in 89.7%, a mean epididymal sperm numeration at 66.0 ±105.5 million, subnormal mean epididymal vitality at 57.8%. Progressive epididymal motility. Total testicular motility and testicular vitality were decreased (respectively: 2.5±4.7%, 6.0±6.8% and 41.1±25.3%). The mean number of epididymal motile progressive spermatozoa was satisfactory (10.2±18.83 million).

The presence and quality of epididymal spermatozoa was not affected by the genetic severity of the disease (p = 0.65). Likewise, and after several univariate analyses there was no statistically significant correlation between the parameters evaluating clinical severity and those relating to epididymal sperm.
Limitations, reasons for caution: The lack of standard values for epididymal and testicular sperm parameters made harder the choice of cut-offs to establish correlation. This leads us to choose the WHO recommendations for sperm count and vitality and the mediane for motility. Our study needs to be completed by a multivariate analyse.
Wider implications of the findings: Regarding to the better quality of life of CF patients nowadays and to our results- with no significant correlation between genetic and/or clinical severity and spermatogenesis, the surgical sperm collection can be proposed only in case of a conceptional project for men in couple or before transplantation and immunosuppressive agents
Trial registration number: none

P-101 Male Infertility During the Syrian Crisis: A Case-Control Study

Z. Khrait[1], R. AL-Nasser[2]

[1]Fakih Fertility Center, IVF, Dubai, United Arab Emirates ;
[2]British-Syrian IVF & Fetal Medicine Center, Fertility, Damascus, Syria

Study question: To explore the differences in semen analysis parameters among Syrian males before and during the Syrian crisis to identify the impact of war on male fertility.
Summary answer: Semen samples obtained during the Syrian war contained semen in significantly higher quantities but of lower quality. Sperm morphology is subject to aberrations.
What is known already: Several studies conducted on veterans and civilians exposed to war-related injurious trauma showed that war operations and trauma had no impact on male infertility in terms of fathering a child after exposure to war incidents.
Study design, size, duration: Control samples were collected in 2009-2010 for 847 participants (before the war), and case samples were collected in 2014-2015 for 1108 participants (during the war). The semen analysis parameters of each case were obtained electronically from hospital records. Both verbal consent and ethical approval were secured. Data analyses were conducted with SPSS version 23.0 with 95% confidence intervals.
Participants/materials, setting, methods: A total of 1108 male cases from the war in Syria (2014-2015) were included in the study and were compared with 847 controls (2009-2010). Exclusion criteria included a BMI of greater than 30, age older than 55 years, confirmed diagnosis of systematic disease, extensive exposure to radiation and chemicals not related to wartime events (such as exposures among radiologists and chemists), and administration of medications with a known impact on fertility.
Main results and the role of chance: The mean semen volume was significantly higher in cases (3.18 ± 1.68 ml vs 3.45 ± 1.75 ml) than in controls (p <.001). In contrast, the means of all other parameters (density; motility categories A, B, and C; and percentage of normal sperm) were significantly lower among cases than among controls (all P-values <.001).
Conclusion: Semen samples obtained during the Syrian war contained semen in significantly higher quantities but of lower quality. Sperm morphology is subject to aberrations that highlight the risk of fertility problems. Motility and normal sperm percentage are the most affected parameters.
Limitations, reasons for caution: While the findings of our study are promising, the extent to which psychological stress affects spermatogenesis remains unclear. A large randomized controlled trial is recommended to fully elucidate the specific confounding factors implicated in spermatogenesis and to understand the effect of stress, particularly war, on the deterioration of sperm quality.
Wider implications of the findings: It is recommended that fertility health should an area of focus for those exposed to wartime events.
Trial registration number: not applicable

P-102 Microfluidic sperm selection for couples with a history of aneuploid embryos

A. Parrella[1], D. Tavares[1], M.S. Wang[1], M. Haddad[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Does selecting the highest progressively motile spermatozoa with optimal genomic integrity enhance the likelihood of generating euploid embryos and achieving higher pregnancy rates?
Summary answer: Microfluidic sperm selection (MFSS) identified spermatozoa with the highest chromatin integrity, leading to higher implantation and delivery rates.
What is known already: Genomic impairment of the male gamete can hinder embryo cleavage and implantation. Dysfunction of the male genital tract increases both single-strand (ss) and double-strand (ds) DNA nicks and breaks that can

inhibit the developmental competence of embryos. In particular, ds DNA breaks present in the spermatozoa of fertile donors, at a proportion as high as 40%, may contribute to embryo aneuploidy with consequent implantation impairment.
Study design, size, duration: From October 2016 through January 2020, 26 consenting couples underwent a new ICSI cycle in which spermatozoa were selected by MFSS. Most couples had a history of high sperm chromatin fragmentation (SCF) in their ejaculate, a high proportion of aneuploidy embryos, or recurring implantation failure after ICSI.
Participants/materials, setting, methods: SCF was measured by TUNEL on raw semen specimens as well as after density gradient centrifugation (DGC) and MFSS. ICSI was carried out with spermatozoa selected by the two different methods, and resulting embryos underwent preimplantation genetic testing for aneuploidy (PGT-A). Fertilization and clinical pregnancy outcomes, following replacement of thawed euploid blastocysts, were recorded and compared between the two sperm selection methods.
Main results and the role of chance: A total of 26 men (39±7 years) had a mean sperm concentration of 43.3±41.6x10^6/mL, 34.6±17 motility, and 2.4±1% morphology. After DGC and MFSS, the sperm concentration was 4.1±5 and 3.4±4x10^6/mL, with 70±32% and 95±15% motility, respectively (*P*<0.0001). Average SCF decreased from 22% in raw samples to 18% following DGC, and became 2.8% after MFSS processing (*P*<0.0001).

A total of 14 men underwent 29 ICSI cycles with their female partners (37.3±5 years) with DGC-selected spermatozoa, achieving a 56.7% fertilization rate (177/312), resulting in 63.2% (55/87) morphologically good-quality embryos; 18.4% were euploid at time of transfer in 9 couples, resulting in a 21.4% (3/14) CPR and 33% pregnancy loss (1/3). Subsequently, they underwent ICSI with MFSS, achieving a 74% fertilization rate (137/186; *P<0.001*), with 61% (51/84) good-quality embryos of which 45.2% (38/84) were euploidy *(P<0.001*). A total of 10 couples received a replacement, achieving a 75% implantation rate (9/12; *P*<0.001), resulting in a 90% CPR/cycle (9/10); most delivered (*P*<0.001) or are ongoing.

Next, we treated solely with MFSS 12 couples with a history of all aneuploid embryos at an outside center. They underwent ICSI at our center, achieving an 85% fertilization rate, a 60% (9/15) implantation rate, and the same CPR.
Limitations, reasons for caution: This study represents a preliminary experiment on a small number of subjects. While the oocyte contribution to aneuploidy cannot be discounted, MFSS was able to yield the highest progressively motile spermatozoa with optimal genomic integrity capable of enhancing the chances of generating euploid embryos.
Wider implications of the findings: The occasional presence of ds-DNA in the male gamete has been considered responsible for increasing chromosomal structure abnormality. MFSS of highly motile and genetically competent male gametes may enhance the chances of obtaining a euploid conceptus for transfer.
Trial registration number: not applicable

P-103 Comparison the ICSI outcomes of three protocols including fresh and frozen-thawed testicular sperm and donor semen (AID) for non-obstructive azoospermia (NOA) patients

L. Zhang[1]

[1]*li.zhang, Department of Obstetrics and Gynecology, Beijing, China*

Study question: Are there different outcomes of intracytoplasmic sperm injection (ICSI) in NOA patients with fresh and frozen-thawed testicular sperm versus AID sperm?
Summary answer: Comparing similar outcomes with fresh and frozen-thawed testicular sperm, NOA patients showed best ICSI outcome with AID sperm.
What is known already: Approximately 60% of azoospermia cases are due to NOA caused by testicular dysfunction.NOA patients can become fathers through micro-TESE which is associated with a high sperm retrieval rate (SRR) of 30-75%. So they have two treatments either synchronous oocyte retrievals for their partners or testicular sperm cryopreserved when they could gain sperm by surgery.
Study design, size, duration: Comparing the outcomes of NOA patients both undergoing ICSI with fresh and frozen-thawed testicular sperm versus NOA patients undergoing ICSI with AID sperm was conducted to achieve this goal after excluding infertility caused by female factors.
Participants/materials, setting, methods: We analyzed the outcomes of 474 NOA patients undergoing 413 ICSI cycles with fresh testicular sperm, 198 ICSI cycles with frozen-thawed testicular sperm and 170 azoospermic patients with donor sperm undergoing 197 ICSI cycles between January 2015 and March 2019. The parameters were fertilization rate (FR), 2PN cleavage rate (2PNCR), blastocyst formation rate (BFR), implantation rate (IR), cumulative pregnancy rate (CPR), cumulative live-birth rate (CLBR), miscarriage rate (MR) and no embryo available cycle rate (NEACR).
Main results and the role of chance: Comparing fresh and frozen-thawed testicular sperm, NOA patients using AID sperm showed the better outcome after ICSI-ET (for FR, BFR, IR, CPR, CLBR and NEACR, all p values were 0.000). NOA patients had the similar ICSI outcomes with fresh and frozen-thawed testicular sperm and this results were not effected by male female age, female BMI, male age, male BMI, male FSH, male LH and male T after adjusting confounding factors by linear and logistic regression analyse.
Limitations, reasons for caution: The small number of transfer cycles for NOA patients (due to the exclusion criterias) reduced the precision of our estimates. However, our results provide a valuable indication of the ICSI outcome for NOA patients using fresh or frozen-thawed testicular sperm.
Wider implications of the findings: Our results provide a valuable information about similar ICSI with fresh or frozen-thawed testicular sperm for counselling of NOA patients. They maybe choice AID sperm if they want a better ICSI outcome.
Trial registration number: 81521002

P-104 Does sperm DNA fragmentation influence blastocyst ploidy?

D. Mavrelos[1], **B. Sowry**[2], **B. Jones**[3], **G. Morris**[1], **S. Lewis**[4], **J. Ben Nagi**[5]

Study question: Is high sperm DNA fragmentation associated with reduced blastocyst euploid rate?
Summary answer: We show a significantly lower euploid blastocyst rate in couples with high sperm DNA fragmentation.
What is known already: Sperm DNA fragmentation has been associated with clinical pregnancy miscarriage. A putative mechanism is karyotypic abnormalities in the blastocysts resulting from conception with sperm with high DNA fragmentation.
Study design, size, duration: We included 174 couples undergoing treatment during the study period. Data for each ART cycle was held on IDEAS version 6 Mellowood Medical and analysed using SPSS version 24.0.

Female and male partners age was grouped into age ranges <35; 35 – 37; 38 – 39; 40 – 42; >42 years for analysis.
Participants/materials, setting, methods: We included 174 couples undergoing treatment during the study period. Data for each ART cycle was held on IDEAS version 6 Mellowood Medical and analysed using SPSS version 24.0.

Female and male partners age was grouped into age ranges <35; 35 – 37; 38 – 39; 40 – 42; >42 years for analysis.
Main results and the role of chance: Median maternal age was 39 years (IQR 37 – 41) and paternal age 40 years (36 – 44). During the study period 797 blastocysts were biopsied and 246 (31%) were reported euploid. Euploidy rate by maternal age was <35; 78/155 (50%), 35 – 37; 72/171 (42%), 38 – 40; 65/173 (27%), 41- 42 27/150 (15%) and >42; 4/56 (7%). Couples with a female partner under 35 and abnormal sperm DFI had a significant lower euploidy rate compared to couples with normal DFI (31/76, 41% vs. 47/79, 59%), p=0.0198. There was no significant difference in older age groups, 35 – 37 (45/119, 38% vs. 27/52, 52%) p=0.085, 38 – 40 (38/130, 29% vs. 27/108, 25%) p=0.465, 41 – 42 (18/96, 19% vs. 9/72, 11%) p= 0.159 and >42 (4/43, 9% vs. 0/9, 0%), p=0.17 .
Limitations, reasons for caution: This is a small retrospective study with important clinical implications but prospective studies are needed for confirmation.
Wider implications of the findings: Abnormal sperm DNA fragmentation is associated with less euploid blastocysts in couples with a female partner under 35 years of age.
Trial registration number: NA

P-105 Impact of male infertility fellowship training on the vasectomy reversal learning curve

G. Wood[1], E. De Paula Miranda[2], F. Tenorio Lima Neto[3]

[1]Urologist, Urology, Sao Paulo, Brazil ;
[2]Universidade Federal do Ceará, Urology, Fortaleza-CE, Brazil ;
[3]Instituto de Medicina Integral Professor Fernando Figueira, Urology, Recife-PE, Brazil

Study question: How many vasectomy reversal procedures are needed for a trained microsurgeon to achieve good patency results and reduce operative time?
Summary answer: Vasectomy reversal is a challenging procedure, and at least 55 procedures are needed to achieve a good surgical time.
What is known already: Male infertility microsurgery (MIM) is an area in intense development, requiring intensive surgeon training and its results are highly dependent on surgeon's skills and domain of microsurgical techniques. Vasectomy reversal (VR) is the most cost-effective option for couples desiring offspring after vasectomy, and is one of the most difficult microsurgical procedures. We report the learning curve results for VR performed by a single surgeon after his MIM fellowship training.
Study design, size, duration: In a retrospective cohort fashion, we reviewed the charts of all patients who underwent VR from June 2016 to August 2019 by a single surgeon who finished a MIM fellowship training in May 2016. All procedures were performed using an operating microscope. A multilayer technique was used for vasovasostomies (VV), and the LIVE technique for vasoepididymostomies.
Participants/materials, setting, methods: At the end of the study duration, 69 patients were included. They were divided into tertiles by dates. We assessed and compared the following variables: surgical time, complications, postoperative semen analysis parameters, patency, and pregnancy rates.
Main results and the role of chance: 26 patients were included in each tertile. There were no differences between tertiles regarding baseline characteristics. The proportion of men who underwent bilateral VV decreased from the first to the third tertile (88% to 62%, p = 0.08). Although this difference was not statistically significant, we believe that it might have impacted the results of the third tertile. The surgical time progressively reduced from the first through the third tertile, and the trend curve reached a plateau after 55 cases (203 to 156 minutes, p < 0.01). Patency rates were high since the first tertile (85%, 90% and 93%, from the first to the third tertile, p = 0.75). There were no statistical differences regarding the patency rates among the groups, but they seemed to improve through the tertiles. Likewise, the post-operative total sperm count had a clinically, but not statistically, significant improvement through the tertiles (88%, 93% and 100%, p = 0.78). Meanwhile, the post-operative total motile sperm count was similar among the groups (33, 22 and 26 million/mL, consecutively). The overall pregnancy rate for patients with more than 12 months of follow up was 42%.
Limitations, reasons for caution: The retrospective nature of the results presented here should be taken into account before the generalization of our conclusions. Additionally, the surgeon was submitted to intense microsurgery training before the beginning of this study, which may not be the case for all urologists interested in the infertility field.
Wider implications of the findings: Vasectomy reversal is a challenging procedure, and at least 55 procedures are needed to achieve a good surgical time. MIM fellowship training provides microsurgical skills that help to accelerate the procedure learning curve.
Trial registration number: Not applicable

P-106 Contribution of sperm genomic and extragenomic markers as a critical determinant of embryonic development and embryo viability in spontaneous and assisted conceptions

V. Dhawan[1], D. Deka[2], N. Malhotra[2], V. Dadhwal[2], N. Singh[2], R. Dada[1]

[1]All India Institute Of Medical Sciences, Anatomy, New Delhi, India ;
[2]All India Institute Of Medical Sciences, Obstetrics & Gynaecology, New Delhi, India

Study question: Does the transmission of sperm genomic and extragenomic cargo hold any relevance in early embryonic development and embryo viability in successful pregnancy outcomes?
Summary answer: The dynamic intertwined role of sperm DNA and RNA elements delivered at fertilization have postfertilization functions and navigate early embryonic development in successful pregnancy outcomes.
What is known already: The suite of complex repertoire of sperm RNA delivered to the oocyte at fertilisation have the potential to navigate the early embryonic development. The epigenetically marked sperm genome successfully orchestrates in synchrony with the extragenomic cargo. Sperm with disturbed genomic integrity and dysregulated levels of sperm RNA may be responsible for a successful fertilisation but may affect the pregnancy outcomes and even affect the health of the offspring.
Study design, size, duration: A case control study of male partners of couples experiencing RPL (n=75), recurrent implantation failure (n=75) and 30 controls at AIIMS, New Delhi, India. Study duration was 2 years.
Participants/materials, setting, methods: A case control study of male partners of couples experiencing RPL (n=75), recurrent implantation failure (n=75) and 30 controls at AIIMS, New Delhi, India.
Main results and the role of chance: The transcript levels of *SOX3, WNT5A, RPS6, RBM9, RPL10A* showed significant difference beyween RPL patients and controls. While the levels of *FOXG1, RPS6, RBM9, RPL10A, RPS17* and *TOMM7* showed significant difference between RIF patients and controls. The mean ROS and DFI was seen to be significantly higher (in both RPL and RIF patients as compared to controls in both RPL and RIF patients (p <0.001). The odds of occurrence of RPL and RIF was 12.41 and 13.68 times higher, whose ROS> 28 % [(OR 12.41, 95% CI: (6.28-22.29) and OR 13.68 (6.52-28.71)] (p<0.001). While the odds of occurrence of RPL and RIF 12.68 and 18.87 times higher, whose DFI>30 (OR 12.68, 95% CI: (6.53-23.55) and OR 18.87 (6.52-28.71), (p<0.001). The mean sperm telomere length was seen to be lower in RPL (p=0.054) and RIF (p=0.0294) patients with respect to controls.
Limitations, reasons for caution: A potential limitation of this study is the smaller sample size recruited for the current study. Also the contribution of maternal factors and the possible role of other environmental factors which may affect implantation and early embryogenesis cannot be ignored.

Wider implications of the findings: The complex interplay of the various transcripts have seen to have significant effects in pregnancy outcomes and health trajectory of the future progeny. Any perturbation in this has the potential to affect the early embryonic development and embryo viability. This may further alter sperm methylation pattern adversly affecting sperm epigenome.
Trial registration number: Not Applicable

P-107 Epigenetic Assessment by RNA Sequencing of Non-Obstructive Azoospermic Men to Predict Successful Testicular Sperm Retrieval

K. Hancock[1], A. Parrella[1], S. Cheung[1], B. Barker[1], Z. Rosenwaks[1], G.D. Palermo[1]

[1]Weill Cornell Medicine, The Ronald O. Perelman and Claudia Cohen Center for Reproductive Medicine, New York, U.S.A.

Study question: Can epigenetic profiling of key genes provide information on the germinal epithelium function of men with non-obstructive azoospermia (NOA) and the likelihood of retrieving spermatozoa?
Summary answer: By sequencing transcripts in NOA men, we identified genes related to maturational arrest in men with different sperm retrieval outcomes with testicular sperm extraction (TESE).
What is known already: Azoospermia accounts for about 15% of male infertility cases, and while it is rarely caused by pre-testicular factors, the most common forms are testicular and post-testicular. The more challenging type is secretory azoospermia, in which scattered persistent germinal epithelium strive to support the germline meiotic process, failing to yield spermatozoa via testicular biopsy in almost 50% of cases. To judge the reproductive potential of these individuals, we assessed the gene expression profile to predict the ability to identify injectable gametes.
Study design, size, duration: Over a 3-month period, we executed a prospective study on 3 consenting men who yielded no sperm after extensive semen analysis. Differential expression was carried out on the ejaculate and compared to a fertile donor. Subsequently, they underwent TESE, and gene expression analysis was carried out both in comparison to a man with obstructive azoospermia (OA), as well as their ejaculated specimen, in relation to whether spermatozoa were retrieved with TESE.
Participants/materials, setting, methods: Three men presented with no spermatozoa in their ejaculates after an extensive sperm search and were diagnosed as NOA. Subsequently, they underwent TESE. RNA expression was performed on the leftover ejaculate specimen and on the testicular specimens from these individuals. Purified RNA was sequenced by Illumina HiSeq at 2x150bp per lane with ~58M reads/sample. A log2fold change of >1 and $P<0.001$ were considered significant.
Main results and the role of chance: Three consenting men (36.3±5yrs) were included in this study. All underwent extensive semen analysis of their ejaculate, and no spermatozoa were found. These men were diagnosed with NOA following urological evaluation. Quantitative analysis of RNA extracted from these ejaculated samples averaged a concentration of 2.3±1 ng/ul and an RNA integrity of 7.0±1. Compared with the ejaculated donor, we found ~3000 genes differentially expressed for each man, with 1379 in common, most associated with meiotic arrest (TEX11, DMC1, MEOB, MEI1, STX2).

These men underwent TESE and a gene expression analysis in comparison with an OA control, ~3000 genes were identified, with 702 in common, including TSPYL1 and TSPYL2, associated with spermatogenesis.

Spermatozoa were successfully identified in the TESE specimen of 2 men (38.5±6yrs) at a 0.08±0.1x10^3/ml concentration. RNA concentration was 5.57±1 ng/ul with 7.0±1 integrity. Genes associated with cell proliferation (*MAPRE1*, *RAN*), apoptosis (*ARL6IP1*), embryo development (*IL6ST*), and spermatogenesis (*AKAP11*) were underexpressed in the ejaculate compared to testicular biopsy ($P<0.001$).

In a 35-year-old man with no spermatozoa in testicular biopsy, RNA-sequencing revealed several genes that were uniquely overexpressed in the ejaculate compared to the testicular. These were associated with spermatogenesis(*DAZAP2*, *SYNJ2BP*), cell cycle arrest(*CAB39*), DNA replication(*NFIB*), and cilia formation(*IFT57*) ($P<0.001$).
Limitations, reasons for caution: This is a preliminary analysis, which needs to be corroborated by further observations. The source of the RNA is inconsistent because in the case of spermatozoa absence, only cells from the male genital tract and from the compromised geminal epithelium were available.
Wider implications of the findings: Our epigenetic analysis demonstrated that key genes related to spermatogenesis were unbalanced, suggesting a maturational arrest as the cause for the azoospermia. The identification of specific genes in men with failed TESE may provide valuable information on the ability to successfully predict the likelihood of retrieving spermatozoa with TESE.
Trial registration number: not applicable

P-108 Can Cytomegalovirus (CMV) infection affect male reproductive function? Results of a retrospective single-center analysis

A. Natali[1], G. Cito[1], R. Picone[2], R. Fucci[2], E. Micelli[2], A. Cocci[1], M. Di Mauro[3], C. Giachini[2], F. Rizzello[2], A. Minervini[1], M. Carini[1], M.E. Coccia[2]

[1]Careggi Hospital - University of Florence, Dept. of Urology, Florence, Italy ; [2]Careggi Hospital - University of Florence, ARTs Center, Florence, Italy ; [3]University of Catania, Dept. of Urology, Catania, Italy

Study question: To investigate the impact of chronic CMV infection on semen parameters in men with couple infertility and the influence on the reproductive outcomes of CMV-seronegative women suffering from tubal factor
Summary answer: CMV did not seem to play a key role in male reproductive function, as well as in influencing sperm fertility potential in assisted reproductive outcomes.
What is known already: Cytomegalovirus (CMV) is mainly investigated for the consequences of prenatally transmission from mother to fetus, that can lead to severe disturbances of development. However, the impact of infection on the male reproductive health has been received little consideration, despite a potential negative effect of the virus on the spermatogenesis.
Study design, size, duration: From February 2016 to January 2019, all the couples referring to our ARTs Centre for infertility due to female tubal factor, were retrospectively reviewed. All the men were divided into two groups: Group 1 included CMV IgG-seropositive men, Group 2 comprised CMV IgG-seronegative patients.
Participants/materials, setting, methods: On the day of fresh IVF/ICSI treatment, we collected data of the seminal characteristics, as follows: volume, pH, total sperm count/ml, total sperm concentration, viability, progressive motility (PR), non-progressive motility (NP), immobility, total motility and normal morphology. Two-pronuclear (2PN) fertilization rate (FR), 1-2-3PN FR, cleavage rate (CR), miscarriage rate (MR), pregnancy rate (PR) and live birth rate (LBR) were collected.
Main results and the role of chance: 222 men were included: 115 (51.8%) in the Group 1, 107 (48.2%) in the Group 2. There was reported a low trend towards higher sperm concentration/ml, total sperm count and viability in CMV IgG-seronegative males, compared to CMV IgG-seropositive, but no statistically differences were found among groups. Semen volume, pH, motility and normal sperm morphology were similar between the two groups. Considering the subgroup of men, partners of CMV IgG-seronegative females, 65 couples (29.2%) were selected. Overall, median 2PN FR was 67%, total FR 83%, CR 100%, PR/cycle 26.2%, MR 10.8%, LBR/cycle 15.4%. No significant differences were found regarding the reproductive and pregnancy outcomes between CMV IgG-seropositive men and those seronegative.
Limitations, reasons for caution: We did not test the presence of CMV DNA in the seminal samples, due to the time and cost of performing polymerase chain reaction (PCR) and cell culture, compared to the more rapid and inexpensive detection of CMV IgG and IgM assays.
Wider implications of the findings: The viral infection did not seem to play a key role in male reproductive function and in influencing sperm fertility potential in the assisted reproduction. CMV serology screening could be crucial to identify primary acute infection by detecting IgM seropositivity, in order to prevent virus transmission by sperm sample.
Trial registration number: not applicable

P-109 Impact of male body mass index on Invitrofertilisation outcome-Live birth rate.

R. Mushtaq[1], C. Yearwood[2], Y. Khalaf[2], T. El-Toukhy[2]

[1]CARE Fertility United Kingdom, Clinical, Bedford, United Kingdom ;
[2]Guy's and St Thomas foundation trust hospital, Assisted conception unit, London, United Kingdom

Study question: Does male body mass index effect outcome of assisted reproductive technology?
Summary answer: Male body mass index does not influence Invitrofertilisation live birth rate after adjusting for important confounding factors.
What is known already: Male factor infertility could be contributory in up to 50% of cases seen in assisted reproduction clinics. Obesity is becoming pandemic and is contributory factor in overall fall noted in semen parameters worldwide. There are many studies on impact of female BMI on outcomes of IVF. There is conflicting evidence regarding the effect of raised paternal BMI on outcome of assisted reproductive technology. Most of the studies are small and retrospective.
Study design, size, duration: It is a prospective observational study, including 438 couples having IVF or ICSI treatment at Guy's and St Thomas' hospital, London between July 2015 and June 2016.
Participants/materials, setting, methods: Couples undergoing first or second IVF cycle between July 2015 to June 2016 where recruited before starting the IVF cycle. Both male and female BMI were measured and recorded at the start of treatment. All IVF/ICSI cycle characteristics were recorded and all pregnancies followed up till delivery
Main results and the role of chance: Of the 438 couples included in the study, 165 (38%) male partners had a normal BMI (18.4-24.9) and 273 (62%) had a raised BMI (25-41.9). There was no significant difference between the two groups in sperm parameters. The clinical pregnancy and live birth rates were not significantly different between the two groups (33% vs 35% and 25% vs 31%, respectively, P=0.19). After adjusting for important confounders, including female partner age, female BMI, duration of infertility, pre-treatment AMH level, total dose of gonadotrophins used during ovarian stimulation, number of oocytes collected, method of oocyte fertilisation (IVF vs ICSI) and number of embryos transferred, the likelihood of a live birth outcome was not significantly different in the raised male BMI group compared to normal male BMI group (OR 1.22, 95% CI 0.69-2.14, P=0.49). There was no significant difference in the live birth rate per cycle between overweight (BMI 25-29.9, n=193) and obese (BMI 30-41.9, n=80) male partners (28% vs 38%, P=0.1).
Limitations, reasons for caution: These results are from prospective but small study with live birth rate as the end point .
Wider implications of the findings: Larger proportion of men had high BMI in our study. This could be reflective of rising obesity. While our study has not shown a significant impact of male BMI on live birth rate in IVF cycles, the health implications of high BMI in population should be considered. .
Trial registration number: not applicable

POSTER VIEWING SESSION
EMBRYOLOGY

P-110 Irregular cleavage in early embryogenesis does not reduce the euploidy after reaching the blastocyst

S. Watanabe[1], K. Yoshikai[1], M. Tomida[1], S. Suzuki[1], Y. Matsuda[1], T. Kato[2], E. Nakano[1], H. Kurahashi[2], T. Sawada[1]

[1]Sawada Women's Clinic, ART Lab., Nagoya, Japan ;
[2]Institute for Comprehensive Medical Science- Fujita Health University, Division of Molecular Genetics., Toyoake, Japan

Study question: Does euploid rate decrease when the irregular first or second cleavage embryos reach the blastocyst?
Summary answer: The euploidy of the irregular first or second cleavage blastocysts was equivalent to the normal cleavage blastocysts.
What is known already: There are some reports that aneuploidy is high when the irregular cleavage embryos develop into blastocysts but there are reports that the rate of transfer pregnancy and miscarriage of irregular cleavage blastocysts is equivalent to that of the normal cleavage blastocysts.
Study design, size, duration: Retrospective analysis was conducted on 96 discarded blastocysts with consent from patients out of embryos collected and cultured in our clinic from 2013 to 2018. All of these embryos were time-lapse monitored by EmbryoScope (Vitrolife).
Participants/materials, setting, methods: The subject embryos were biopsied with TE and NGS chromosome analysis was performed. These embryos were classified by time-lapse videos, those with 2 cells in the first cleavage and 4 cells in the second cleavage are the good cleavage groups, those with 3 or more cells in the first cleavage, or those with 5 cells or more in the second cleavage are the irregular cleavage groups.
Main results and the role of chance: As a result of image analysis by time-lapse monitoring, there were 53 good cleavage groups and 43 irregular cleavage groups. The proportions of euploid embryos, aneuploid embryos and mosaic embryos were 43.4% (23), 45.3% (24) and 11.3% (6) in the good cleavage group, 41.9% (18), 46.5% (20), and 11.6% (5) in the irregular cleavage group, there was no significant difference in euploid rate between the two groups (The odds ratio of the euploid rate of the irregular cleavage group to the good cleavage group was 0.94).
Limitations, reasons for caution: Because PGT-A is not approved in Japan, this study was conducted using only discarded embryos that were not used for transfer with the consent of the patient.
Wider implications of the findings: This study showed that Irregular cleavage in early embryogenesis did not reduce the euploid rate after reaching the blastocyst. Irregular cleavage embryos that have reached the blastocyst need not be excluded from transfer.
Trial registration number: not applicable

P-111 MicroRNAs secreted by human embryos are potential biomarkers for clinical outcomes of assisted reproductive techniques

Z. Li[1], F. Fang[2], X. Chengliang[1]

[1]Huazhong University of Science and Technology, Institute of Reproductive Health, WuHan, China ;
[2]Huazhong University of Science and Technology, Department of Obstetrics and Gynecology- Union Hospital- Tongji Medical College, WuHan, China

Study question: Investigate whether the miRNAs secreted by human embryos in culture medium can be used as embryonic biomarkers.
Summary answer: Our results indicate that miRNAs in human embryo culture media may serve as novel and invasive biomarkers for embryo selection during IVF/ICSI-ET cycles.
What is known already: MicroRNAs (miRNAs) are important regulators of many biological functions, including embryo implantation and development. Recently, it is reported that miRNAs in biofluids are predictive for physiological and pathological processes.
Study design, size, duration: The culture media were prospectively collected from embryos of patients who underwent routine *in vitro* fertilization (IVF) or intracytoplasmic sperm injection (ICSI) at reproductive medicine center with informed consent. And
Participants/materials, setting, methods: A high-throughput miRNA sequencing method was applied to detect the miRNAs profiles in culture media of embryos with different reproductive outcomes (15 samples were mixed for each group). Furthermore, qRT-PCR and droplet digital PCR (ddPCR) to verify the target miRNAs at single sample level (100 cleavage samples in total, 50 with successful pregnancy and 50 with failed pregnancy). Receiver operating characteristic (ROC) analyses were performed for differentially expressed miRNAs.
Main results and the role of chance: The miRNA sequencing showed that embryos with successful pregnancy secreted different miRNA profiles into the culture media, compared with embryos with failed pregnancy. These differentially expressed miRNAs were predicted to be involved in multiple biological processes, cellular components and molecular functions. And 18 miRNAs were selected for validation by qRT-PCR in mixed samples and significantly different expression of these 10 miRNAs between two groups were identified. The ddPCR results revealed that hsa-miR-26b-5p, hsa-miR-451a and hsa-miR-21-5p could be stably detected in the culture medium of one single embryo at cleavage stage. After statistical analysis, we found that the cleavage embryos with successful pregnancy presented decreased expression of hsa-miR-26b-5p and hsa-miR-21-5p in the culture media. Moreover, the Receiver Operating Characteristic

(ROC) curve analysis indicated that hsa-miR-26b-5p and hsa-miR-21-5p could serve as potential biomarkers for reproductive outcomes.
Limitations, reasons for caution: More clinical trials are needed to determine the sensitivity and specificity of miRNA biomarkers for embryo selection and more basic research are also necessary to develop better detection methods of miRNAs with low input.
Wider implications of the findings: Together, our findings highlight the important predictive potential of miRNAs secreted by human embryos in culture media, which is meaningful for noninvasive embryo selection during IVF cycles.
Trial registration number: none

P-112 An analysis of 2.1PN (2PN+1 micronuclei) formation.

N. Okuyama, MSc[1], N. Oka[1], N. Aono[1,2], T. Hashimoto[1], K. Kyono[1,2]

[1]Kyono ART Clinic Takanawa, Department of Gynecology, Tokyo, Japan ;
[2]Kyono ART Clinic Sendai, Department of Gynecology, Sendai, Japan

Study question: What factor causes 2.1 PN zygotes?
Summary answer: High-aged female patients (OR: 1.17, 95%; CI: 1.09-1.25; *P*<0.001) and frozen-thawed oocytes (OR: 3.85, 95%; CI: 1.79-8.26; *P*<0.001) were more likely to produce 2.1PN zygotes.
What is known already: We confirm fertilization when two pronuclei (PN) and second polar body are seen, and in some cases, 2PN + micronuclei (2.1PN) is recognized. It is reported that some 2.1PN zygotes may develop to blastocyst and lead to successful clinical pregnancy and live birth; however, there is a risk that 2.1PN zygotes have the possibility of triploid (Capalbo et al., 2017). A limited number of studies have reported on 2.1PN, but its mechanism is still unclear.
Study design, size, duration: This retrospective single-center study was performed from January 2015 to December 2018 including a total of 659 patients and 1161 cycles. A total of 7939 oocytes were inseminated either by conventional IVF (cIVF) or ICSI. Logistic regression analysis was conducted to investigate the cause of 2.1PN. Inseminated oocytes were cultured in time-lapse monitoring system. We defined a 2.1PN when two equal-sized PN, second polar body, and less than 1/3 the size of micronuclei were observed.
Participants/materials, setting, methods: We analyzed the associations between the number of PN and embryo development; background profiles such as female age, serum AMH, and BMI; ICSI or cIVF; ejaculated sperm or TESE sperm; fresh oocytes or vitrified-warmed oocytes; and with or without artificial oocyte activation (AOA). Good quality blastocyst rates were defined according to Gardner's criteria. Chi-square test and logistic regression analysis were conducted where appropriate.
Main results and the role of chance: Fertilization results were as follows: 26.7% (n=2122) for 0PN, 3.2% (n=255) for 1PN, 62.1% (n=4928) for 2PN, 1.0% (n=83) for 2.1PN, 4.1% (n=328) for 3PN, and 2.8% (n=223) for >3PN. There were statistically significant differences in the blastocyst formation rates and good quality blastocyst rates between 2PN, 2.1PN and 3PN embryos, (49.6% vs 30.1% vs 14.3%, *P*<0.001) (34.0% vs 20.5% vs 7.0%, *P*<0.001). High-aged female patients (OR: 1.17, 95%; CI: 1.09-1.25; *P*<0.001) and vitrified-warmed oocytes (OR: 3.85, 95%; CI: 1.79-8.26; *P*<0.001) were more likely to obtain 2.1PN zygotes. No association was found between 2.1PN formation and serum AMH (OR: 0.96, 95%; CI: 0.86-1.06; *P*=0.448), BMI (OR: 0.96, 95%; CI: 0.89-1.03; *P*=0.295), ICSI or cIVF (OR: 1.33, 95%; CI: 0.61-2.11; *P*=0.702), ejaculated or TESE sperm (OR: 1.40, 95%; CI: 0.65-3.00; *P*=0.392) and with or without AOA (OR: 1.18, 95%; CI: 0.28-5.09; *P*=0.821).
Limitations, reasons for caution: PGT-A was not analyzed due to the regulation of the Japan Society of Obstetrics and Gynecology.
Wider implications of the findings: This study indicated that 2.1PN may be derived from oocyte factors such as advanced female age and oocyte cryopreservation. 30.1% of 2.1PN zygotes developed to blastocyst; however, 2.1PN zygotes may be triploid (Capalbo et al., 2017). Hence, a careful choice for embryo transplantation is needed.
Trial registration number: none

P-113 Fertilization by direct pressing of zona pellucida-bound human sperm onto the oocyte membrane

S. Hatakeyama[1,2], Y. Araki[2], Y. Araki[2], S. Ohgi[1], A. Yanaihara[1]

[1]Yanaihara Women's Clinic, Obstetrics and Gynecology, Kamakura, Japan ;
[2]Gunma Paz University, Graduate School of Health Sciences, Takasaki, Japan

Study question: Can fertilization be obtained by pressing single sperm onto an unfertilized oocyte after in vitro fertilization (IVF) without breaking the oocyte membrane?
Summary answer: Fertilization was obtained by pressing zona pellucida (ZP)-bound sperm directly onto the oocyte membrane, a procedure that we designated as assisted sperm fusion insemination (ASFI).
What is known already: Rescue intracytoplasmic sperm injection (ICSI), which is ICSI of unfertilized oocytes after conventional IVF, has been reported to prevent total fertilization failure. However, recent studies have shown that the outcome of rescue ICSI is unsatisfactory, resulting in a poor fertilization rate and a high degeneration rate. A micromanipulation technique that permits fertilization without breaking the oocyte membrane would be expected to reduce further the degeneration rate after rescue ICSI.
Study design, size, duration: This study of the ASFI method was performed between January 2019 and December 2019 on 49 subjects. The results of ASFI were compared with those obtained in a previous trial of rescue ICSI that was performed between July 2018 and December 2018. The present study was approved by the local ethics committee.
Participants/materials, setting, methods: The acrosome reaction (AR) rate of 49 motile sperm collected from the ZP was assessed. Sixty-nine motile sperm bound to the ZP were aspirated directly using an injection pipette. These motile sperm were pressed onto the membrane of 69 unfertilized oocytes at 6 hours after IVF; pressing was performed with the injection pipette for 30 seconds.
Main results and the role of chance: The AR rate of sperm collected from the ZP was significantly higher than that of control sperm (98.0% vs. 28.6%, p <0.01). The mean and standard deviation of ages of the women in ASFI and rescue ICSI were 36.1 ± 3.9 and 37.7 ± 4.3 years, a difference that was not significant (p >0.05). All sperm collected from the ZP adhered to the oocyte membrane after ASFI. Time-lapse cinematography showed that sperm pressed onto the oocyte membrane remained there for approximately 30 minutes before being incorporated into the oocyte membrane. There was no significant difference in fertilization rate (69.6% vs. 70.0%), degeneration rate (0% vs. 4%), number of good-quality embryos at day 3 (58.3% vs. 51.4%), or blastocyst formation rate (58.5% vs. 42.4%) between the ASFI and rescue ICSI groups, respectively.
Limitations, reasons for caution: The major limitation of this study was the use of sperm bound to the ZP. For more general application, a method of artificially inducing AR will need to be established. Moreover, our sample size was relatively small; further studies with a larger number of patients will be needed.
Wider implications of the findings: ASFI is expected to improve the survival rate of oocytes and to increase the number of the embryos available for implantation. Additionally, ASFI may contribute to the elucidation of the mechanism of fertilization, given that the technique permits observation of the process of fusion between the oocyte and sperm.
Trial registration number: not applicable.

P-114 Non-invasive prediction of the blastocyst formation by morphokinetics discriminant analysis

A. Iaconelli Jr.[1], A. Setti[2,3], D. Braga[2,3], L. Vingris[4], E. Borges Jr.[1,3]

[1]Fertility Medical Group, Clinical department, São Paulo- SP, Brazil ;
[2]Fertility Medical Group, Scientific research, São Paulo- SP, Brazil ;
[3]Instituto Sapientiae - Centro de Estudos e Pesquisa em Reprodução Assistida, Scientific research, São Paulo, Brazil ;
[4]Fertility Medical Group, IVF laboratory, São Paulo- SP, Brazil

Study question: Is the discriminant analysis of embryo morphokinetics able to predict the blastocyst formation chance on the 5th day of embryo development?
Summary answer: Early kinetic parameters may predict which embryo is able to develop into blastocysts and those failing to blastulate.
What is known already: At the early stage of embryonic development, the transcription of embryonic genes is quiescent, and development is conducted by maternal proteins and RNAs. Subsequently, embryonic genome

activation (EGA) occurs, followed by the developmental control switching to the nuclear genome. Studies have suggested that morphological grade is not accurate enough to predict the developmental potential. Most embryos reach the cleavage-stage, regulated by maternal factors, and EGA never occurs. Extended embryo culture and transfer at blastocyst stage is an alternative which allows the selection of embryos at more advanced stages, after EGA, increasing the implantation rate and minimizes the multiple pregnancies risk.

Study design, size, duration: Kinetic data were analyzed in 139 patients and 1219 zygotes cultured until day 5 in a time-lapse incubator system, between March/2019 and November/2019. Timing to specific events from the point of insemination was determined using time-lapse imaging. A stepwise discriminant function analysis determined which kinetic markers discriminate between embryos that reached the blastocyst stage or not. Moreover, cut-off points were established halfway between the averages that were significantly different between the blastocyst and non-blastocyst embryos.

Participants/materials, setting, methods: This study was performed in a private university–affiliated IVF center. The analyzed kinetic markers were: pronuclei appearance (tPNa), timing to pronuclei fading (tPNf), timing to two (t2), three (t3), four (t4), five (t5), six (t6), seven (t7), and eight cells (t8). Durations of the second (t3-t2) and third (t5-t3) cell cycles (cc2 and cc3, respectively), as well as timing to complete synchronous divisions s1 (t2-tPNf), s2 (t4-t3) and s3 (t8-t5) were calculated.

Main results and the role of chance: A total of 563 embryos reached the blastocyst stage (46.15%). The discriminant function correctly classified 76.1% of original cases, best predicting blastocyst formation (95.0%). The cross-validated classification showed that overall 75.9% were correctly classified. In this model, mean t2 (25.29 ± 3.19 vs. 27.26 ± 5.33), t7 (54.21 ± 8.40 vs. 57.34 ± 11.62), s2 (1.43 ± 2.69 vs. 3.24 ± 4.64) and s3 (8.48 ± 7.84 vs. 13.75 ± 10.05) were significantly different ($p<0.001$) between the blastocyst and the non-blastocyst group, respectively. Cut-off points were established halfway between those averages, at 26.27 for t2, 55.78 for t7, 2.34 for s2 and 11.12 for s3, for the prediction of blastocyst development.

Limitations, reasons for caution: Retrospective nature of this study and the small sample size may be a reason for caution.

Wider implications of the findings: The identification of markers of the blastocyst formation potential may lead to the benefits of the extended embryo culture without exposing the embryo to the deleterious effects of the in vitro culture for an extended period of time (i.e. epigenetic changes in trophectoderm cells leading to abnormal implantation and placentation).

Trial registration number: Not applicable

P-115 Intracytoplasmic sperm injection (ICSI) is not superior to conventional in vitro fertilisation (IVF) in non-male factor infertility: a systematic review and meta-analysis

A. Finet[1], E. Arbo[2], M. Colombani[3], B. Darne[4], V. Gallot[5], V. Grzegorczyk-Martin[1], S. Languille[4], T. Freour[6]

[6]CHU de Nantes, Service de biologie et médecine de la reproduction, Nantes, France

Study question: Does ICSI perform better than conventional IVF in non-male factor infertility in terms of live birth rate (LBR)?

Summary answer: ICSI is associated with lower LBR per cycle than conventional IVF in non-male factor infertility.

What is known already: Over recent decades, the use of ICSI has noticeably increased and is now significantly more frequently used than conventional IVF in most countries. As the prevalence of male infertility has not increased concomitantly, the relevance of ICSI in non-male factor infertility can be questioned, especially when its economic and/or psychological consequences are considered. Numerous studies comparing ICSI and conventional IVF in various cases of non-male factor infertility report heterogeneous results, thereby supporting the need for a meta-analysis.

Study design, size, duration: Systematic review and meta-analysis of published research articles. Searches were conducted on MEDLINE, EMBASE, and the Cochrane Library from 2004 to June 2019 using medical subject headings and free text terms for 'ICSI', 'IVF', 'non male factor', 'unexplained infertility', 'fertilisation failure', 'pregnancy', 'live birth'.

Participants/materials, setting, methods: Studies preselected on title and abstract were assessed using adapted Newcastle-Ottawa Quality Assessment Scales. Only articles describing primary outcome of live birth were included. Risks of bias were assessed using ROBIN-I tools. Study selection, bias assessment and data extraction were performed by two independent reviewers according to Cochrane methods. Risk ratio (RR) IVF/ICSI and 95% confidence interval (CI) were estimated using random effect model. Pre-specified sensitivity analysis and meta-regression on mean female age were performed.

Main results and the role of chance: Thirty-nine full-text articles were preselected out of 1,615 references. Of these, 17 were included in the meta-analysis, corresponding to 395,414 assisted reproductive technology cycles (136,178 IVF and 259,236 ICSI cycles). IVF showed significantly higher LBR per cycle when compared to ICSI (RR=1.13; 95%CI=1.05-1.23). No statistical difference was found for clinical pregnancy rate per cycle (RR=1.09; 95%CI=0.93-1.29). Fertilization rate was significantly lower in IVF cycles (RR=0.80; 95%CI=0.71-0.89), while proportion of cycles with total fertilization failure was not statistically different (RR=0.97; 95%CI=0.75-1.25).

Sensitivity analyses, even those after removing studies at high risk of bias or outlier studies, led to similar results and conclusions. Meta-regression showed a significant association between RR of live birth and mean female age, in favour of IVF ($p<0.001$).

Limitations, reasons for caution: The validity of meta-analysis results depends mainly on the quality and the number of published studies available. Indeed, this meta-analysis contains only one randomised controlled trial.

Wider implications of the findings: Conventional IVF should be preferred to ICSI in non-male factor infertility. The use of ICSI should be confined to male factor infertility. This evidence will help improve patient counselling.

Trial registration number: Prospero CRD42019136383

P-116 A prospective randomized sibling-oocyte study of two uninterrupted media systems for culturing blastocysts.

M. Calonge[1], D. Machuca[1], B. Morales[1], C. Troncoso[1], M. Meseguer[2]

[1]IVI Santiago de Chile, IVF Laboratory, Santiago- RM, Chile ;
[2]IVI Valencia, IVF Laboratory, Valencia, Spain

Study question: There is any difference in the probability of getting a live birth when the embryos are cultured in two single step media Vitrolife or Lifeglobal ?

Summary answer: No statistically significant difference in live birth rates between study groups, being uninterrupted embryo culture a feasible strategy with satisfactory outcomes.

What is known already: Currently, commercial media are available in different formulations to support specific stages of embryo development. Culture of embryos is possible under different conditions: whether the media is refreshed, changed or left undisturbed for the 5-6 days of embryo culture. Continuous culture can be interrupted or uninterrupted depending on the renewal of the medium on day 3. Both culture systems have demonstrated excellent clinical outcomes. Very well knows brands like Vitrolife and Lifeglobal have uninterrupted culture media with different specifics formulations but also are different in prices and time of expiration.

Study design, size, duration: We performed a prospective randomized study between November 2017 and December 2018. A total 137 patients from IVI Santiago were included in the study. All mature oocytes were randomized before ICSI to be cultured under either one of the two uninterrupted media formulations tested; Vitrolife or Lifeglobal. Clinical outcomes were compared between study groups.

Participants/materials, setting, methods: Inclusion criteria were patients younger than 37 years and recipient of fresh/vitrified oocytes, with a minimum of 7 MII to ICSI . Exclusion criteria was patients with severe pathologies in sperm sample. All transfer and vitrification of embryos were performed in D5/D6 according to established protocol. Fertilization, blastocyst, pregnancy,

implantation miscarriage and live birth rates were compared between both study groups. Variable significance was analyzed through chi square and logistic regression.

Main results and the role of chance: One hundred and thirty seven study subjects participated in the study, from which 108 underwent an oocyte donation cycle. In total, 1884 MII oocytes were randomized to both media formulations. Nine hundred and thirty four oocytes were microinjected and cultured in Vitrolife medium and nine hundred and fifty in Lifeglobal medium. Fertilization rates were comparable between groups being 74% in Lifeglobal and 78% Vitrolife group. Moreover, no significant differences were obtained in basculation rates (62% Lifeglobal and 54% Vitrolife) , pregnancy rates (67% Lifeglobal and 58% Vitrolife), implantation rates (%62 Lifeglobal and 53%Vitrolife) and miscarriage rates (15% Lifeglobal and 4%Vitrolife). On the other hand, the best 1 or 2 blastocysts based on morphology grading, independent of from which study group coming from were transferred (average 1.16). More blastocysts were selected to transfer in the Lifeglobal group because of their had a better morphology (58% v/s 42%) nevertheless the differences were not statistically significant. Finally in our main objective live birth rate, no statistical differences were found (48% Lifeglobal and 53%Vitrolife)

Limitations, reasons for caution: More studies can be conducted to ingress the number of patients to confirm our findings.

Wider implications of the findings: In agreement with other studies our results confirm that uninterrupted culture media is providing optimal results. As both brands analyzed had comparable results we might suggest each laboratory can select one of those taking into account other important characteristics of management such as prices and durability.

Trial registration number: 1706-SCL-064-MC

P-117 Observations from a multi-centre study using spent culture media for NI-PGT-A

M. Jasper[1], F. Bardan[1], C. Robinson[1], S. Myers[1], M. Fraser[1]

[1]PerkinElmer Health Sciences Australia Pty Ltd, PerkinElmer Health Sciences Australia Pty Ltd, Adelaide, Australia

Study question: Does non-invasive preimplantation genetic testing for aneuploidy (NI-PGT-A) of spent embryo culture media require specific culturing conditions?

Summary answer: Individual laboratories rigorously follow defined embryo culturing protocols to maximise pregnancy outcome and the implementation of non-invasive testing may be possible with minimal protocol changes.

What is known already: Several laboratories are testing the feasibility of using spent embryo culture media for Non-Invasive Pre-implantation Genetic Testing for Aneuploidy (NI-PGT-A). Results published to-date show different rates of concordance with embryo biopsy between laboratories. Variability in the culturing conditions and methodologies being tested may explain the observed difference, as culture conditions are likely to impact the accumulation of both embryonic and contaminating maternal and sperm DNA in spent embryo culture media. As such, optimization of culturing conditions may significantly influence the concordance of results for NI-PGT-A and could assist a controlled evaluation of its use in place of biopsy-based PGT.

Study design, size, duration: NI-PGT using the PG-Seq™ Rapid Non-Invasive PGT kit (PerkinElmer) was performed on spent embryo culture media samples from several laboratories implementing different culturing conditions. The influence of culturing conditions, including culture volume and collection time on concordance between NI-PGT results and embryo biopsy results was analysed and conditions found to have an influence were identified.

Participants/materials, setting, methods: Laboratories provided spent culture media samples for protocol development and/or testing. Once the embryo was removed from the culture droplet, the culture media was collected and stored at -20°C, with ethics approval. Equivalent template volumes of spent embryo culture media were amplified using the PG-Seq™ Rapid Non-Invasive PGT kit protocol, a novel single tube amplification and indexing workflow specifically optimized for NI-PGT-A, and DNA yield was assessed before sequencing.

Main results and the role of chance: Whole genome amplification resulted in the amplification of 77-100% of spent embryo culture media samples provided by the different laboratories (n=9). Ploidy concordance with the embryo biopsy ranged from 23-88% for autosomal chromosomes and 27-63% for sex chromosomes for samples from laboratories using a single-step culturing system (n=2). This was lower than the concordance rates of 45-85% for autosomes and 61-93% for sex chromosomes from laboratories using a two-step culturing system (n=7). Sex chromosome concordance varied between laboratories regardless of the culturing system used, suggesting that embryological processes, such as the technique and accuracy of cumulus cell removal, are important influencers on the accuracy in NI-PGT-A testing. Media droplets ranged in size from 12-70ul, with a mean drop volume of 32ul, and a mean collection time of 60hr (4-144hr). Assisted hatching was perform for some but not all protocols.

Limitations, reasons for caution: Limited numbers of media samples were available for each culturing protocol and researchers performing the data analysis were not blind to the culturing conditions or PGT-A biopsy results. Maternal DNA contamination of media may be underestimated, as it was only possible to detect when the embryo in culture was male.

Wider implications of the findings: Currently there are still many questions on what effect embryology has on the quantity and quality of embryo DNA found in spent culture media. Successful NI-PGT-A may require specific culturing conditions and individual laboratories are best placed to further identify key steps to generate quality concordant results from spent media.

Trial registration number: Not applicable

P-118 Spontaneous blastocyst collapse during pre-vitrification equilibration is related to a lower pregnancy rate: a prospective cohort study

M. Murakami[1], S. Mizumoto[2], K. Tanaka[2], H. Otsubo[2], Y. Nagao[2], T. Kuramoto[3]

[1]Kuramoto Women's Clinic, Research laboratory, Fukuoka, Japan ;
[2]Kuramoto Women's Clinic, IVF laboratory, Fukuoka, Japan ;
[3]Kuramoto Women's Clinic, President, Fukuoka, Japan

Study question: Is there an association between the spontaneous collapse pattern of a blastocyst in an equilibration solution (ES) before vitrification and implantation success?

Summary answer: Ongoing pregnancy rates (PRs) after warmed ET decreased in blastocysts that collapsed completely during equilibration before vitrification.

What is known already: Previous time-lapse studies have found that blastocysts that spontaneously collapse during embryo culture are less likely to hatch in mice and implant in humans, suggesting a negative impact of the collapse on reproductive outcomes. Conversely, it has been shown that artificial shrinkage of human blastocysts before vitrification improves embryo survival and/or pregnancy rates. However, shrinkage is not induced in some vitrification protocols, including ours, as blastocyst viability was already high. To date, no study has been conducted to examine the effect of spontaneous blastocyst collapse during pre-vitrification equilibration on the clinical outcome.

Study design, size, duration: This study included 471 patients undergoing their first autologous IVF/ICSI cycle and freeze-all strategy at the blastocyst stage in our clinic between June 2018 and October 2019. For patients with multiple vitrified blastocysts, embryos for transfer were selected hierarchically based only on morphological scoring (Gardner score) during culture. To minimize bias, only the data from single ETs with Day 5 blastocysts (Score 4, excluding CC) in the first warmed cycle of each patient were analyzed.

Participants/materials, setting, methods: Blastocysts were vitrified-warmed in in-house prepared solutions using Rapid-i carriers. Prior to vitrification, intact blastocysts were equilibrated in 10% ethylene glycol (12 min, 37°C). Their spontaneous collapse patterns were assessed under an inverted microscope before being vitrified in 15% DMSO + 15% ethylene glycol + 0.5 M sucrose. Blastocyst collapse was defined as the separation of the trophectoderm cells from the zona pellucida. Collapsed blastocysts with/without blastocoel cavity were called partially/completely collapsed blastocysts.

Main results and the role of chance: Non-collapsed (NC), partially collapsed (PC), and completely collapsed (CC) blastocyst ETs were 22.9% (108/471), 53.5% (252/471), and 23.6% (111/471) of the ET cycles, respectively. Most embryos (99.6%, 441/443) survived warming. PRs per ET tended to decrease as blastocysts progress from one collapse pattern to another. In this study, the ET cycles were divided into NC/PC and CC groups to facilitate data

analysis. Maternal age was similar between the groups. Clinical PRs per ET were 61.7% (NC/PC) versus 51.4% (CC) (odds ratio (OR): 1.52, 95% confidence interval (CI): 0.97-2.39, *P* = 0.061). Ongoing PRs per ET were 55.8% (NC/PC) versus 37.8% (CC) (OR: 2.07, 95% CI: 1.31-3.30, *P* = 0.001). A logistic regression analysis was performed on the ongoing PRs to account for the effects of some possible confounding factors, including the complete blastocyst collapse, blastocyst morphology, MII oocyte number, and maternal characteristics (age, parity (yes/no), smoking (yes/no), and BMI). In addition to the maternal age (years, OR: 0.89, 95% CI: 0.84-0.94, *P* < 0.001) and blastocyst morphology (good (4AA/4AB/4BA) versus not, OR: 1.60, 95% CI: 1.09-2.36, *P* = 0.017), the blastocyst collapse (yes versus no) had a significant effect on the results (OR: 0.48, 95% CI: 0.31-0.77, *P* = 0.002).

Limitations, reasons for caution: Cryoprotectant concentration of our ES is relatively low. Thus, when considering the collapse pattern as a criterion for selecting embryos for transfer, caution is needed as ES osmolarity can influence blastocyst shrinkage. Further studies with more participants are required to confirm the results.

Wider implications of the findings: This is the first study to demonstrate a relationship between spontaneous blastocyst collapse during pre-vitrification equilibration and a decreased pregnancy rate. Studying the collapse pattern may assist in selecting the most viable blastocysts after warming and increase IVF success rates.

Trial registration number: UMIN000039264

P-119 Influence of culture media on embryo developmental pattern and ploidy status: a sibling oocyte study.

A. Abdala[1], I. Elkhatib[1], A. Bayram[1], A. Arnanz[1], A. El-Damen[1], B. Lawrenz[1,2], H.M. Fatemi[1], N. De Munck[1]

[1]IVIRMA Middle East, Fertility Clinic, Abu Dhabi, United Arab Emirates ; [2]Women´s University Hospital Tuebingen, Obstetrical Department, Tuebingen, Germany

Study question: Is there a difference in embryo development and euploidy rate between blastocysts cultured in continuous culture media (CCM) or sequential culture media (SCM)?

Summary answer: While the blastulation on day 5 is increased in CCM, the usable blastocyst and euploidy rates are not significantly different between CCM and SCM.

What is known already: Culture medium is fundamental for *in vitro* blastocyst development. While CCM supplies all nutrients that embryos need to grow ("let the embryo choose"), SCM mimics physiological conditions ("back to nature"). Many studies evaluated whether CCM improves clinical outcomes as compared to SCM, hence, comparisons failed to identify a superiority. Recent data suggest that euploidy rates may be affected by culture media, however, non-consensus has been reached due to the variability of experimental designs, underpowered studies and heterogenicity that might affect outcomes. The lack of standardization of the comparative studies drives to controversial conclusions of which culture media improve euploid outcomes.

Study design, size, duration: A single center observational cohort study was performed between September 2018 and March 2019, including 1452 mature oocytes (MII). Patients who underwent preimplantation genetic testing for aneuploidies (PGT-A) with at least four fresh autologous MII inseminated by ICSI were included. Severe male factor was excluded. According to clinical practice, sibling MII oocytes were randomly split between two media: 751 in Global Total LP (CCM) and 701 in Sage cleavage and blastocyst media (SCM).

Participants/materials, setting, methods: Zygotes were cultured up to day 7 with both media refreshed on day 3 under 6% CO_2, 5% O_2 and 89% N_2, pH=7.2-7.4. Fertilization, cleavage, D5 blastulation, usable blastocyst (total blastocysts biopsied/total blastocysts formed) and euploidy rates were recorded. Blastocyst expansion, inner cell mass (ICM) and trophectoderm (TE) quality were graded according to Gardner´s scoring system, prior TE biopsy on day 5, 6 or 7. TE samples were analyzed for PGT-A by next generation sequencing.

Main results and the role of chance: Patient mean age was 34.3±6.0 years old. No differences were observed in fertilization and cleavages rates (77.4% vs 75.5%, p=0.468, and 97.6% vs 99.1%, p=0.089 for CCM and SCM, respectively). Total number of blastocysts formed was similar between CCM and SCM (3.4±5.5 vs 2.9±2.3, p=0.075). However, blastulation rate on day 5 was significantly higher for embryos cultured in CCM (72.2% vs 63.1, p=0.017). The usable blastocyst rate was not significantly different between the two groups compared (76.5% vs 79.3%, p=0.448 for CCM and SCM). From a Poisson regression model adjusted for confounding factors, no differences were observed in euploidy rate between CCM and SCM (OR=2.4387, CI 95%: 0.93-6.38, p=0.0699 for CCM and OR=1.1791, CI 95%: 0.94-1.48, p=0.1572, for SCM). Only patients age was associated with the euploidy rates, regardless the type of culture medium (OR=0.9494, CI 95%: 0.93-0.97, p<0.001). A linear mixed model was performed controlling for confounding factors and a significant increase in toP-quality blastocysts (ICM= A or B and TE=A) was found when embryos were cultured in SCM (OR=-0.2545, p=0.814 for CCM and OR=0.5070, p=0.036 for SCM).

Limitations, reasons for caution: The current results are based on a retrospective observational study.

Wider implications of the findings: Under controlled conditions, *in vitro* outcomes are comparable when using a CCM or SCM, although quality of blastocysts can be improved when embryos are cultured in SCM. As expected, patient's age has the most important impact on euploidy rate.

Trial registration number: None

P-120 Embryos that divided chromosome correctly develope to the morphologically-good blastocyst in spite of abnormal cytokinesis at 1st mitosis

S. Hashimoto[1], Y. Nakaoka[2], Y. Morimoto[3]

[1]Osaka City University Graduate School of Medicine, Reproductive Science Institute, Osaka, Japan ; [2]IVF Namba Clinic, IVF Namba Clinic, Osaka, Japan ; [3]HORAC GrandFront Osaka Clinic, HORAC GrandFront Osaka Clinic, Osaka, Japan

Study question: Why do human embryos normally develop after abnormal cytokinesis at 1st mitosis?

Summary answer: Only embryos that underwent correctly chromosomal division developed to the morphologically-good blastocyst in spite of abnormal cytokinesis at 1st mitosis.

What is known already: It has been shown that a live birth from embryos which underwent abnormal cytokinesis at 1st mitosis. During abnormal cytokinesis, there are two main patterns in chromosomal division, such as dual spindle formation without syngamy and multipolar spindle formation with syngamy. It's unlikely to believe these abnormally chromosome-separated embryos could develop to babies. There is the potential to include morphologically-abnormal cytokinesis without abnormal chromosome partitioning, such as fragmentation.

Study design, size, duration: This study was approved by the ethical committee of the Japan Society of Ob/Gy. We assessed chromosomal behavior during 1st mitosis in human zygotes and their development in vitro using 140 donated zygotes. Pronuclear ova were donated from infertility couples after obtaining their informed consent.

Participants/materials, setting, methods: Donated pronuclear ova were injected with a mixture of mRNAs encoding EGFP-EB1 and mCherry-histone-H2B. Dynamic changes of their chromosomes were monitored continuously using a confocal microscope inside an incubator every 15 min for 24 h. After live imaging, morphological changes of embryos were recorded by a conventional time-lapse system using a light microscope.

Main results and the role of chance: To directly examine possible idea for inclusion of embryos without abnormal chromosome partitioning into abnormal cleavage, we observed chromosomal behavior during 1st mitosis using live cell imaging system. One hundred-forty zygotes underwent 1st mitosis after RNA injection. Abnormal cytokinesis at 1st mitosis was observed in 45 zygotes (32%). In 12 zygotes, normal chromosome division was observed under a confocal microscope (27%) despite abnormal cytokinesis. Three zygotes developed to the blastocyst stage from normally chromosome-divided embryos (25%). One of these blastocysts were categorized as morphologically-good (4BB) by Gardner's strict criteria. Monitoring of chromosomal behavior at 1st mitosis using a confocal microscope enables us to distinguish embryos which underwent correct chromosomal division in spite of abnormal cytokinesis. The data of the present study suggest that embryos which underwent chromosomal division correctly could develop to live babies in spite of abnormal cytokinesis at 1st mitosis.

Limitations, reasons for caution: It is not ethically permitted in clinical fields to monitor the chromosomal behavior at 1st mitosis of human embryos under a confocal microscope. Further studies are required to detect the difference between correct and incorrect chromosomal division using a light microscope.
Wider implications of the findings: Live imaging using a confocal microscope inside an incubator yielded information about chromosome behavior during preimplantation embryo development that were unobservable by a time-lapse system using a light microscope. Live imaging is expected to play an important role in understanding chromosomal aberrations during pre-implantation embryo development.
Trial registration number: Japan Society of Obstetrics and Gynecology 112

P-121 Prevalence and predictive factors for complete fertilization failure in in vitro fertilization treatment cycles: a retrospective analysis of a large-scale nationwide database study

T. Takahashi[1], K. Ota[1], H. Mizunuma[1]

[1]Fukushima Medical University, Fukushima Medical Center for Children and Women, Fukushima, Japan

Study question: What is the prevalence of and what are the risk factors for complete fertilization failure (CFF) in patients undergoing *in vitro* fertilization (IVF) treatment cycles.
Summary answer: The prevalence of CFF was 13.2% and the major predictive factor for IVF cycles with CFF was a retrieved oocyte number.
What is known already: It is reported that the rate of CFF in IVF treatment cycles ranges from 5 to 15%. A more accurate indicator of prevalence is unknown, and the predictive factors for CFF in IVF cycles based on real-world data are unclear.
Study design, size, duration: A retrospective cohort study was performed, based on 1404648 treatment cycles in registered assisted reproductive technology (ART) data from the Japan Society of Obstetrics and Gynecology between 2007 and 2012.
Participants/materials, setting, methods: We analyzed data from 220,065 fresh cycles of IVF when one or more oocytes were retrieved. An instance of CFF was defined as zero fertilized oocytes obtained. The IVF cycles with CFF or with one or more oocytes fertilized were compared to determine predictive factors for CFF using multivariate logistic regression analyses. The area under the receiver operating characteristic (ROC) curve was used to assess the discriminative ability of the logistic models.
Main results and the role of chance: The total percentage of CFF in IVF cycles was 13.2% (29076/220065). On multivariate analysis, patient age (adjusted odds ratio [aOR]: 1.00, 95% confidence interval [CI]: 1.00-1.01, p<0.01), oocyte number (aOR: 0.78, 95% CI: 0.77-0.79, p<0.01), sperm motility (aOR: 0.99, 95% CI: 0.98-0.99, p<0.01), and male factor infertility (aOR: 1.43, 95% CI: 1.38-1.49, p<0.001) were independent predictive factors of CFF. The percentages of CFF cycles with one, two, three, four, and five oocytes retrieved were 34.2%, 15.3%, 8.6%, 6.0%, and 4.6%, respectively. The efficacy of oocyte number and sperm motility for predicting CFF were evaluated using ROC curves. The areas under the curves for oocyte number and sperm motility were 0.79 and 0.59, respectively. Setting the threshold at 2 for oocyte number offered the best compromise between sensitivity (0.66) and specificity (0.80).
Limitations, reasons for caution: As cases with serious semen abnormalities may have undergone intracytoplasmic injection, a selection bias cannot be ruled out in the IVF treatment cycles analyzed.
Wider implications of the findings: This study showed that collecting a large number of retrieved oocytes may prevent CFF. These results provide information that may be useful for counseling patients before their undergoing ART treatments.
Trial registration number: not applicable

P-122 Investigation of transfer results of human embryos which are vitrified and thawed in cleavage, morula and blastocyst stages

C. Korkmaz[1], U.G. Yıldız[2], U. Fidan[2], B. Baykal[2], S.T. Ceyhan[2], E. Agacayak[2]

[1]University of Health Sciences- Gülhane Training and Research Hospital Ankara-Turkey, IVF Center, Ankara, Turkey ;
[2]University of Health Sciences- Gülhane Training and Research Hospital, IVF Center, Keçiören, Turkey

Study question: What is the rates of clinical pregnancy after the transfer of vitrified and thawed human embryos on Day 3, Day 4, and Day 5 of embryonic development.
Summary answer: Higher rates of pregnancy were determined with the freezing of human embryos on Day 4 and the transfer of those embryos on Day 5.
What is known already: One of the most important stages in clinical infertility treatment today is frozen embryo transfer. The cryopreservation of human embryos allows us to increase the potential of conception for any in vitro fertilization (IVF) cycle to its highest level and to prevent the waste of embryos. Vitrification, which is currently used to freeze human oocytes and embryos at the pronucleus, cleavage, morula, and blastocyst stages, is a simple, low-cost, and effective method.However, there is no consensus regarding which stage of embryonic development is most suitable for vitrification with maximum development after the embryo is thawed.
Study design, size, duration: 148 embryo transfer cycles, using embryos frozen with the closed vitrification method, thawed during the three-year period between January 2016 and December 2018 were investigated. Results of the embryos frozen were compared in three groups based on the day they were frozen Day 3, Day 4, or Day 5. This study is the first one in which pregnancy results are compared following freezing and thawing of human embryos in the cleavage, morula, and blastocyte stages.
Participants/materials, setting, methods: 128 patients, and 148 cycles belonging to this infertile patients, were included in our study. Male majority factor cases were excluded from the study. Closed vitrification method were used during the study. 17.4% of patients' embryos were frozen on Day 3, 55.6% on Day 4, and 27% on Day 5.The clinical pregnancy and ongoing pregnancy results were examined, after thawing.
Main results and the role of chance: The clinical pregnancy and ongoing pregnancy results were examined, after thawing, in all groups according to their infertility reasons, with no significant difference observed in terms of clinical pregnancy and ongoing pregnancy rates (p:0.061, p:0.493). 20% of the embryos frozen on Day 3 were also transferred on Day 3; 52% were transferred on Day 4; and 28% were transferred on Day 5. 26.2% of the embryos frozen on Day 4 were transferred on Day 4, and 73.8% were transferred on Day 5. All embryos frozen on Day 5 were transferred the same day. Clinical pregnancy and ongoing pregnancy rates were observed to be significantly higher in the results of embryos frozen on Day 4 and transferred on Day 5, according to the transfer day (clinical pregnancy rates were 28.5% on day four and 49.1% on day five)
Limitations, reasons for caution: There is a need for comparative studies on vitrification of human embryos at different stages with a larger patient population.
Wider implications of the findings: This study is the first one in which pregnancy results are compared following freezing and thawing of human embryos in the cleavage, morula, and blastocyte stages. Higher pregnancy rates can be achieved by transferring, in the blastocyst stage, embryos that were frozen and thawed in the morula stage.
Trial registration number: 19/48

P-123 The expression of Anti-Müllerian hormone receptor type II (AMHRII) in human oocytes from the in vitro fertilization programme and their maturation with recombinant AMH

J. Bedenk[1], E. Vrtačnik-Bokal[1], N. Jančar[1], K. Geršak[1], I. Virant-Klun[1,2]

[1]University Medical Centre Ljubljana, Department of Obstetrics and Gynaecology, Ljubljana, Slovenia ;
[2]University Medical Centre Ljubljana, Centre for Clinical Research, Ljubljana, Slovenia

Study question: Is AMHRII receptor present in the immature and mature non-fertilized oocytes from the IVF programme; can recombinant AMH affect oocyte maturation in vitro?
Summary answer: AMHRII receptor is more expressed in immature than mature oocytes and immature oocytes can be matured in vitro in the presence of recombinant AMH only.

What is known already: AMHRII, a key receptor for AMH, is expressed in Sertoli and Leydig cells in testes and in granulosa and theca cells in the ovaries. This receptor is crucial for the function of Anti-Müllerian hormone (AMH) in follicular cells, especially as a regulator of growing ovarian follicles. Despite this, we could not find any studies on the expression of AMHRII receptor in human oocytes. Therefore, we decided to analyze the oocytes for AMHRII receptor expression and mature the oocytes in vitro with recombinant AMH in the maturation medium to perhaps demonstrate the direct action of this hormone on oocytes.
Study design, size, duration: During two years, we included two groups of oocytes – 24 immature (GV) and 24 mature (MII) oocytes to perform immunocytochemistry for expression of AMHRII and elucidate whether the maturity stage of oocytes has an effect on expression of AMHRII receptor. In the next step, 15 immature and 15 mature oocytes were analysed on expression of *AMHRII* gene. Immature oocytes (n=15) were matured in vitro in the presence of recombinant AMH to test its activity.
Participants/materials, setting, methods: We used the oocytes from patients included in the in vitro fertilization programme (ICSI) after their written informed consent. Immunocytochemistry was performed using the anti-AMHRII antibody; fluorescence was quantified with Fiji software. Gene expression analysis for *AMHRII*, *ZP1*, *ZP2*, *ZP3*, *ZP4*, *BMP4* and *GDF9* was performed using qPCR after superamplification, as well as in vitro maturation of oocytes with recombinant AMH (R& DSystems 1737-MS, 100 ng/mL) alone in the maturation medium of MediCult IVM System.
Main results and the role of chance: The AMHRII receptor was expressed in both immature and mature ocytes, mostly in a spotted pattern through the whole cell membrane, as well as in the zona pellucida, but in a much lower quantity. There was also accumulation of AMHRII protein around the genetic material (germinal vesicle) in the immature oocytes, as revealed by immunocytochemistry. The qPCR analysis confirmed the expression of gene *AMHRII* as well as the co-acting genes related to zona pellucida (*ZP1*, *ZP2*, *ZP3*, *ZP4*) and development (*BMP4* and *GDF9*) in immature and mature oocytes, which may reflect the potential function of AMHRII in the oocytes. We also proved that *AMHRII* gene was expressed 10x more in immature oocytes than in mature oocytes (P=0,006; Student T-test). All immature oocytes matured in vitro in the presence of recombinant AMH alone (without FSH and HCG) in the maturation medium. Our preliminary data show that AMH does not act only on the follicular cells but may also act on the oocyte directly.
Limitations, reasons for caution: The limitations of this research may be: impaired quality of mature oocytes which did not fertilize after ICSI and a relatively low number of oocytes. A proportion of them degenerated during the immunostaining procedure. This research is still ongoing to increase the number of oocytes.
Wider implications of the findings: Based on our data, we assumed that AMH, in addition to follicular cells, may directly act on oocytes in vitro. This implies a new understanding of the human oocyte maturation process. Further research will show whether recombinant AMH can improve the process of human oocyte maturation in vitro.
Trial registration number: Republic of Slovenia National medical ethics committee, trial number 0120-546/2018/6

P-124 ICSI versus IVF on sibling oocytes: The real efficacy comparing laboratory results and clinical outcomes

S. Chamayou[1], R. Lombardi[1], C. Ragolia[1], C. Alecci[1], G. Storaci[1], R. Sapienza[1], S. Romano[1], C. Cardea[1], A. Liprino[1], E. Maglia[1], A. Guglielmino[1]

[1]U.M.R. Soc. Coop. a.r.l., Unità di Medicina della Riproduzione, Sant'Agata li Battiati-Catania, Italy

Study question: ICSI versus IVF : which technique is more efficient based on *in vitro* results and clinical outcomes in absence of severe male factor? Conclusions from sibling oocytes study.
Summary answer: Despite of the highest fertilization rate in ICSI, IVF-derived embryos have a higher implantation rate compared to ICSI-derived embryos.
What is known already: The ICSI procedure has been invented to treat severe male infertility and full fertilization failure after conventional IVF. Nowadays ICSI tends to be applied in every case to ensure fertilization as reported in the latest report from the European IVF-monitoring Consortium (2014) where ICSI resulted applied in 71.3% of the fresh treatments.
Study design, size, duration: The present study includes 308 couples who underwent assisted reproduction treatment at UMR-centre HERA between October 2009 to April 2019. The couples were counseled for *in vitro* treatment and were proposed to perform ICSI and IVF on sibling oocytes. In none of the cases infertility was due to severe male factor or previous fertilization failure after *in vitro* technique. The average age for female patients was 33.4.
Participants/materials, setting, methods: The patients underwent ovarian stimulation using GnRH agonist or antagonist protocol. After oocytes retrieval, oocytes-cumulus complex were randomly divided into two groups. Oocytes were simultaneously fertilized by ICSI and IVF with the same semen sample. Fertilization and embryo development were assessed by time-lapse monitoring. Embryos were transferred on the same cycle and surplus blastocysts vitrified for further transfer. Fertilization rate, embryo kinetic and embryo implantation rates were compared between ICSI and IVF.
Main results and the role of chance: On 3,400 oocytes collected, 1,270 were fertilized by ICSI and 1,035 by IVF. Fertilization rate was statistically higher in ICSI group compared to IVF group (76.3% in ICSI versus 58.6% in IVF, $p < 0.0001$). There were no statistically significant differences in cleavage rate (98.7% in ICSI versus 98.7% IVF; $p > 0.05$), embryonic quality in GII (39.7% versus 41.8%) and the rate of usable embryo on total produced embryos per technique (49.4% versus 46.2%) between ICSI and IVF ($p>0.05$). The rates of clinical pregnancy (46.6% vs. 46.8%), of abortion (12.7% vs. 13.3%) were also comparable ($p> 0.05$). Implantation rate was statistically higher for embryos from IVF compared to the sibling embryos produced in ICSI (42.6% versus 55.2%, $p <0.05$). Embryo kinetic was faster in ICSI compared to IVF.
Limitations, reasons for caution: Not all vitrified surplus blastocysts have been thawed and transferred. Consequently cumulative pregnancy rate is incomplete.
Wider implications of the findings: ICSI may induce adverse event on embryo competence. In case of absence of indication for ICSI, IVF should be preferred as fertilization method.
Trial registration number: xx

P-125 Identification of the optimal puncture position on oolemma without degeneration in Piezo-ICSI using image analysis: a pilot study

S. Mizuta[1], T. Maekawa[2], Y. Kinishi[3], H. Matsubayashi[2], K. Kitaya[1], T. Takeuchi[2], Y. Hata[3], T. Ishikawa[1]

[1]Reproduction Clinic Osaka, Reproductive Medicine, Osaka, Japan ; [2]Reproduction Clinic Tokyo, Reproductive Medicine, Tokyo, Japan ; [3]University of Hyogo, Graduate School of Simulation Studies, Kobe, Japan

Study question: Is it possible to identify the optimal puncture position on oolemma which may not cause degeneration in Piezo-ICSI using image analysis?
Summary answer: Visualizing the likelihood of unintentional membrane rupture using image analysis can identify positions that result in lower risk of oocyte degeneration following Piezo-ICSI.
What is known already: Oocyte degeneration may take place in Piezo-ICSI as a result of unintentional membrane rupture in the puncturing process. Identifying the appropriate puncturing position may decrease the likelihood of membrane rupture and thus degeneration, but this cannot be done visually. Image feature analysis is generally used to represent the useful features such as color, brightness, and contour. Among capturing image features, Local Binary Patterns (LBP) can efficiently summarize the local structures of images, and it has been applied in texture analysis in various fields including face recognition. There were no studies identifying the optimal puncture position using image analysis.
Study design, size, duration: We retrospectively performed the LBP methodology to analyze the moving images of 131 oocytes following Piezo-ICSI between August 2018 and January 2019. These oocytes were categorized as either having undergone unintentional rupture (UR: n = 30) or no rupture (NR: n = 101).
Participants/materials, setting, methods: LBP values were calculated in the analysis region centered around the puncture position. Median values for UR and NR were calculated to select an effective pattern for rupture evaluation from the 256 shape patterns acquired by LBP. After choosing the three effective patterns with hierarchical clustering, we employed Ward's hierarchical cluster analysis method and calculated the Euclidean distance between the cluster barycenter and each data point to define an index indicating membrane rupture implausibility.

Main results and the role of chance: Two clusters, the cluster A and B, were classified from hierarchical clustering. Following ICSI, 2 out of 27 oocytes from the cluster A and 28 out of 104 from the cluster B resulted in UR, indicating that the cluster A strongly represented NR group and the cluster B weakly represented UR group, with the sensitivity as 0.93. A significant difference between the UR and the NR group was reported from the Euclidean distance calculations between the barycenter of Cluster A and each data point (P = 0.001), where data showed a longer distance from the barycenter amongst the UR group and a shorter distance in the NR group. All degenerated oocytes after ICSI procedure were from UR (27.7%, 8/30). Of these, two were from the cluster A (100%, 2/2) and six were from the cluster B (21.4%, 6/28), while the 2PN rate was 0% and 67.9% in the clusters A and B, respectively. On the other hand, no degeneration was observed from the NR group, and the 2PN rate was 84.0% and 81.6% in the clusters A and B, respectively. Fertilization and degeneration results in NR were significantly better than UR groups.
Limitations, reasons for caution: This was a retrospective pilot study with a small sample size, and this was a single-center study. Moreover, this study did not include embryonic development and clinical outcomes. Further prospective studies in large samples size are needed.
Wider implications of the findings: We can retrospectively classify UR or NR from the shape feature of the oolemma by the image analysis with AI. If we could recognize optimal puncture position by visualizing shape features of the oolemma in real-time, we could reduce degeneration of the oocytes after Piezo-ICSI.
Trial registration number: not applicable

P-126 Day of blastocyst freezing is a better prognostic factor than morphology for livebirth in single frozen embryo blastocyst transfer

M.W. Lui[1], C. Lamb[2], D. Thong[3], S. Pickering[2], K.J. Thong[2]

[1]Queen Mary Hospital- Hong Kong, Obstetrics and Gynaegolocy, Hong Kong, Hong Kong ;
[2]Royal Infirmary of Edinburgh, Edinburgh Fertility and Reproductive Endocrine Centre, Edinburgh, United Kingdom ;
[3]Statistician, independent researcher, Edinburgh, United Kingdom

Study question: Is the day of blastocyst freezing or blastocyst morphology a better prognostic factor for livebirth in single frozen embryo transfer (FET)?
Summary answer: Day-5 blastocyst is associated with higher livebirth rate than day-6 blastocyst, even with a better morphological scoring at freeze.
What is known already: Assessment of development potential is essential in reducing the pregnancy interval in the era of single embryo transfer and optimizing the livebirth rate from treatment. The rate of blastocysts development (day-5 or day-6 blastocysts) (1) and morphological assessment (2, 3) have both been identified as significant prognostic factors for livebirth in blastocyst(s) transfer. However, we are uncertain which of the parameters is a better prognostic factor for livebirth rate for women undergoing FET.
Study design, size, duration: A retrospective study was carried out for all single blastocyst frozen transfer from January 2015 to December 2018 in a single fertility centre. Cases requiring extended culture after thawing and incomplete data were excluded. The cases were identified from the centre's computerized data. Morphological assessment was carried out using the Gardner and Schoolcraft Grading System (4). Good quality embryos were defined as 1-6AA, 3-6AB or 3-6BA.
Participants/materials, setting, methods: A total of 1541 single blastocyst transfers were carried out during the study period and 1162 transfers were included in the analysis. Chi-square testing and binary logistic regression of live birth rate against: age of women at freezing, interval of freezing, embryo quality after thaw and change in quality from freezing to thawing were performed. Women with morulas after thaw were excluded in the analysis using logistic regression.
Main results and the role of chance: The mean age of women at freezing and duration of freezing were 34.0 +/- 3.9 years and 0.9 +/- 1.3 years respectively. The overall livebirth rate was 31.4%. The livebirth rate was the highest for good quality day-5 blastocysts of 39.4%, followed by 25.2% in poor quality day-5 blastocysts. It was lower for good quality day-6 blastocysts of 22.5% and 15.9% in poor quality day-6 blastocysts (p <0.001 for differences and trend).

Logistic regression found the followings to be significant: Age at freezing ($p < 0.001$, OR 0.939, 95% CI 0.908 - 0.971), Day 5 vs Day 6 transfer ($p < 0.001$, OR 2.060, 95% CI 1.443 - 2.978), trophectoderm score of A upon thawing ($p = 0.01$, OR 1.482, 95% CI 1.100 – 1.997), and the expansion score upon thawing ($p < 0.001$ overall via likelihood ratio Chi-square test). Embryos with an expansion score of 1 have 75.7% lower odds of live birth than embryos with grade 6 expansion score (OR 0.243, 95% CI 0.085 – 0.722). The score for inner cell mass was not found to be significant.
Limitations, reasons for caution: Other potential covariates including body mass index, parity and aetiology of infertility were not included in the analysis. Other morphokinetic factors such as abnormal cleavage may have been included into selection process for freezing and thawing, but were not included in the analysis.
Wider implications of the findings: The study provides a simple decision support tool for embryologists to decide on which frozen blastocysts to transfer. Morphological features such as trophectoderm grade and expansion score are predictors of livebirth. Wherever possible, a day 5 blastocyst should be transferred in preference to a day 6 blastocyst.
Trial registration number: not applicable

P-127 Understand chromosomal self-correction of human embryo with non-invasive genomic test

J. Yan[1], M. Li[1], L. Xiang[1], X. Wu[1], Y. Li[1]

[1]The First People's Hospital of Yunnan Province-, Reproductive Medical Center-, Kunming, China

Study question: Can mosaic embryo commit self-correction or elimination process during development? Are there differences between pre-implantation (D1~D5) and post-implantation stage (D5~D14)?
Summary answer: Chromosomal self-correction could be observed in both pre- and post-implantation stage. In this research, most of the aneuploidy cells decreased before Day 5 post fertilization.
What is known already: Chromosomal mosaicism in human pre-implantation embryos has been described, and is regarded as a significant factor that contributes to unsuccessful embryo implantation and spontaneous abortion. It is reported in cleavage stage, the mosaic embryo is up to 70%. and in blastocyst the ratio reduces to about 30%. Current hypothesis is during the development embryo excluded the aneuploidy cells for self-correction. However, lack of proper approaches, the quantitatively reports are still rare. The post-implantation stage situation is also elusive.
Study design, size, duration: From 2019~2020, 36 frozen embryos from 23 patients (age 22~34 years), who determine to donate their embryos after successful pregnancy with informed consent in Reproductive medical center, the first people's hospital of Yunnan province,China.
Participants/materials, setting, methods: For each cleavage embryo, 2~3 blastomeres are tested and the embryo was continually cultured to blastocyst. and collected the medium In Day5, 1~2 TE and 1 ICM are biopsied. For mimicing post-implantation embryo in vitro, three-dimensional blastocyst-culture system(Nature, 2010) is adopted. This method allowed the development of 3D structure of embryo and mimic the in vivo situation better. The culture medium are collected in Day8/10/2. Medium and embryo are sequenced with NGS (Yikon).
Main results and the role of chance: In our study, 92% (297/323) samples are successfully amplified. Data from ICM are considered as represented result for the embryo. In pre-implantation stage, mosaicism portion over 20% is included, and 24% (6/25) of the embryos carrying at least one mosaic chromosome. 72% (17/25) results from mediums are at least consistent with TE or ICM. In pre-implantation stage, the consistent of each blastomeres are 83% (55/66) TE and ICM are 86.3%(19/22). 16%(4/25) self-correction (CNV in blastomeres but not in TE/ICM or the mosaic ratio decreased) and 4%(1/25) novel chromosomal aneuploidy (CNV in TE but not in blastomeres) are observed. 8%(2/25)aneuploidy is detected in medium but not in either blastomere or TE/ICM.

In post-implantation stage, 81.8%(9/11) are developed embryos carrying consistent chromosomal situation. One duplication of chromosome 14 is observed in Day8 but not in Day10 and Day12(1/11) .
Limitations, reasons for caution: The size of the research is still small; the post-implantation and pre-implantation embryos are not the same batch; some

of the donated embryos are not from the ICSI cycle, potentially maternal contamination could not be excluded.
Wider implications of the findings: Non-invasive chromosomal test provides us powerful tool to study the genomic change. We find more mosaicism in medium but not in biopsy, and bsed on current study size, most self-correction could be observed before Day5, for post-implantation stage, more evidence are required.
Trial registration number: NSFC 31700798

P-128 Prospective comparative study between two commercial single culture media using sibling donor oocytes collected from randomized ovaries

C. MIRET LUCIO[1], M. Benavent[1], M. Escriba[1], A. Garcia[1], D. González[1], N. Borges[2], G. Calderon[2], J. Crespo[3], J. Teruel[1]

[1]Equipo Médico Crespo, IVF Lab, Valencia, Spain ;
[2]Embryotools, IVF Lab, Barcelona, Spain ;
[3]Equipo Médico Crespo, Reproductive Medicine, Valencia, Spain

Study question: To compare embryo development and clinical outcomes between two commercial single culture media using sibling donor oocytes collected from randomized ovaries
Summary answer: Our study suggests that different commercial single media used uninterruptedly can yield different blastocyst developmental rates, depending on their formulation and/or environmental culture conditions
What is known already: In recent years, there has been a renewed interest in the use of single media to support human embryo culture *in vitro*. These media are based on a single formulation designed following the principle of allowing developing embryos to choose the nutrients according to their needs. An increasing number of single media have now become commercially available and have been swiftly introduced in IVF laboratories worldwide. Whether all single media are equally suitable for the continuous (one-step) culture of human embryos remains unclear, as recent studies suggest that the formulation, laboratory environment and culture conditions may result in different outcomes
Study design, size, duration: This is a single-center prospective study performed between February and December 2019 that included 84 donors and 94 recipients. Ovaries were randomized using a computer-generated randomization list. Sibling oocytes collected from each randomized ovary were processed and cultured in two commercial single media (A and B). The corresponding series media (fertilization, handling or culture) offered by each brand was used to perform all procedures involving oocytes and sperm samples of the two experimental arms
Participants/materials, setting, methods: Oocytes were injected by ICSI and then cultured individually in miniGPS dishes (LifeGlobal) prepared with either single medium A or B (25ul medium/well) at 37°C, in an atmosphere of 6-7% CO2/5% O2/88-89% N2 of a dry atmosphere incubator (IVFcube, Astec). Laboratory conditions, such as temperature, humidity and volatile organic compounds (VOC) levels were monitored continuously (Octax Log&Guard, Vitrolife) during the study period and pH measured in a weekly basis in the two single media used
Main results and the role of chance: The pH average values were similar in both media (medium A 7.28±0.06 vs medium B-7.27±0.05), and the mean value of VOCs 0.032 ppm. A total of 1103 MII oocytes were injected by ICSI (A, n=558 and B, n=545). The proportion of fertilized oocytes was identical between the two media (A:83.9% and B:79.4%), but oocyte degeneration rate post-ICSI was significantly lower in group A (3.6% vs 7.3%; p=0.0059). The mean number of embryos that reached the blastocyst stage cultured in the single medium A (64.3%) was significantly lower (p=0.004) than that obtained in medium B (73,2%). Similarly, a higher proportion (p=0.031) of blastocysts suitable for clinical use (transferred or cryopreserved) was obtained in medium B (61%) compared to medium A (53.8%).

Ninety-four patients had an embryo transfer on day 5/6 with either fresh or cryopreserved blastocysts cultured in single medium A (n=39) or B (n=56), with a mean number of 1.2 blastocysts transferred/patient in the two groups. No differences were found in terms of clinical pregnancy (69.2% and 64.3%, respectively) or implantation rates (67.4% and 56.1%, respectively) between both groups. Miscarriage rates were similar between group A (18.5%) and group B (12.5%). Three mixed transfers were excluded from the interpretation of results
Limitations, reasons for caution: Continuous embryo culture in single media largely relies on optimal laboratory conditions and a series of osmolality or atmospheric fluctuations, accumulation of volatile organic compounds or ammonium built-up may negatively affect the culture environment. Future research is needed to compare reproductive outcomes in RCT performed with patient's own oocytes
Wider implications of the findings: The present study suggests that commercial single culture media when used in a continuous (one-step) approach may result in different outcomes in terms of proportion of suitable blastocysts for clinical use. Single media formulation, laboratory conditions and the culture environment should be properly validated independently on each laboratory conditions
Trial registration number: Not applicable

P-129 pregnancy is significantly correlated with the blastocyst width and area: a time-lapse study.

R. Sciorio[1], D. Thong[2], K.J. Thong[3], S. Pickering[3]

[1]Royal Infirmary of Edinburgh, Edinburgh Assisted Conception Programme- EFREC, Edinburgh- Scotland, United Kingdom ;
[2]RIE, Efrec, Einburgh, United Kingdom ;
[3]RIE, Efrec, Edinburgh, United Kingdom

Study question: Does blastocyst width and area affect pregnancy outcome in IVF/ICSI cycles?
Summary answer: Clinical pregnancy rate (CPR) is significantly higher for blastocysts with a larger width and area, which was confirmed by logistic regression.
What is known already: In order to maintain pregnancy rates following single embryo transfer, optimisation of embryo culture and selection is vital. Time-lapse monitoring (TLM) has the potential to play a crucial role by providing sequential images of embryo development and minimal disturbance, thereby increasing the probability of selecting embryos with high implantation potential. However, transfer of good quality embryos does not always lead to successful pregnancy. Therefore, in this study *morphometric* evaluation was performed. We used a single assessment of blastocyst area and maximum width to evaluate if these parameters correlated with pregnancy outcomes.
Study design, size, duration: A retrospective analysis of 664 patients who had eSET was carried out between April 2014 and August 2019. Embryos were cultured individually in 6.0% CO_2, 5.0% O_2, 89.0% N_2, using single step medium (G-TL™ Vitrolife, Göteborg, Sweden) in the time-lapse incubator (Embryoscope, ES-D, Vitrolife).
Participants/materials, setting, methods: All embryos were evaluated using calibrated annotation tools of the EmbryoViewer. Drawing tools were used to measure specific variables such as the maximum blastocyst width and blastocyst area. Data obtained was assessed in terms of CPR at 7 weeks gestation. Statistical analysis was performed with Mann-Whitney *U*-test and Logistic Regression.
Main results and the role of chance: Variables analysed in this study were correlated to clinical outcomes. The age [median (range) years old] of women was 34 (22-44). Our results show women who were pregnant had a significantly (P<0.01) larger blastocyst width [median (range) µm] 184 (125-239) versus those who were not pregnant 160 (120-230). A significantly (P <0.01) larger [median (range) μm^2] blastocyst area 26099 (12101-45280) was seen in pregnant versus non pregnant women, 22251 (10992-37931).

A univariate logistic regression performed showed that blastocyst width [(OR = 1.026, 95% CI = (1.019, 1.033)] was found to be significant with P-value <0.0001. This shows that for every µm increase of blastocyst width, the odds of clinical pregnancy increase by 2.6%.

A univariate logistic regression performed also showed that blastocyst area [(OR = 1.00008, 95% CI = (1.00006, 1.00011)] was found to be significant with P-value <0.0001. The lower odds ratio is explained by a larger range in blastocyst area. This shows that, for every μm^2 increase of blastocyst area, the odds of clinical pregnancy increase by 0.008%. Hosmer-Lemeshow tests of calibrations were performed to verify calibration.
Limitations, reasons for caution: 6.6% of patients (44/664) were excluded from the study because dimensions could not be measured accurately. Although our findings show a clear effect of blastocyst dimensions on clinical pregnancy rate, further studies are necessary to confirm these observations.
Wider implications of the findings: Confirmation of our findings could result in establishment of a new algorithm to improve embryo selection at the blastocyst stage. However, this may not exclude the importance of other morphological features/grades in embryo selection.
Trial registration number: not applicabale

P-130 A prospective randomised control study comparing reproductive outcome of day 5 Quarter laser zona thinning assisted hatching (qLZT-AH) in frozen thawed embryo transfers

H. Sharma[1], K.D. Nayar[1], G. Kant[1], S. Draboo[1], M. Singh[1], R. Bhattachrya[1], S. Gupta[1], K.D. Nayar[1]

[1]Akanksha IVF Centre- Mata Chanan Devi Hospital, Reproductive Medicine, New Delhi, India

Study question: Can quarter zona laser thinning assisted hatching (qLZT-AH) improves reproductive outcome in day 5 frozen embryo transfer cycles?
Summary answer: Quarter laser thinning assisted hatching (qLZT-AH) on day 5 frozen thawed embryos is associated with improved implantation rate, clinical pregnancy rate over no assisted hatching.
What is known already: Hatching is a process where blastocyst escape the Zona pellucida (ZP) membrane prior to implantation. This is accomplished in-vivo by secretion of hatching factors and lysine production by trophectoderm of embryo but in in-vitro fertilisation when embryos are frozen under ultra low temperature, may lead to zona hardening. This may inhibit or reduce the chances of spontaneous hatching.

With the advent of laser assisted hatching (LAH), this complication could be overcome with focussed laser light to produce opening in ZP with a single pulse of few millisecond, with no mechanical, thermal or mutagenic side effects.
Study design, size, duration: A prospective randomised control study was conducted from 1st January to 31st December 2019. All patients whose frozen embryos were thawed on day 5 were included. Two hundred day 5 FET cycles were randomised by computer generated list and divided into 2 groups. Group A (n=100), in which Quarter laser zona thinning assisted hatching (qLZT-AH) was done after thawing while in group B (n=100) no laser assisted hatching was done after thawing.
Participants/materials, setting, methods: All normoresponder patients whose embryos were frozen on day 5 were included in this study and patients with endometrium pathologies were excluded. Quarter laser zona thinning assisted hatching (qLZT-AH) was performed after thawing in group A, where 25% of surface area and 50% thickness is removed by using laser while in group B no laser assisted hatching was done. Groups were compared on the basis of implantation rate, clinical pregnancy rate and miscarriage rate.
Main results and the role of chance: None of the Frozen embryo transfer cycle was cancelled and no loss of embryo was reported during thawing process. The cryosurvival rate was 96% in group A and 95% in group B which is in the range of cryopreservation key performance indicators. No significant difference in female age, BMI and AMH was observed between the two groups.
There was a statistically significant increase in implantation rate (35% vs. 23.07%, p=0.004) and clinical pregnancy rate (50% vs. 35%, p=0.031) when day 5 frozen thawed transfers assisted with qLZT-AH was done, while no difference in miscarriage rate (6% vs. 5.70%, p=0.906) was noted.
Limitations, reasons for caution: Larger randomised control studies are needed to strengthen these results.
Wider implications of the findings: We have demonstrated that day5 frozen embryo transfers assisted with quarter laser zona thinning assisted hatching (qLZT-AH) results in better reproductive outcome than if no hatching is done. This study strengthen the current trend of freezing more embryos at blastocyst stage and then assisting with qLZT-AH can further improve results.
Trial registration number: MCDH/2019/15

P-131 Is there a cohort-effect of low fertilization in human embryos? Analysis of live birth rate in 7,782 oocyte donation cycles.

M. Torra[1], D. Garcia[1], R. Vassena[1], A. Rodriguez[1]

[1]EUGIN, Clinica Eugin, Barcelona, Spain

Study question: Does fertilization rate *per se,* rather than having few embryos available for embryo transfer, affect live birth rates in ICSI cycles?
Summary answer: Fertilization rate *per se* does not affect clinical pregnancy and live birth rates after ICSI
What is known already: Low fertilization rates (FR) after ICSI reduce the embryos available for transfer. The number of embryos is a predictor of pregnancy and live birth (LB) rates, and controlling for this variable is imperative in order to understand the cohort effect of FR. A high percentage of non-fertilized oocytes at D+1 could underlie molecular and cellular alterations in either oocytes or sperm, which may partially affect also the embryos that continue their development. By comparing cycles with the same number of generated embryos, but different FR, we test whether FR *per se* affects pregnancy and LB rates after fresh embryo transfer.
Study design, size, duration: Retrospective cohort study of 7,782 oocyte donation cycles performed in one fertility clinic between 2011 and 2019. Between 5-14 metaphase II oocytes (MII) were assigned to each oocyte recipient. Each cycle gave rise to 4, 5 or 6 D+1 embryos after elective ICSI. Reproductive results were analyzed per groups with the same number of embryos (4-5-6), regardless of the number of MII needed to obtain those embryos (varying FR within groups).
Participants/materials, setting, methods: A minimum of 5 MII were assigned to each recipient hence, cycles with 4 embryos presented 33-80% FR, cycles with 5 embryos 38-100% FR, and cycles with 6 embryos 43-100% FR. For each group of embryos (4-5-6), the FR range was divided in categories containing >160 cycles each. Mean embryo morphological score, pregnancy and LB rates after fresh ET, were compared within groups and along FR available categories using ANOVA, Chi^2 and linear-by-linear tests.
Main results and the role of chance: Oocytes were inseminated with partner sperm in 84.1% of cycles (FR: 77.3%; LB rate: 35.6%) or donor sperm in 15.9% of cycles (FR: 77.9%; LB rate: 39.8%), equally distributed within the three groups. Fresh transfer of 1 (9.1% of cycles), 2 (90.7%) or 3 (0.2%) embryos was performed on D+2 (28.1%) or D+3 (71.9%) post-ICSI. Cycles with 4, 5 and 6 D+1 embryos were 2,873, 2,962 and 1,947, respectively. When considering all cycles that yielded 5 embryos, the most common occurrence, clinical pregnancy and LB rates were comparable across FR range (38.5%-100%), varying between 42.8% and 47.4% for clinical pregnancy (p=0.46), and between 35.7% and 39.9% for LB rate (p=0.56). Similarly, no significant differences were observed when considering mean embryo morphological score, pregnancy or LB rates in cycles that yielded 4 or 6 embryos (p>0.05 in all cases). Although clinical pregnancy rates and LB rates predictably increased with the number of embryos obtained overall (32.0%, 36.6% and 38.0%, for 4, 5 and 6 embryos respectively, p<0.001), we did not find an effect of FR *per se* on the performance of the cohort of embryos generated.
Limitations, reasons for caution: A minimum of 5 MII were assigned to recipients, therefore it was not possible to perform the analysis for the whole range of FR. Our results should not be extended to cycles with FR <30%. Studies specifically focusing on low and very low FR are needed to clarify this further.
Wider implications of the findings: FR *per se* does not affect reproductive outcomes. Cycles with lower FR after ICSI result in similar LB rate than cycles with higher FR if the number of generated embryos is the same. These results can inform patient counseling, and the management of oocyte donation programs.
Trial registration number: NA

P-132 Morphokinetic analysis of embryos originated from vitrified oocytes in infertile patients

A. Coello[1], M. Meseguer[1], M. Nohales[1], L. Alegre[1], J. Remohi[2], A. Cobo[1]

[1]IVIRMA Valencia, IVF laboratory, Valencia, Spain ;
[2]IVIRMA Valencia, Ob/Gyn, Valencia, Spain

Study question: Does oocyte vitrification alter embryo morphokinetic parameters in infertile patients?
Summary answer: Morphokinetics of embryos generated from vitrified oocytes is similar to that observed in fresh oocytes in infertile patients, except for time to first cell división.
What is known already: Although oocyte vitrification seems not to alter embryo morphology and clinical outcomes, some differences have been found in kinetic parameters of embryos originated from vitrified oocytes compared to those of embryos coming from fresh oocytes in donor cycles. These differences have revealed a delay of 1 hour in each cell division until early blastocyst stage in the vitrification group. Currently, there is lack of information about embryo morphokinetic parameters after oocyte vitrification in autologous cycles.
Study design, size, duration: This was a retrospective study including 2617 embryos originated from fresh oocytes (475 cycles) and 716 embryos derived from vitrified oocytes (118 cycles). All embryos were cultured in a time-lapse monitoring system (Embryoscope, Vitrolife and Geri, Genea). Embryo developmental events were annotated together with the corresponding timing of events in hours after intracytoplasmic sperm injection (ICSI).

Participants/materials, setting, methods: Kinetics parameters analyzed included: time to pronuclear appearance and fading (PNa, PNf), cleavage divisions until 8 cells (t2-t8), early, expanded and hatching blastocyst (tB, tBE, tBHi), as well as second cell cycle duration (cc2) and the synchrony in the division (s2). Embryos were classified according to the hierarchic tree model by Meseguer et al. 2011. Implantation and clinical pregnancy rates were also evaluated. The analyzed variables were compared using chi-square test and 95% confident intervals.
Main results and the role of chance: No significant differences in morphokinetic parameters were found between embryos originated from fresh and vitrified oocytes, except for t2. The proportions of embryos allocated to categories A–E in the hierarchical tree were similar between groups. The blastocyst formation rate was 52.0% (95% CI: 49.7%-54.3%) in the fresh oocytes group and 45.3% (95% CI: 40.7%-49.9%) in the vitrified oocyte group. No differences on implantation rate [41.5% (95% CI: 34.2%–48.8%) *vs.* 48.9% (95% CI: 34.9%–62.9%)] and clinical pregnancy rate [39.8% (95% CI: 31.6%-48.0%) *vs.* 55.0% (95% CI: 39.6%-70.4%)] were found between the fresh and vitrified group respectively.
Limitations, reasons for caution: The retrospective nature of this study is the main limitation. Additionally, the smaller sample size compared to previous morphokinetic analysis in donor cycles makes it difficult to drawn definitive conclusions.
Wider implications of the findings: The delay observed in donor cycles has not been confirmed in this study, most probably because patient's infertility condition is affecting the morphokinetics of embryos originated from fresh oocytes and, therefore, the effect of vitrification is not reflected in the analysis.
Trial registration number: 1511-VLC-062-AC

P-133 Amount of cell-free mitochondrial DNA in spent culture medium correlates with morphokinetic parameters of human blastocysts

M. Kobayashi[1], R. Suzuki[1], K. Tsukamoto[1], H. Hasegawa[1], T. Kyoya[1], A. Kikumoto[1], T. Sakurai[2], S. Saito[2], J. Kobayashi[2], H. Iwata[3]

[1]Kanagawa Ladies Clinic, Embryology Labolatory, Yokohama, Japan ; [2]Kanagawa Ladies Clinic, Department of Gynecology, Yokohama, Japan ; [3]Tokyo university of agriculture, Faculty of Agriculture Department of Animal Science, Atsugi, Japan

Study question: Does the amount of cell-free mitochondrial DNA (cf-mtDNA) in spent culture medium (SCM) correlate with the morphokinetic parameters (MPs) of human blastocysts?
Summary answer: The duration of blastocyst expansion (tEB - tB and tEB - tSB) and presence of blastocyst collapse correlated with the amount of cf-mtDNA in SCM.
What is known already: The mitochondrion is an important organelle for embryonic development. cf-mtDNA can be detected in SCM, and it has been reported that the amount of cf-mtDNA in SCM of early cleavage-stage embryos (day 3) reflects subsequent embryonic development and pregnancy outcomes. Accumulating evidence shows that MPs of human blastocysts obtained from time-lapse monitoring (TLM) facilitates the selection of competent blastocysts for clinical pregnancy. However, there have been no reports regarding the relationship between the amount of cf-mtDNA in SCM and MPs of embryos.
Study design, size, duration: This was a retrospective cohort study. We targeted 20 couples who underwent in vitro fertilization (IVF)/ intracytoplasmic sperm injection (ICSI) treatment between January and December 2019. We measured the cf-mtDNA copy number in the SCM (20 μL) of embryos (total: 53) that were individually cultured to the expanded blastocyst stage for 5 or 6 days. Incubation was performed using a time-lapse incubator (EmbryoScope; Vitrolife, Sweden).
Participants/materials, setting, methods: Amount of cf-mtDNA, maternal age, type of insemination method, total embryo culture hours, morphological blastocyst quality (according to Gardner–Schoolcraft grading), certain MPs, and presence of blastocyst collapse (BC) were analyzed. DNA extracted from the SCM was quantified by real-time PCR (CFX Connect™; Bio-Rad, USA) using a specific primer set. Statistical analysis was performed using Spearman's correlation or Mann-Whitney-U-test.
Main results and the role of chance: The amount of cf-mtDNA did not correlate with maternal age ($r = -0.15$, $P = 0.28$), the total culture hours ($r = 0.18$, $P = 0.19$), or the type of insemination method (mean cf-mtDNA ± standard deviation; IVF: 12.0 ± 7.1, ICSI: 13.4 ± 7.8, $P = 0.56$). In addition, the mean cf-mtDNA content did not differ among morphological inner cell mass (A: 11.9 ± 8.0, B: 14.2 ± 6.8, C: 13.2 ± 5.0, $P = 0.31$) or trophectoderm (A: 12.1 ± 6.4, B: 12.1 ± 8.2, C: 15.9 ± 5.8, $P = 0.20$) grades. The analysis of MPs by TLM showed that the time taken from starting of blastulation to the expanded blastocyst (tEB - tSB) and from the blastocyst stage to the expanded blastocyst (tEB - tB) significantly correlated with the amount of cf-mtDNA in the corresponding SCM (tEB - tSB: $r = 0.46$, $P < 0.01$, tEB - tB: $r = 0.47$, $P < 0.01$). Furthermore, during the blastocyst stage, the mean cf-mtDNA content was higher for blastocysts that experienced BC than in those that did not experience BC (BC group: 14.9 ± 7.7 vs. non-BC group: 7.67 ± 3.9, $P < 0.01$).
Limitations, reasons for caution: The main limitation of this study was the small sample size; hence, we were unable to expand our hypothesis to clinical pregnancy outcomes at this point.
Wider implications of the findings: This is the first report showing an association between the amount of cf-mtDNA in SCM and MPs of blastocysts. It has been reported that the duration of expansion and presence of BC is associated with clinical outcomes. Thus, cf-mtDNA may be a useful non-invasive marker for blastocyst selection.
Trial registration number: not applicable

P-134 Original autologous partial oocyte vitrification program "ICSI-Vit-program": evaluation of the cumulative pregnancy rate and impact on the number of supernumerary cryopreserved embryos

P. Boyer[1], M. Gervoise-Boyer[1], C. Siraudin[1], A. Amar-Hoffet[1], D. Montjean[1]

[1]Hôpital Saint-Joseph, Laboratoire de Biologie de la Reproduction, Marseille Cedex 08, France

Study question: Does "ICSI-Vit-program" consisting in partial vitrification of MII-oocytes and delayed ICSI on thawed oocytes affect cumulative pregnancy rate after fresh and frozen embryo transfer ?
Summary answer: ICSI-Vit program during autologous ICSI cycle increases cumulative early pregnancy rate lowers the number of cryopreserved embryos and helps to promote single embryo transfer policy
What is known already: Partial vitrification of MII oocytes was introduced and validated in our laboratory as a tool to limit embryo freezing to meet legal requirements. Post-warming oocyte survival rate was reported to average 85% in IVF-treated patients. This implies a loss of 15% of oocytes and therefore a potential decrease in the number of embryos available. However, the top quality embryo rate is not higher than 50% with fresh oocytes and not all the supernumerary embryos can be cryopreserved. Data do not answer the question: could a non-survival oocyte after vitrification/thawing lead to a transferable embryo if it had been freshly fertilized
Study design, size, duration: To study cumulative pregnancy rate (the sum of pregnancies obtained in fresh oocytes, frozen embryos and when applicable vitrified/warmed oocytes cycles)
in couples included in ICSI-Vit program, we conducted a retrospective analysis of 378 ICSI-Vit cycles from September 2011 to December 2018 including 363 frozen embryo transfers compared to 420 conventional ICSI cycle without oocyte vitrification and fertilization of the entire MII oocyte cohort performed between January 2003 and July 2011including 353 frozen embryo transfers.
Participants/materials, setting, methods: Cycles with MII oocyte number ≥12 at pick-up were included, cycles without embryo transferred were not included. Data collection: Patient age, numbers of collected oocytes, vitrified oocyte after pick-up; fresh embryos obtained after fresh oocytes ICSI, Vit-fresh oocytes ICSI or frozen transferred embryos, early pregnancies (hCG blood test >100 IU) and deliveries were collected. Statistical analysis was performed. Cumulative rates were calculated including: fresh embryos transferred, frozen embryos and embryos from Vit-fresh oocytes.
Main results and the role of chance: We showed that vitrifying a part of Metaphase II oocytes during ICSI-Vit program allowed superior cumulative pregnancy rate when comparing with conventional ICSI (67,9%, *vs* 49,7% $p<0,05$). Besides, patients enrolled in ICSI-Vit program had fewer embryos transferred (1,2±0,5 vs 1,6±0,5 in conventional ICSI cycles [$p<0,05$]) and a mean of 1,5±0,7 embryo was transferred in vitrified/warmed oocytes cycles ([$p<0,05$]). Moreover we observed lower mean number of cryopreserved embryos in ICSI-Vit program during fresh embryo transfer cycles (1,2±1,4 vs 3,3±2,9 in

conventional ICSI cycles [p<0,05]) and 0,6±0,6 embryos were cryopreserved in vitrified/warmed oocytes cycles. Women included in both programs were of same mean age and had equal mean number of collected oocytes. However, fertilization rate of fresh oocyte was lower in ICSI-Vit program (65,7% vs 69,9% in conventional ICSI [p<0,05]), although no difference was found between fresh oocytes and sibling vitrified/warmed in ICSI-Vit program (65,8% vs 65,4%). These encouraging results may bring a tremendous change in IVF strategy by providing an opportunity for better oocyte use.

Limitations, reasons for caution: Oocyte vitrification can be proposed with oocyte storage instead of embryos when necessary. The compared groups were treated at different periods and cryopreservation methods were different (slow freezing in ICSI group and vitrification ICSI-Vit). This inconsistency may partially explain the benefit described. That point is being investigated.

Wider implications of the findings: Our results validate the vitrification of oocytes as an alternative to freezing embryos which may remain a real difficulty for various legal, ethical or religious reasons. ICSI-Vit program gives couples the opportunity to have multiple ICSI cycles with fresh embryo transfers in a context free of ovarian hyper-stimulation

Trial registration number: not applicable

P-135 Slow developing embryos undergoing compaction or cavitation on day 5 substantially contribute to live birth rates after single day 6 vitrified-warmed blastocyst transfer

J. Gunst[1], M. Vynck[2], A. Van de Vijver[3]

[1]AZ Sint Jan Brugge-Oostende, Laboratory Medicine - Centre for Reproductive Medicine, Brugge, Belgium ;
[2]AZ Sint Jan Brugge-Oostende, Laboratory Medicine, Brugge, Belgium ;
[3]AZ Sint Jan Brugge-Oostende, Centre for Reproductive Medicine, Brugge, Belgium

Study question: Does the status of slow developing embryos on day 5 and subsequent vitrification on day 6 impact clinical outcome in a vitrified-warmed transfer cycle?

Summary answer: Slow developing embryos that reach blastocyst stage by day 6 have a potential for live birth which is independent of the status on day 5.

What is known already: Transfer of a single blastocyst either in a fresh cycle or after vitrification / warming is becoming widely applied. An important aspect is the selection of the embryos that are eligible for transfer and/or for cryopreservation. Slow developing embryos on day 5, showing signs of compaction or cavitation, are either discarded or left in culture until day 6 for re-evaluation using scoring systems that assess blastocyst expansion and morphology of inner cell mass (ICM) and trophectoderm (TE). We investigated the potential of embryos that reached blastocyst grade >3 by day 6 in regard to clinical outcome after vitrification / warming.

Study design, size, duration: This single-center retrospective cohort study was undertaken between 2011/01 and 2018/12. Day 5 embryos with slow development, expressed as compaction or cavitation (blastocyst grade 1/2), were cultured to day 6. Blastocysts that had reached stage >3 were vitrified. We included 433 patients with 601 day 6 vitrified warmed blastocyst cycles resulting in 567 (94.3%) single vitrified warmed blastocyst transfers (SVBTs). Cycles with PGT, donor oocytes, re-vitrification and an aberrant day 5 status were excluded.

Participants/materials, setting, methods: Microdrop vitrification was performed using RapidVit Blast Kit/RapidVit Omni Kit (Vitrolife). Blastocysts were exposed to vitrification solutions 1&2 in microdroplets under oil, followed by solution 3 without oil and subsequent vitrification using a closed device (Rapid-i; Vitrolife). Warming was performed using RapidWarm kits, with no oil in Warm 1 solution followed by microdroplet warming in solutions 2, 3 and 4 under oil. All procedures were carried out at 37°C. Clinical outcome was assessed after SVBT.

Main results and the role of chance: For the 567 SVBTs that were performed on day 6, the status of development on day 5 was characterized as compaction (n=171; including embryos showing starting, partial and completed compaction; C), early blastocyst grade 1 (n=218; BL1) and blastocyst grade 2 (n=178; BL2). The percentage of day 6 SVBT with good quality blastocysts was 69.6%, 68.3% and 77.5% for status C, BL1 and BL2, and 30.4%, 31.7% and 22.5% for poor quality blastocysts, respectively. The overall resulting live birth rates (LBR) were 28.1% / 28.0% and 27.5% for day 6 SVBT from C, BL1 and BL2 derived embryos. LBR were higher for SVBT of good (BB or better) quality blastocysts (C: 29.4% / BL1: 30.2% / BL2: 31.9%) compared to those performed with poor (lower than BB) quality blastocysts (25.0% / 23.2% / 12.5%, respectively).

Considering the number of embryos included in this analysis, the LBR obtained from these slow developing embryos is unlikely to be a chance finding.

Limitations, reasons for caution: This is a single-center study, which was performed with a modified microdrop vitrification/warming protocol where all steps were carried out at 37°C and some steps did include an oil overlay. Thus, our results should be tested with a vitrification/warming protocol that uses room temperature.

Wider implications of the findings: Slow developing embryos on day 5 that reach blastocyst stage by day 6 substantially contribute to LBR in a vitrification/warming program. This holds even true for day 6 morphologically poor quality blastocysts. These findings, if confirmed, may challenge current practice to discard slow developing embryos on day 5 from vitrification.

Trial registration number: not applicable

P-136 Can monozygotic twinning in ART be explained by absence of zygotic polarization?

A. Mikich[1], G. Collar[1], M.I. Kulmann[2], M. Ferreira[3], S. Mattiello[3], N. Frantz[3]

[1]Federal University of Rio Grande do Sul, Morphological Sciences, Porto Alegre, Brazil ;
[2]Nilo Frantz Reproductive Medicine, Clinical embryology, Porto Alegre, Brazil ;
[3]Nilo Frantz Reproductive Medicine, Human Reproduction, Porto Alegre, Brazil

Study question: Is the absence of zygotic polarity associated with Monozygotic twinning (MZT) in ART cycles?

Summary answer: Yes, zygotic polarity was not observed in any of the zygotes that resulted in MZT. Enlarged periviteline space (PVS) and low Z-score were also detected.

What is known already: The incidence of MZT is increased after ART procedures. The origin of MZT associated with IVF is still unclear. Blastocyst culture and ICM splitting during hatching, ICSI and assisted hatching (AH) are some of the factors possibly associated with MZT. Little attention has been given to zygotic events that may contribute to monozygosity. Following sperm-oocyte interaction, pronuclei (PNs) develop and migrate toward a central position in the zygote. Alignment of PNs onto the polar axis is a fundamental event for normal first cleavage and development. Non-polarization leads to random ICM location in the blastocyst and anomalies in development.

Study design, size, duration: We retrospectively analyzed zygote images taken 16-17 hrs post-ICSI, from 14 frozen embryo transfer cycles that resulted in MZT gestations, between 2017 and 2019. The zygotes analyzed were the ones that gave rise to the blastocysts transferred in the 14 MZT gestations. Morphology of the transferred blastocysts and cycle characteristics were also examined.

Participants/materials, setting, methods: Observations of images and statistical analysis were carried out to investigate putative origin of MZT. The pattern of alignment of the PNs toward the polar bodies (PBs), angle between the PBs, periviteline space (PVS) and Z-score were assessed. Inner cell mass and expansion /hatching were assessed in day-5 blastocysts. Ovarian stimulation, oocyte number, fertilization rates, assisted hatching and cytogenetic analysis were considered. MZT was assessed by ultrasound at 6-7 and 8-9 weeks of gestation.

Main results and the role of chance: The transfer of a single blastocyst (7 cases) and of a single day-3 embryo (1 case) resulted in two GSs. One single blastocyst transfer resulted in three GSs, each with an embryo; another single transfer resulted in one GS with two embryos. When two blastocysts were transferred, two cases presented a single GS with two embryos and one case showed three GS with one embryo each. One double blastocyst transfer resulted in three GSs. 16 out of 18 zygotes did not present their PNs in alignment with the PBs. Two zygotes presented peripherally positioned PNs with their longitudinal axis aligned with one PB and the meridional axis aligned with the other PB. Majority of zygotes (15/18) presented a great angle separating the two PBs and an enlarged PVS (14/18). 12 zygotes scored as Z3-Z4 and 6 as Z2. ICM of eight blastocysts was large and tightly compacted, of seven embryos it formed two distinct cell masses. Blastocysts were expanded and 11 were herniating at transfer. There was no significant differences between the number of follicles, collected oocytes, fertilization rate, assisted hachting and cytogenetic analysis between the cycles with MZT and contemporary cycles that resulted in single gestation.

Limitations, reasons for caution: Results were based on observations made on zygotes and blastocysts of 14 IVF cycles. The occurrence of GSs derived from natural conception cannot be eliminated. A larger cohort of cases from different IVF centers should be studied to confirm our findings.

Wider implications of the findings: MZT represents an undesired IVF outcome, due to the possible adverse health consequences for the babies and their mothers. A careful zygotic assessment should be performed and taken into account, together with blastocyst ICM morphology, before elective single embryo transfer or double embryo transfer.
Trial registration number: N/A

P-137 The impact of single blastomere cell cycle duration of early cell division on blastocyst formation and blastocyst quality.

M. Kljajic[1], T. Krebs[2], D.H.A. Maas[2], N. Saymé[2]

[1]Saarland University Medical Center, IVF Laboratory, Homburg, Germany ; [2]Team Kinderwunsch Hannover, Department of Obstetrics- Gynecology & Assisted Reproduction, Hannover, Germany

Study question: Does the time duration of the second and third cell cycle for single blastomere affect blastocyst development and blastocyst quality?
Summary answer: The time duration of the second and third cell cycle strongly affects blastocyst development as well as blastocyst quality.
What is known already: In the last decade, the introduction of time-lapse technology enables almost continuous monitoring of embryo development. This technology generates comprehensive information regarding morphology and kinetics of embryo development and facilitates observation of dynamic, and often transient, events occurring between static observation periods. Together, these have been defined as 'morphokinetic' variables. Strong correlations between embryo kinetics and positive outcomes have been demonstrated in various studies. Some of the studies which involved cleavage time, cleavage interval, and cleavage synchrony reported that embryos with high developmental potential could be effectively identified using these parameters.
Study design, size, duration: Cell cycle duration is calculated using time-lapse, according to a single cell division. The injection time of ICSI was designated as "time zero" (t0), and computer software was used to calculate the time duration of the first (cc1a, t2-tPNf), second (cc2a, t3-t2; cc2b, t4-t2) and the third cell cycle (cc3d, t8-t4). Obtained results of cell cycle duration were later associated with the embryo capability to forming a blastocyst as well as with blastocyst quality.
Participants/materials, setting, methods: A total of 87 blastocysts from 20 patients undergoing an antagonist cycle for ICSI treatment between November 2019 and December 2019 were evaluated. All blastocysts were cultured in Embryoscope™ according to the manufacturer's specifications (Vitrolife, Sweden). The Gardner and Schoolcraft scoring system was used to describe blastocyst quality. Correlations between the data were calculated using logistic regression analysis. Statistical significance was defined as $p<0.05$. All statistical analyses were performed using SAS software.
Main results and the role of chance: Morphokinetic data showed that the time duration of first (cc1a), and second (cc2a; cc2b) cycle were significantly different between embryos that reached the blastocyst stage and those embryos that did not. The first cell cycle was calculated as a time difference between pronuclei disappearance and the first cell cleavage, where time duration was significantly different ($p<0.05$) in successfully formed blastocysts versus arrested or non-blastulating embryos. What is more this parameter as well significantly affects blastocyst quality ($p<0.05$). Almost the same results were obtained for the second cell cycle where was confirmed that duration of single blastomere division (cc2a: $p< 0.001$) and (cc2b: $p<0.01$) significantly correlate with blastocyst formation potential. Therefore, blastocyst quality was also affected by the time duration of a single blastomere division cycle (cc2a, $p<0.01$; cc2b, $p< 0.05$). On the other hand, the duration of the third cell cycle (cc3d) between embryos which successfully reached the blastocyst stage and those embryos that failed were not statistically significant. What is more, blastocyst quality neither was affected by this morphokinetic parameter.
Limitations, reasons for caution: The disadvantage of the relatively small patient cohort was balanced with a wider range of patients' age (25-37). Further research should link these morphokinetic parameters with pregnancy rate and live birth rate as well.
Wider implications of the findings: The potential of the present findings is considerable as we believe that these results are helpful for a better understanding of the association between embryo morphokinetic parameters and blastocyst development. Also, the present work illustrates the possibility of additional information that can potentially be incorporated into an embryo classification model.

P-138 Insights into early human development from abnormal fertilisation

G. Coticchio, Ph.D.[1], F. Gurioli[1], R. Sciajno[1], C. Lagalla[1], N. Tarozzi[1], M. Nadalini[1], C. Zacà[1], A. Borini[1]

[1]9.baby, Family and Fertility Center, Bologna, Italy

Study question: Does morphokinetic analysis of human abnormal fertilisation, one- (1PN) and three-pronuclear (3PN) fertilisation, offer cues to better understand the very early steps of development?
Summary answer: 1PN/3PN morphokinetic analysis gives insights into unknown aspects of fertilisation, concerning for example the role of the polar body, origin of pronuclei and pronuclear chromatin.
What is known already: The basic morphological attributes of human fertilisation have been known since the dawn of human IVF. For decades, such a knowledge has derived from static observation at a single time point. Initial application of Time-Lapse Microscopy (TLM) in the late 1990's revealed the beauty and morphokinetic complexity of fertilisation. However, in-depth dynamic observation of fertilisation has been pursued only in the last few years, with findings that have shed new light on cytoplasmic phenomena (e.g. the cytoplasmic wave and halo) and the importance of cell symmetry for embryo development. Unfortunately, abnormal fertilization has been largely neglected, despite potential for research.
Study design, size, duration: This retrospective study involved TLM observation of 378 normally (2PN) and abnormally (1PN and 3PN) fertilised oocytes utilised in ICSI cycles carried out between 2017 and 2019. Maximum three sibling fertilised oocytes (one normal and one or two abnormal) per patients were analysed to reduce possible patient-specific biases. Oocytes of patients with different diagnoses of infertility were included in the analysis, while cases involving cryopreserved gametes or surgically retrieved sperm were excluded.
Participants/materials, setting, methods: Microinjected oocytes were assessed by a combined TLM-culture system (Embryoscope). Oocytes not amenable to TLM assessment, due to excess of residual corona cells or inadequate orientation for observation of polar body II (PBII) emission, were not analysed. Fifteen parameters were identified and monitored, relevant to meiotic resumption, pronuclear dynamics, chromatin organization, cytoplasmic/cortical modifications and embryo quality. Diverse statistical tests were used depending on the numerical category of parameters compared between groups.
Main results and the role of chance: All major fertilisation phenomena – e.g. polar body II (PBII) extrusion, cytoplasmic wave, cytoplasmic halo presence and disappearance, PN migration, PN juxtaposition (where applicable) and nucleolar precursor bodies (NPB) redistribution – were discerned in the three PN categories. As a general trend, both 1PNs and 3PNs extruded the PBII with a delay of more than 0.6 hours ($P=0.0007$), but only 1PNs accumulated a developmental delay, starting from disappearance of the cytoplasmic halo, that amounted to almost 6 hours at the time of cleavage ($T=26.5$, 32.6 and 27.3 in 2PNs, 1PNs and 3PNs, respectively; $P<0.0001$). More intriguing finding, with significant developmental implications, derived from the observation of specific fertilisation events. For example: a) PBII extrusion was observed in the majority (45/75, 60%), but not all, of 1PNs and in a large proportion (61/136, 44.8%) of 3PNs; b) both the cytoplasmic wave and cytoplasmic halo were observed, not only in 2PN and 3PN, but also in all but one 1PNs; c) NPB clustering and localization in a confined nuclear region (NPB polarization) occurred in 2PNs (100%), 3PNs (96%) and, astonishingly, in most 1PNs (73%). Finally, on day 2/3, 1PNs were relatively more affected by developmental delay and blastomere fragmentation (data not shown).
Limitations, reasons for caution: This is a pilot study requiring extension and refinement of data, as well as independent verification.
Wider implications of the findings: These observations suggest a reappraisal of fertilisation. For example: 1PNs, with/without PBII emission, might be mono- or digynic, respectively; 3PNs not always derive by failed PBII extrusion; the cytoplasmic wave, generated by the microtubular aster, can form in the absence of the male pronucleus; NPBs polarize in isolated pronuclei.
Trial registration number: Not applicable

P-139 The impact of Vitrification in the outcome of IVF in an oocyte donation program.

P. Tatsi[1], T. Chartomatsidou[1], E.G. Papanikolaou[2], R. Najdecki[2], F. Chouliara[2], I. Asuchidou[2], C. Ioakeimidou[2], E. Timotheou[1]

[1]Assisting Nature, Embryology Laboratory, Thessaloniki, Greece ; [2]Assisting Nature, Clinical Department, Thessaloniki, Greece

Study question: How does Vitrification and double Vitrification (cryopreserved embryos produced from cryopreserved oocytes) affect the result of an oocyte donation program?
Summary answer: Oocyte and embryo Vitrification does not affect the outcome of IVF with donor oocytes. However, cryopreserved embryos from vitrified donor oocytes exhibit reduced implantation potential.
What is known already: Vitrification of oocytes, embryos and blastocysts is successfully performed worldwide in IVF Treatments and Oocyte Donation Programs. Vitrification of Oocytes and Embryos does not impair oocyte and embryo viability or implantation potential. No statistically significant difference is observed in the outcome after blastocyst embryotransfer originated from fresh versus vitrified donor oocytes. In addition, embryos derived from fresh donor oocytes show an extremely high implantation potential and exceptional clinical pregnancy and live birth rates. On the other hand, few is known regarding cryopreserved embryos that were produced from cryopreserved donor oocytes.
Study design, size, duration: This study was conducted between January 2015 and December 2018 to examine the impact of Vitrification and compare the pregnancy and live birth rate after embryotransfer of day 5 embryos of fresh oocytes-fresh embryotransfer (FROFRE) versus vitrified donor oocytes-embryotransfer (CROFRE) and cryopreserved embryos derived from fresh oocytes (FROCRE) and cryopreserved embryos originated from cryopreserved oocytes (CROCRE). A total of 425 donations were included in the study.
Participants/materials, setting, methods: A total of 425 oocyte recipient cycles were included in the study. 111 FROFRE cycles, 92 CROFRE cycles, 184 FROCRE and 38 CROCRE cycles. 896 fresh oocytes were utilized in FROFRE cycles and 736 vitrified oocytes were thawed and used in CROFRE cycles. ICSI was implemented in all cases and embryotransfer and vitrification was performed on day 5 on blastocyst stage. Positive hCG, clinical pregnancy and live birth rates were monitored.
Main results and the role of chance: Positive β-hCG, clinical pregnancy rate and live-birth rate per embryotransfer were compared between our groups, FROFRE-CROFRE-FROCRE-CROCRE. Furthermore, embryo quality and blastulation rate was similar among fresh donated oocytes and from vitrified oocytes. β-hCG was 69%, 59% and 54% between FROFRE, FROCRE and CROFRE groups respectively. No statistically significant difference was observed in the clinical pregnancy rate, which was 55% (FROFRE), 52%(FROCRE) and 47%(CROFRE) and the live birth rate 46% (FROFRE), 44% (FROCRE) 42% (CROFRE). The CROCRE cycles exhibited the lowest rates 35% (β-hCG), 19% (clinical pregnancy) and 15% (live birth). Oocyte vitrification and warming is common and effective method of delivering donor oocytes to patients and success rates all over the world are as high and similar to results in fresh donor egg cycles. One remaining question is if these previously frozen oocytes, once warmed, inseminated and cultured to later embryonic stages can be again re-vitrified and warmed with similar results as in fresh oocyte donation cycles. According to our findings there is a significant impact of double-vitrification in pregnancy and live birth rates.
Limitations, reasons for caution: Although our primary results show that clinical impact in success rates of double-vitrification is significantly impaired in our oocyte donation program, this needs further investigation in larger randomized studies. Few CROCRE cases were included and the embryos studied were chosen for second, third or final embryotransfer after previous CROFRE cycle.
Wider implications of the findings: It is important to study and perceive if embryos derived from vitrified donor oocytes perform similarly to fresh oocytes after double vitrification and warming. The couples interested in oocyte donation and IVF treatments should be thoroughly informed about their options and success rates.
Trial registration number: Not Applicable

P-140 Clinical pregnancy and perinatal outcomes of twice-frozen-thawed embryo transfers: a retrospective comparative study

B. Cai[1], W. Yali[1], X. Yanwen[1], Z. Canquan[1]

[1]First Affiliated Hospital of SunYat-sen University, reproductive medicine center, Guangzhou-Guangdong, China

Study question: Dose repeated-frozen-thawed human embryos can achieve comparable clinical pregnancy and perinatal outcomes to conventional once frozen-thawed embryos ?
Summary answer: Acceptable clinical outcomes could be expected from transfer of recryopreserved blastocysts, while perinatal outcome was not affected and clinical pregnancy parameter was lower but not significant.
What is known already: Vitrification is becoming the most widely adopted embryo cryopreservation technique for higher embryo survival rate and live birth rate than other methods.In order to avoid the risk of multiple pregnancies, most countries recommend reproductive centers to transfer only one blastocyst per cycle, causing surplus of surviving embryos might occasionally be used in FET cycles. But to our knowledge, limited data was available for FET outcome with twice cryopreserved human embryos, and the sample size was small .With the increase number of repeated cryopreserved embryo transfer cycles, the impact of repeated-frozen-thawed manipulate to clinical pregnancy outcomes needs further to be elucidated.
Study design, size, duration: The purpose of this retrospective cohort study was to evaluate the pregnancy and perinatal outcome of revitrified human day5/6 blastocysts derived from surplus of surviving blastocysts in the last FET cycles. Cohorts of 320 transfered blastocysts with either twice-frozen-thawed and once-frozen-thawed between January 2016 and December 2018 were included in the study. Only IVF/ICSI cycles were included,PGT cycles were excluded. Match-pair analysis was used to control for some patient basic characteristics,then compared two groups.
Participants/materials, setting, methods: During the match-pair analysis, we paired twice-frozen-thawed and once-frozen-thawed groups' patients data through maternal Age,body mass index, endometrial thickness. The two groups' paired ratio was 1 (80 cycles):3 (240 cycles). The total 320 transfered blastocysts gave live birth to 105 infants, of which twice-frozen-thawed (22 infants) and once-frozen-thawed groups (83 infants). Finally,we compared clinical pregnancy outcome parameters between the two groups,included implantation,clinical pregnancies,live deliveries, miscarriage rate, infants' birth body length, birth weight and so on.
Main results and the role of chance: We regarded once-frozen-thawed FET as the control group to compare with twice-frozen-thawed FET group. By statistical comparison(twice-frozen-thawed versus control),we found maternal age(31.60±4.24 versus 32.33± 4.34, P >0.05,), body mass index (21.62±3.34 versus 22.53± 4.74kg/m², P >0.05), endometrial thickness (9.78±1.54 versus 9.53± 1.64, P >0.05), Embryo transfer cycles(2.11±1.34 versus 2.83± 1.55, P >0.05) and number of embryos transferred (1.0 versus 1.0, P >0.05) were all not significantly different between two groups. While clinical pregnancy rate(36.25% versus 46.25%,P >0.05) , implantation rate (36.25% versus 46.25%, P >0.05) and live birth rate (27.50% versus 34.58%, P >0.05) were all lower in twice-frozen-thawed group,but the difference was not significant by the Chi-square test .Unexpectedly , miscarriage rate (7/29-24.14% versus 29/111-26,13%,P >0.05) was lower in twice-frozen-thawed group but not significantly. As for the perinatal data, no significantly differences were observed in gestational age(38 w±3.4d versus 38 w±5.3d, P >0.05), sex ratio(11/11 versus 48/35,Boy/Girl), birth body length (49.15±4.12cm versus 49.09±3.88 cm, P>0.05) and birthweights (3220.00±422.3 g versus 3116.99±453.6, P>0.05) between groups. Likewise, in the live birth individuals,there were no significant differences between the two groups on the incidence of pre-term birth (3/22 versus 11/83), low birthweight(2/22 versus 7/83), small for gestational age, large for gestational age and macrosomia.
Limitations, reasons for caution: Because the refrozen group's sample size was limited,we did not distinguish some confounding factors associated with clinical pregnancy outcomes, included type of infertility,cause of infertility, different development stage,and the embryo morphological score,insemination method,endometrial preparation protocol , embryo cryopreservation duration and the long-term effects of re-vitrification method on offspring's health outcomes.
Wider implications of the findings: The results provide feasibility to use refrozen blastocysts in FET which can obtain an acceptable clinical outcome expectation ,when there is no other primary cryopreservation blastocyst to choose. Meanwhile, patients should be fully informed of possible reduction in clinical outcome parameters.
Trial registration number: not applicable

P-141 Comparison of clinical results of embryo culturing using last generation incubators: is there a better option?

M.D.L.Á. Valera Cerdá[1], C. García Gimeno[1], L. Bori Arnal[1], J.M. De los Santos Molina[2], A. Pellicer Martínez[3], M. Meseguer Escrivá[2]

[1]IVIRMA, Research Laboratory, Valencia, Spain ;
[2]IVIRMA, IVF Laboratory, Valencia, Spain ;
[3]IVIRMA, President- Reproductive Medicine, Valencia, Spain

Study question: Is there a significant difference in clinical results using different last generation time-lapse incubators (TLM) for embryo culturing, using benchtop incubators (CI) as a reference?
Summary answer: We did not find significant differences in pregnancy and implantation rates between last generation incubator systems. When grouped, TLM showed better outcome compared to CI.
What is known already: Time-lapse systems (TLM) bring to IVF laboratories a clear advantage, providing new information of embryo development without perturbing their culture. However, their performance as incubators must be tested versus those conventional benchtop incubators (CI), to assure they provide a proper environment for embryo culturing. To date, there is insufficient evidence of actual significant differences in clinical outcomes varying on the type of incubator used, although some studies show a slight improve with time-lapse systems. Previously published studies have found a significant increase in good-quality blastocyst and euploidy rates using time-lapse incubators. However, comparative studies on the matter are usually incomplete.
Study design, size, duration: We present a retrospective study including 8446 ICSI cycles performed in IVIRMA Valencia from two consecutive years, both with own and donated oocytes. Fertilized oocytes were cultured until blastocyst stage using different systems: CI (Astec, Japan) or incubators with TLM, including Embryoscope, Embryoscope Plus (Vitrolife, Denmark) and Geri (Genea, Australia). Out of 26100 viable embryos, 9817 were selected for transfer, 7574 in single embryo transfer (SET), with clinical outcome data of 9103 transferred embryos available.
Participants/materials, setting, methods: All incubators included in the study are well stablished and routinely used in the clinic for embryo culturing. Scoring and selection for transfer or freezing were performed according to the ASEBIR criteria, by morphological assessment combined with morphokinetic selection methods. A statistical analysis was performed for comparing clinical results between incubators, using the Statistical Package for Social Sciences (SPSS). Results are presented as pregnancy, ongoing pregnancy and implantation rates per incubator, separately by oocyte origin.
Main results and the role of chance: The statistical analysis shows that there is no significant difference in the clinical results of cycles using the different types of TLM. For autologous cycles, the pregnancy rate of fresh transferred embryos (N=744) was 59.4% for Embryoscope (ESD), 64.1% for Embryoscope Plus (ESD+) and 61.7% for GERI (P=0.305). For Egg donation cycles, having a total of 2384 transferred embryos, pregnancy rates resulted in 72.9% for ESD, 74.1% for ESD+ and 69.3% for GERI (P=0.173). Regarding implantation rates, in procedures with own oocytes resulted in 48.14% using ESD, 50.35% for ESD+ and 50.79% using GERI incubators (P=0.855). As results for cycles with donated oocytes, the implantation rate was 61.42% for ESD incubators, 61.99% for ESD+ and 58.78% with GERI, not having a statistically significant difference (P=0.288). When comparing CI with TLM for autologous cycles, the pregnancy rate of fresh transferred embryos was 69.0% for TLM and 66.1% for CI (P=0.046), while ongoing pregnancy also resulted significantly higher in the standard cycles when compared TLM 60.9% vs CI 54.5% (p=0.047).
Limitations, reasons for caution: Other variables should be assessed as well, such as embryo quality, good-quality embryo rate and life-birth rate per incubator. Furthermore, this study only compares four types of incubator but there are many more available.
Wider implications of the findings: The results of this study can serve as a quality check of the procedures in the clinic. It reassures that all TLM used in the clinic yield similar results and there is no bias in the clinical results depending on which TLM is used.
Trial registration number: Not applicable

P-142 Increased DNA fragmentation in blastocysts triggers the release of miR-294 in spent culture medium

D. Makri[1], W. Maalouf[1]

[1]University of Nottingham, Child Health- Obstetrics- and Gynaecology, Nottingham, United Kingdom

Study question: To study whether extended apoptosis in embryonic blastomeres enhance the packaging and release of miR-294 by blastocysts.
Summary answer: Induced DNA fragmentation at the early blastocyst stage causes increased release of miR-294 in the culture medium.
What is known already: MicroRNAs are important regulators of cell signaling, growth, and cell death. Pre-implantation embryos release microRNAs in the surrounding micro-environment and cell-free microRNAs reflect on the quality and ploidy status of embryos. It is known that miR-290 members are regulators of apoptosis in cells. In pre-implantation embryos, miR-294 levels in media directly correlate with apoptosis in the blastomeres. However, there is a lack of mechanistic explanation behind this observation. It is not clear whether high miR-294 in cells causes DNA fragmentation or increased apoptosis results in intense release of miR-294, which could serve a secretory function.
Study design, size, duration: Mouse zygotes (N=28) were cultured to the small blastocyst stage. At this stage, UV radiation was used to induce DNA damage in order to mimic the final stages of apoptosis. The culture was extended to allow for cellular responses to DNA damage. The blastocysts were stained at Day 5 of development to verify DNA damage. Media samples were individually processed and analysed for miR-294. UV-treated and control samples were compared for microRNA levels (t-test).
Participants/materials, setting, methods: Frozen mouse zygotes (B6C3F-1 x B6D2F-1) were cultured at 37°C, 5% CO_2 to the early blastocyst stage. The blastocysts (N=15) were exposed to UV radiation (5 s, 302 nm) and cultured for 16 more hours. Control embryos were cultured in parallel (N = 13). The embryos were stained with the TUNEL method to assess DNA damage. Media samples (20µl) were individually analysed for miR-294 expression using PCR technology.
Main results and the role of chance: UV radiation can be used to induce DNA damage and study apoptosis-triggered mechanisms. For embryos, exposure to 302 nm for 5 s at the early blastocyst stage causes increased DNA breakage but maintains blastocyst viability for enough time to investigate molecular changes. The direct effects of UV radiation on DNA breakage was verified, with the UV-treated group showing higher extent of apoptosis (and reduced cell count) compared to the control embryos. The average miR-294 Ct in the SCM of the UV group was 25.1 ± 1.1 (ΔCt 6.3 ± 1) and in the control group 27.1 ± 1.5 (ΔCt 8.3 ± 1.5). The results from the t-test showed that the blastocysts with UV-induced DNA damage released significantly more miR-294 in the media compared to controls ($p<0.01$).
Limitations, reasons for caution: These results are limited to mouse embryos and further research is needed for applications in other species.
Wider implications of the findings: UV radiation is a useful approach to mimic the last stages of apoptosis and study related cellular responses. Apoptosis in pre-implantation embryos triggers the intense packaging and release of miR-294 in the extra-cellular environment with possible actions as a singaling molecule for communication with the endometrium.
Trial registration number: Not applicable

P-143 Oocyte central granularity is associated with reduced fertilization rates and altered fertilization dynamics

C. Moutier[1], M.C. Guglielmo[1], P.V. Novara[1], F. Brambillasca[1], A. Bartolacci[1], M. Mignini Renzini[1], M. Dal Canto[1], J. Buratini[1]

[1]Biogenesi Reproductive Medicine Centre, Istituti Clinici Zucchi, Monza, Italy

Study question: Is cytoplasmic central granularity (CCG) in oocytes associated with alterations in fertilization rates and dynamics?
Summary answer: Oocyte CCG is associated with reduced fertilization rates, as well as delayed pronuclei disappearance and first cell division after ICSI.
What is known already: Oocyte quality is a major determinant of ICSI success. Oocytes are routinely selected according to morphological criteria before ICSI, but the relationship between different oocyte morphological features and developmental competence is not entirely known. Oocyte CCG is associated with alterations in the actin cytoskeleton and meiotic spindle, both playing critical roles in meiosis completion, pronuclei formation and all steps of embryo mitotic divisions. Faster fertilization morphokinetics is associated with higher rates of embryonic development.
Study design, size, duration: We performed a retrospective analysis comparing fertilization rates and fertilization morphokinetic parameters of control (morphologically normal) and CCG oocytes, obtained from patients under 40 years of age subjected to ICSI in our Fertility Centre from January 2016 to July 2019. ICSI cycles were selected in order to equally distribute infertility factors in both experimental groups. Morphokinetic parameters were assessed by time-lapse technology.
Participants/materials, setting, methods: A total of 1075 metaphase II oocytes were injected by ICSI obtaining an overall fertilization rate of 76,5% (823/1075). Morphokinetic parameters until the first division were compared

between CCG and control oocytes (n=141/group). Maternal age and body mass index (BMI) did not differ between experimental groups (CGC: age=34,44 ± 3,13; BMI=23,35 ± 4,13. Control: age=34,40 ± 3,14; BMI=22,64 ± 3,42).
Main results and the role of chance: Fertilization rate was significantly lower in CCG oocytes compared to control [69,1% (141/204) *vs.* 78,3% (682/871); p < 0,01]. Time of pronuclei fading was longer (p = 0,02) for CGC oocytes compared to control oocytes (24,52h ± 3,39 and 23,72h ± 4,13 respectively). The first mitotic division was delayed in embryos obtained from CCG oocytes compared to control embryos (27,43h ± 3,57 *vs.* 26,53h ± 3,88 respectively, p = 0,02).
Limitations, reasons for caution: The retrospective nature of the study and the need of further studies to assess if CCG is also associated with subsequent embryo competence to implant and provide a live birth.
Wider implications of the findings: Our study contributes to a better understanding of the relationship between oocyte morphology and quality, while providing valuable references for the improvement of ICSI outcomes.
Trial registration number: Not Applicable

P-144 A metabolomics approach to identify aneuploid embryos to increase the effectiveness of ART cycles

S. Cabello-Pinedo[1], H. Abdulla[2], M.L. Seth-Smith[1], M. Escriba[3], J. Crespo[3], S. Munné[1], J.A. Horcajadas Almansa[1]

[1]Overture Life SL, Scientific department, Madrid, Spain ;
[2]Texas A&M University Corpus Christi, Chemistry, Corpus Christi, U.S.A. ;
[3]Juana Crespo Clinic, Embryology, Valencia, Spain

Study question: Can euploid embryos be identified in a non-invasive manner by measuring the concentration of specific metabolomic biomarkers in spent culture media?
Summary answer: Specific metabolites in embryo spent culture media are correlated with euploidy status of blastocyst stage embryos.
What is known already: Embryo Implantation potential and euploidy rates decrease with advancing maternal age. Preimplantation Genetic Testing (PGT) has been used to avoid the transfer of aneuploid embryos, which would not result in a successful pregnancy. However, embryo biopsy is invasive and operator-dependent resulting in wide variability in pregnancy rates. Although DNA can be detected in spent media, correlation with trophectoderm biopsy varies widely between different studies. Recently, metabolomics studies on spent culture media have shown promising results to predict implantation potential. In this study we aim to determine if euploidy status can also be ascertained by non-invasive metabolomics analysis.
Study design, size, duration: This study includes spent media samples collected before trophectoderm biopsy from embryos that were later analyzed by PGT (NGS). Among them, 60 out of 116 were classified as aneuploid, 42 as euploid and 14 as mosaic. Samples were analyzed to find metabolites differentially abundant in the different embryo groups, leading to the definition of a method that allows selection of euploid embryos for transfer without the need for biopsy avoiding possible damage to viable embryos.
Participants/materials, setting, methods: Patients undergoing PGT were included in this study. Spent media samples were collected just before biopsy, ultrafiltered to remove molecules >3KDa and run through a UPLC- Fusion Orbitrap MS/MS system at 500,000 FWHM mass resolution. Different machine learning techniques were applied to reduce the huge number of metabolites to a limited number of informative biomarkers for euploidy.
Main results and the role of chance: The analysis of mass spectrometry (MS) led to the identification of a sub-set of biomarkers whose concentration differed between aneuploid, euploid and mosaic embryos. The concentration of this subset of biomarkers was increased in aneuploid embryos and reduced in euploid and mosaic embryos. Fifty-four out of the 60 aneuploid embryos (90%) showed a reduced concentration of aneuploid profile specific metabolites and different from euploidy.

The challenge of this study relies on the wide range aneuploidy profiles found in blastocysts, from monosomies to trisomies for each possible chromosome, alone or in combination with other abnormalities. Each aneuploidy may produce different metabolic alterations, resulting in very diverse and heterogenous metabolic profiles. Given the diversity of the aneuploid group, and the positive identification of such profiles into the aneuploid category, the sub-set of identified biomarkers are probably definitory of a particular\specific metabolic profile and could hardly be found by chance.
Limitations, reasons for caution: The study was retrospective but a prospective clinical trial is underway. In addition, all the samples were collected in the same clinic using the same culture media. The test needs to be validated in multiple clinics and culture media.
Wider implications of the findings: 90% aneuploidy positive identification without biopsy is as high as the highest reported NI-PGT results. Further advantages of metabolomics is that is cheaper than NI-PGT (NGS) and does not require change in embryology protocols. Combined with markers for embryo viability other than euploidy might yield further improvements in embryo selection.
Trial registration number: NA

P-145 A new role of Repulsive Guidance Molecule C as a ligand of neogenin enhanced in follicular development of ovary in the mouse

J.H. Lee, Ph.D.[1,2], Y.J. Kim[1], K.H. Choi[3], K.Y. Kang[3], H.S. Kim[3], H. Jeong[3], H. Kang[4], Y.R. Park[3], S.J. Kim[5], M.K. Kwon[5], H.O. Kim[5], M.K. Koong[5], Y.S. Kim[5], T.K. Yoon[5], J.J. Ko[2]

[5]CHA Fertility Center Seoul Station, IVF Clinic, Seoul, Korea- South

Study question: In the ovary, Repulsive Guidance Molecule c (RGMc) stimulated neogenin signal has a specific function for follicle development and oocyte maturation?
Summary answer: Neogenin is specifically localized at the follicle and RGMc as ligand promotes follicle development and the maturation of the oocyte in the ovary.
What is known already: Neogenin has reported a gene level expression in the mammalian ovary. However, neogenin as a multiple function receptor remains unknown as the main role and ligand for folliculogenesis in the ovary of mammals.
Study design, size, duration: This is an animal model study for the role of and RGMc as a ligand of neogenin during the follicular development phase in the ovary of the mouse. We compared the study between controls (n=25 head) versus RGMc treatment (n=25 head) groups. We analyzed the follicular development ratios of mouse ovary with RGMc + PMSG induction. And we study uP- and down-regulation whole transcriptome clusters of RGMc treated ovary.
Participants/materials, setting, methods: We identified the gene, the protein expression of neogenin and the localization in the ovary. Then we studied the role of the neogenin through superovulation by PMSG with RGMc treatment as a ligand of neogenin for *in vivo* follicle development activation. And afterwards, we performed an entire transcriptome next generation sequencing process for the identification of the RGMc effect, which linked the specific factors to the follicle development in the ovary.
Main results and the role of chance: Neogenin is abundantly expressed in the ovary and located at the developmental oocyte phase from primordial and antral follicles. Therefore, the RGMc treated ovary exhibits a 40% increase in the number of follicles compared with the control ovary. And RGMc treated ovary present Oct3/4, Nanog, p63, and Neogenin significantly higher gene expressed than control ovary. The especially experimental group, Nanog and p63 three times higher expression than the control group. In the western blot data also present similar pattern like RT-PCR. To identify the transcriptomic signature between RGMc-treated and control mice, RNA-seq was performed. As a result, total of 275 genes was differed by more than 4-fold change between the RGMc-treated and control groups. Among the total 275 genes, 197 and 78 genes were relatively uP-regulated in RGMc-treated and control group, respectively (Figure 4A and 4B). The 197 genes overexpressed in the RGMc group were significantly enriched to cilium organization, axonemal dynamin complex assembly, microtubule bundle formation, icosanoid metabolic process, prostaglandin metabolic process, and prostanoid metabolic process. The 78 genes down-regulated in the RGMc group were significantly enriched to ovulation cycle process, hormone biosynthetic process. Specifically, RGMc treated ovary shows specific uP-regulation factors as a prostaglandin linked signal.
Limitations, reasons for caution: This study did not the analysis of the human samples because of animal experiments for follicle development and oogenesis. Therefore, further investigations aimed specific analysis of RGMc in human at improving controlled ovarian hyperstimulation study with RGMc of poor ovarian response.

Wider implications of the findings: RGMc as a ligand of neogenin involved follicle development and maturation of oocytes. RGMc stimulated the PSDN signaling pathway for follicular development. This platform can apply to poor ovarian responses as a specific stimulator for enhanced follicle development for the *in vitro* fertilization patients of the poor ovarian responder.
Trial registration number: 2018R1D1A1B07050138, 2018R1C1B5045516, 2018R1D1A1B07044016 and 2019R1A2C1086882.

P-146 Soluble protein Cripto-1 promotes aberrant cell divisions in human embryonic cells

V. Porokh[1], P. Vanhara[1], Z. Holubcova[2], A. Hampl[1]

[1]Masaryk University- Faculty of Medicine, Histology and Embryology, Brno, Czech Republic ;
[2]Reprofit International- Clinic of Reproductive Medicine, Research&Development, Brno, Czech Republic

Study question: Do secretory factors present in culture media affect the fidelity of mitotic divisions during preimplantation embryo development?
Summary answer: Cripto-1 signaling induces the formation of multipolar mitoses hence increasing the risk of aneuploidy in early human embryogenesis.
What is known already: Mitotic errors are common in preimplantation development. Abnormal segregation of genetic material results in aneuploidies, spontaneous abortions, and birth defects. Despite its major importance for assisted reproduction, our knowledge of molecular mechanisms governing cell division in early human embryos remains rudimentary.
Study design, size, duration: A basic research study involving low-passaged human embryonic stem cells (hESCs; lines CCTL12, CCTL14, MUES1) and spent cultivation media from 30 IVF cycles. Media from successful cultures with >80% fertilized eggs developing into blastocysts (n=15) were compared with cultivations in which all embryos arrested in cleavage stage (n=15). A combination of microscopic and immunoanalytical assays was used to investigate the link between embryonic secretome and cell division errors.
Participants/materials, setting, methods: The pluripotent stem cells were derived from the inner cell mass of human blastocysts donated for research. The single-step medium (CSCM-C, Irvine) from each group culture was collected on the day-5/day-6 following ICSI and frozen in -20°C prior to analysis. The immunoaffinity proteomic array and ELISA were performed to assess soluble factors in the stem cell/human embryo microenvironment.
Main results and the role of chance: Immunofluorescent staining of cultured hESCs revealed that 9-15% of mitotic cells exhibited supernumerary centrosomes and aberrant mitotic spindles. The presence of more than 2 centrosomes and the formation of multipolar division apparatus was found to promote the incidence of aneuploidy in later stem cell generations. Immunoaffinity assay of 120 soluble proteins detected 18 molecules that were specifically produced by low passage hESCs with a high incidence of multipolar mitoses. Functional experiments led to the identification of the soluble form of Cripto-1protein as a factor capable to induce multicentrosomal phenotype. To complement results from the hESCs model, the analysis was undertaken on the spent media from human embryo cultures. Our finding that the soluble Cripto-1 was enriched in the microenvironment of human embryos which failed to reach the blastocyst stage supports the notion that this secretory molecule adversely affects genomic stability during preimplantation development.
Limitations, reasons for caution: The limitation of this preliminary study must be interpreted with caution due to the small study size. Further research is needed to evaluate whether the secretion of Cripto can be used as a negative indicator of embryo´s developmental competence in clinical practice.
Wider implications of the findings: Here, we present soluble Cripto-1 as a potential inducer of multipolar mitosis that may compromise the developmental potential of human embryos. The future investigation of soluble factors in the spent embryo culture medium holds the potential to discover novel non-invasive biomarkers of human embryo quality and developmental potential.
Trial registration number: not applicable

P-147 Effect of Hazardous Air quality index on embryo development in an IVF laboratory in New Delhi, India

G. Kant[1], K.D. Nayar[1], M. Singh[1], S. Draboo[1], H. Sharma[1], F. Khan[1], S. Gupta[1], R. Bhattacharya[1], D. Nayar[1]

[1]Akanksha IVF Centre, Reproductive Medicine, New Delhi, India

Study question: Does the hazardous atmospheric air can impact embryo development in the IVF laboratory even after standard air quality management and use of air filters?
Summary answer: There was a decrease in key performance indicators of IVF lab with increased fragmentation, poor embryo development and reduced reproductive outcome.
What is known already: According to WHO survey amongst 1650 cities in the world, Delhi the capital has worst air quality. With the air quality index falling drastically from Moderate (101-200) level between January to September to severe or hazardous (500+) level from October to December. The factors for poor air quality is stubble burning, road dust, cold weather and vehicle pollution. Studies have supported that air quality is critical to embryo development and for overall success of IVF. Both animal and human studies have suggested an association between poor air quality conditions and impaired embryo development, resulting in decreased implantation and pregnancy rates.
Study design, size, duration: A retrospective study was conducted from 1st January to 31st December 2019. Patients were divided in 2 groups. Group (A) from October to December, when atmospheric air quality was hazardous and Group (B) patients from January to September, when atmospheric air quality was within normal range. Both groups were compared on the basis of fertilisation rate, fragmentation rate, Day 3 grade A embryo development rate, implantation rate and clinical pregnancy rate.
Participants/materials, setting, methods: All patients undergoing fresh day 3 embryo transfers from the month of January to December were included. Out of the total 276 patients, 60 patients had their embryo transfer in the month of October to December (study group), while 216 were those from month of January to September (control group). Same culture media was used throughout the period. There was no change in clinical or embryology team.
Main results and the role of chance: The average AQI in Delhi was recorded around 500 between October to December 2019, while the maximum was recorded more than 1200. The quality of atmospheric air was correlating with the quality of embryo development. In group A (Oct-Dec). Fragmentation rate was significantly higher in Group A than Group B.(Fragmentation <10% : 53.03% vs 70.6%; p= 0.00001, Fragmentation 10-20% :30.80% vs. 18.78%; p=0.0002, Fragmentation >20%: 16.16% vs 10.6%; p=0.029). There was also a statistically significant decline in fertilization rate (62.5% vs. 70.07%, p=0.008), Day 3 A grade embryo formation rate (53.03% vs 70.6%; p=0.00001), Implantation rate (11.6% vs 25%; p=0.011), Clinical Pregnancy rate (15.7% vs 43.1%; p=0.025).
Limitations, reasons for caution: Multi centric studies are needed to strengthen these results.
Wider implications of the findings: We have demonstrated that poor atmospheric air during October to December in Delhi INDIA has a negative impact on embryo development which also decreases reproductive outcome even after standard air quality management. During this period either case can be avoided or more stringent air quality should be maintained.
Trial registration number: MCDH/2019/09

P-148 Does the number of oocytes affect the cumulative clinical pregnancy rate following the transfer of all frozen–thawed embryos

L. Kedar[1,2], A. Ben-Haroush[1,2], A. Wertheimer[1,2], O. Sapir[1,2], E. Shlush[1,2], Y. Shufaro[1,2], G. Oron[1,2]

[1]Belinson, Belinson Infertility and IVF Unit- Helen Schneider Hospital for Women- Rabin Medical Center- Beilinson Hospital, Petach Tikva, Israel ;
[2]Tel-Aviv University, Sackler Faculty of Medicine, Tel-Aviv, Israel

Study question: Does the number of oocytes affect the cumulative clinical pregnancy rate from the transfer of all frozen-thawed embryos.
Summary answer: The cumulative pregnancy rate from frozen-thawed embryo transfers is strongly related to the number of oocytes retrieved, regardless of the fresh transfer outcome.
What is known already: Recent studies show that the number of oocytes retrieved is correlated with the live birth rate of the fresh embryo transfer. While most studies have addressed the outcome of the fresh embryo transfer, only limited data is available on the cumulative pregnancy rate following the transfer of all fresh and frozen-thawed embryos in patients that utilized all their embryos which is the most significant outcome.
Study design, size, duration: The study included all oocyte collection cycles between January 2009 and September 2019 in a tertiary medical center that had

a fresh embryo transfer and utilized all their frozen-thawed embryos originating from the same cohort of retrieved oocytes.
Participants/materials, setting, methods: Cumulative pregnancy rate was calculated as any pregnancy from a transfer of frozen-thawed embryos originating from the same cohort of retrieved oocytes. The number of oocytes was divided into quartiles and the cumulative pregnancy rate from the frozen-thawed embryos was calculated in each group. Logistic regression analysis was utilized to adjust for potential confounders including maternal age, treatment cycle number, primary or secondary infertility, fresh embryo transfer outcome and the number of oocytes retrieved.
Main results and the role of chance: During the study period, there were 1,306 oocyte retrieval cycles that had a fresh embryo transfer and utilized all their frozen-thawed embryos originating from the same cohort of retrieved oocytes. In the first quartile (Q1) 1- 8 oocytes were retrieved (n=369), Q2 (25-50%) 9-11 oocytes (n=263), Q3 (50-75%) 12-16 oocytes (n=399) and Q4 (>75%) >17 oocytes (n=275). The cumulative pregnancy rate from frozen-thawed embryo transfers originating from the same cohort of retrieved oocytes increased with the number of oocytes retrieved Q1 76/369 (20.6%); Q2 87/263 (33.1%); Q3 137/399 (34.3%); Q4 106/275 (38.5%) p<0.001. This increase in the cumulative clinical pregnancy rate was significant with the number of oocytes retrieved among patients who conceived in the fresh transfer and (p=0.002) of those who did not (p=0.01). On a logistic regression model, maternal age and the number of oocytes were significant independent predictors for a cumulative clinical pregnancy rate from the frozen-thawed embryo transfers regardless if a pregnancy was achieved in the fresh transfer.
Limitations, reasons for caution: The limitation of the study is in the retrospective nature of the study.
Wider implications of the findings: Our findings might challenge the concept of optimal stimulation when looking at the cumulative pregnancies arising from transfer of all frozen-thawed embryos originating from the same cohort of retrieved oocytes. With agonist triggering and freeze all strategy, targeting for a higher stimulation is not only safe but also quite effective.
Trial registration number: not applicable

P-149 Deep learning model for improving embryo selection and deselection

A. Polsky[1], D.H. Silver[1], M. Feder[1], Y. Gold-Zamir[1], S. Rosentraub[1], E. Shachor[1], A. Weinberger[1], P. Mazur[2], V.D. Zukin[2], A.M. Bronstein[3]

[1]Embryonics- Ltd., Research and development, Tel Aviv, Israel ; [2]Clinic of Reproductive Medicine 'Nadiya'- Kyiv- Ukraine, Embryology, Kyiv, Ukraine ; [3]Technion – Israel Institute of Technology, Computer Science, Haifa, Israel

Study question: Can time-lapse imaging files of developing embryos be used as input for a deep learning algorithm to improve implantation probability predictions?
Summary answer: Application of time-lapse imaging files to a deep learning algorithm produced higher positive and negative predictive values than an external panel of embryologists.
What is known already: Although manual annotation and quality assessment of embryos fertilized in vitro remains the gold standard for embryo selection, efforts to improve embryo outcome prediction have become increasingly computational with research progressively turning toward artificial intelligence (AI). The majority of AI-based algorithms for embryo selection either require user-defined input parameters, or use little of the available embryo information (e.g., still images as opposed to time-lapse). Moreover, published algorithms often do not report clinically relevant performance metrics, making it difficult to transition the results from research to the clinic.
Study design, size, duration: The dataset consisted of 8,789 retrospectively collected time-lapse videos from embryos cultured to the blastocyst stage. Initial training of a machine learning (ML) model, UBar, was executed on 4,087 of the embryos, which were graded by an external panel of embryologists from various countries. Time-lapse videos were the input for the model, which was cross-validated on 272 embryos with known implantation data (KID). Prediction of implantation probability came from the cross-validation data only.
Participants/materials, setting, methods: Embryos in this study came from patients who underwent fertility treatment between 2012 and 2019 at the Clinic of Reproductive Medicine "Nadiya" in Kiev. Resulting time-lapse videos were used for developing, training, and 10-fold cross-validation of the model. Initial model training used a recurrent neural network to recover panel grades. The network was then trained to classify embryos based on their known implantation outcomes. UBar predictions were compared to embryologists' grades and implantation outcomes.
Main results and the role of chance: An encoder was trained on over 2.5 million images from unlabeled (unknown outcomes) time-lapse videos, maximizing the information available in the visual data, and "translating" it into feature vectors. A memory-based network was built to create initial predictions based on embryologists' grades. Because grades somewhat correlate with implantation success, the network used the results from graded videos to set initial feature weights. Videos from KID embryos were then used as input to train the network to predict implantation probability.
Performance of the UBar predictions exceeded that of the expert panel as calculated by the area under the receiver operating characteristic curve (AUC of the ROC): 0.82 and 0.58, respectively. For a clinically relevant performance assessment, the positive and negative predictive values (PPV and NPV) were calculated for UBar predictions and compared to those of the expert panel. Both the PPV (93%) and the NPV (58%) of UBar significantly surpassed the corresponding values of the expert panel (PPV=81% and NPV=23%), implying that application of UBar in a clinical setting could potentially improve embryo transfer outcomes. The increased NPV is particularly meaningful as an indication that UBar more accurately identifies embryos that would likely not implant.
Limitations, reasons for caution: In order to further improve results, the model will be applied to a larger amount of samples originating from multiple IVF clinics. New ML models will also be developed, and clinical parameters will be explored in future experiments to account for external factors that may influence implantation aptitude.
Wider implications of the findings: Our ML-based embryo outcome prediction model predicts implantation probability more effectively than a panel of expert embryologists. Adjunct use of UBar in IVF clinics could aid in selection of embryos with the highest implantation competence for transfer, as well as deselection of potentially non-implantable embryos.
Trial registration number: Not applicable

P-150 The impact of advanced maternal age on early and late morphokinetic parameters

O. Lebovitz[1], Y. Atzmon[1], N. Aslih[1], M. Michaeli[1], D. Paltov[1], E. Shalom-Paz[1]

[1]Hillel Yaffe Medical Center Affiliated with Rappaport Faculty of Medicine-Technion- Haifa, IVF Unit- Department of Obstetrics and Gynecology, Hadera, Israel

Study question: Are there any differences between morphokinetic parameters (MP) and embryo quality (EQ) of embryos derived from young versus advanced maternal age (AMA) women?
Summary answer: Embryos derived from younger women presented a significantly different MP in younger versus AMA women. These differences could later cause differences in EQ.
What is known already: The introduction of TLI has provided a more precise understanding of early embryo developmental stages by assigning unique quantitative identifiers to each embryo. Data regarding possible association between embryo morphokinetics and maternal age is limited and conflicting.
Study design, size, duration: Using a time-lapse incubator we retrospectively compared between MP and quality of embryos derived from young (<30 years) and AMA women (41-44 years). This study included 364 ICSI cycles (173 cycles from young and 191 from AMA) performed between January 2016 and December 2018.
Participants/materials, setting, methods: Embryo development was analyzed with TLI system (EmbryoScope, Unisense FertiliTech). The following kinetic markers were assessed: time to pronuclei fading (tPNf), and appearance of two to eight cells (t2-t8). For embryos cultured to blastocyst, time to morula (tM), start of blastulation (tSB) cavitated and expanded blastocyst (tB, tEB) were also recorded. Alpha-ESHRE and KIDScore algorithm were used to determine the transferred embryo quality. Embryos derived from young women were compared with those derived from AMA.
Main results and the role of chance: A total of 2021 oocytes were evaluated. 60.5% (n=1223) of oocytes were derived from patients under 30 years and 39.5% (n=798) from women 41 years old and above. A trend towards faster polar body disappearance observed among patients <30 years compared to patient ≥41 years old. (24.7hr vs 25.2hrs respectively, p=0.05). The mean time

points for younger patients were significantly shorter at t3, t4, t5, and t6 compared to AMA women (37.2, 39.8, 50.1 and 53.6 hrs. versus 38.4, 40.4, 51.2 and 54.7 hrs. respectively) (P<0.05). For embryos cultured to the blastocyst stage tSB, tB and tEB were significantly shorter for embryos derived from younger patients compared to embryos derived from AMA group (100.7, 108.9, 116.8 hrs. versus 104.7, 115.0, 126.6 hrs. respectively, p<0.001). There were no significant differences between the two groups at t2, t7, t8 and tM.

The proportion of toP-quality embryos (KID 4-5) was significantly higher among transferred embryos of younger women compared with AMA women (87.1% versus 76.7%; p=0.007, respectively). Similar results obtained for alpha scoring (alpha 2-3) (83.3% vs 72%; p=0.001 respectively).

Limitations, reasons for caution: Limitations of the present study are those inherent to the TLI technique which is a static system and might be operator dependent. Since the embryos cannot be rotated once entered to the embryoscope, situations like blastomeres overlap or irregular divisions might be difficult to observe by the embryologist.

Wider implications of the findings: This is the first study to compare the time-lapse analysis of younger with AMA women up to the blastocyst stages. Since increasing women's age was associated with slower embryo developmental kinetics, these parameters can be potentially utilized to improve embryo selection and cycle outcome in AMA women undergoing IVF treatment.

Trial registration number: N/A

P-151 Embryologists' perceptions following implementation of an electronic witnessing system in an in vitro fertilisation laboratory network

J. Swain[1], K. Wirka[2], B. Hayward[2], A. Catherino[2], R. Holmes[3]

[1]CCRM IVF Network, IVF Laboratory, Lone Tree, U.S.A. ;
[2]EMD Serono, Fertility & Endocrinology, Rockland, U.S.A. ;
[3]CCRM Boston, IVF Laboratory, Newton, U.S.A.

Study question: How do embryologists perceive the value of an electronic witnessing system (EWS) with regard to sample traceability, mismatch prevention, workload interruption, laboratory efficiency, system implementation and overall embryologists' confidence?

Summary answer: The EWS was well perceived by embryologists in all evaluated domains; it enhanced confidence and peace of mind at the end of a work day.

What is known already: Double witnessing has become an important additional task to prevent potential sample misidentification within the *in vitro* fertilisation (IVF) laboratory setting. Best practice dictates the use of double witnessing, but while necessary, this can be time consuming and implementation may vary between laboratories. Electronic witnessing, although not mandated in most parts of the world, has emerged as a potential way to mitigate current manual double witnessing challenges; however, embryologists' perspectives regarding the value of such technology has not been evaluated.

Study design, size, duration: This study involved administration of a web-based survey to embryology staff at eight fertility laboratories across the United States and Canada to gather attitudes and perception regarding an EWS (Gidget® [Genea BIOMEDX]). The survey remained open for 2 months. There were 73 questions related to: demographics and work experience, sample traceability, mismatch prevention, workload and interruptions, laboratory efficiencies, EWS implementation, managerial tasks and embryologist confidence.

Participants/materials, setting, methods: The questionnaire was sent to embryologists, managers and non-managers in all laboratories. Participants consented to take the anonymous survey that was composed of Likert scale statements, open-ended questions and ranking questions related to EWS. The values corresponded to categorical variables (strongly disagree, disagree, neutral, agree, strongly agree), with an option for 'no viewpoint' or 'choose not to answer' for some questions. Survey results are shown as proportion agreeing with statements and 95% confidence intervals (CI).

Main results and the role of chance: The survey response rate was 96.2% (50/52). Mean (±standard deviation) experience in a clinical IVF setting was 12.94 (±8.67) years for all embryologists (n=45) and 18.67 (±6.79) years for the subset of managers (n=15); experience with the EWS was 10.9 (±6.30) months and 12.4 [±5.47] months, respectively. Overall (% [95% CI]), 78.3 (63.6, 89.1)% of respondents agreed that EWS improved sample traceability and 80.4 (66.1, 90.6)% agreed that EWS reduced labelling errors. Just 60.9 (45.4, 74.9)% agreed that EWS reduced the risk of sample mismatch errors by minimising disruptions. Visual completion of the dashboard provided peace of mind when leaving work to 82.6 (68.6, 92.2)% of respondents, and 84.8 (71.1, 93.7)% felt more confident knowing that procedures were completed according to the EWS. Most respondents (73.9 [58.9, 85.7]%) agreed that EWS allowed double witnessing to be conducted quickly and accurately, and that labelling standardization increased efficiency (84.8 [71.1, 93.7]%). The majority of respondents considered EWS training easy (78.3 [63.6, 89.1]%) and would recommend the EWS to another embryologist (88.9 [75.9, 96.3]%), while 26.1 (14.3, 41.1)% had concerns with transitioning from manual to EWS. Managers agreed (93.3 [68.1, 99.8]%) that sample chain of custody was easily followed using EWS audit reports.

Limitations, reasons for caution: The survey was sent to one network of embryology laboratories as it relates to a single EWS. Embryologists' perceptions may be influenced by length of experience with a particular system and by their general embryology experience and knowledge.

Wider implications of the findings: This study indicates that the implementation of an EWS was well perceived by most embryologists. Sample identification, traceability, mismatch prevention, laboratory efficiency and embryologist confidence was perceived to be improved. For the first time, these data captured embryologists' opinion on the value of an EWS.

Trial registration number: NA

P-152 Multinucleation has no impact on an embryos ability to develop, implant or sustain a viable pregnancy to live birth

V. Songkhunawej[1], L. Burmeister[2], K. Sorby[1]

[1]Number 1 Fertility, Embryology, East Melbourne, Australia ;
[2]Number 1 Fertility, Clinician, East Melbourne, Australia

Study question: The aim of our study was to investigate the impact of multinucleation on ART outcomes including embryo development, utilisation, pregnancy loss and live birth.

Summary answer: Presence of multinucleation appears to have no negative impact on embryo development nor the embryo's ability to implant and sustain a viable pregnancy.

What is known already: Detected as early as 1987 by Tesarik et al, multinucleation in embryos is thought to arise from abnormalities in DNA synthesis during cleavage. Previous literature demonstrated that multinucleation in embryos was linked to increased aneuploidy rate (Kligman et al, 1996) and lower implantation and live birth rate (Hardarson et al., 2001). However, development of time-lapse technology has dramatically improved embryo assessment from just a static timepoint to continuous monitoring, enabling more robust detection of multinucleation. Recent studies suggest that ploidy (Balakier et al., 2016) in addition to perinatal outcomes (Seikkula et al., 2018) are not impacted by multinucleation.

Study design, size, duration: In this retrospective study, data was collected from cycles dating from 1st February 2018 to 31st December 2019. In this period, there were a total of 8409 embryos assessed. To date, pregnancy and live birth data were available for 363 embryos.

Participants/materials, setting, methods: Embryos were cultured in the Embryoscope+ to day 5 or 6 and assessed for routine morphokinetic parameters. Multinucleation assessment included: presence or absence at the 2-cell and 4-cell stages, number of blastomeres affected, number of nuclei seen. Utilisation, clinical pregnancy and live birth rates were assessed. Transfers were single day 5 embryos. To simulate observation of multinucleation in laboratories not using time-lapse, multinucleation was assessed in eleven planes at the static timepoint of 42 hours.

Main results and the role of chance: Multinucleation was seen in 31.77% of embryos under time-lapse. However, when assessing at 42 hours, only 8.1% of embryos had visible multinucleation. The occurrence of multinucleation was more likely at the two cell stage in comparison to the four cell stage (*20.60% vs 6.20%; p = 0.001*) with 4.98% of embryos having multinucleation persisting through both the two and four cell stages. Prevalance of multinucleation was not impacted by age, presence of smooth endoplasmic reticulum discs, uneven pronuclei, uneven two cell blastomeres or ploidy. Time to cavitation (both absolute and relative to syngamy) which was used as a marker of embryo development, did not appear to be impacted by the presence of multinucleation (*78.10h vs 78.34h; p = 0.0585*) as well as embryo utilisation (*51.03% v 47.05%; p = 0.8731*). The clinical pregnancy rate was no different when comparing embryos with or without multinucleation (*30.12% v 26.77% respectively; p = 0.4848*). Reassuringly, the same was seen in the pregnancy loss rate where non-multinucleated embryos had a rate of 23.61% versus those with

multinucleation at 16.00% (*p = 0.5761*). Furthermore, birth weight and gender ratios were not significantly different between groups.
Limitations, reasons for caution: Despite having a large sample size for our main analysis, after filtering down to embryos that were transferred and had live birth data available, a larger sample size would be more desirable for birth outcomes. Interobserver variability is also likely, due to multiple embryologists making embryo assessments.
Wider implications of the findings: Multinucleation does not appear to have an impact on the capacity of the embryo to develop to blastocyst, implant or sustain a viable pregnancy to live birth. Multinucleation appears to be an insignificant factor in the developing embryo and should not be used as a criteria for stratification of embryos.
Trial registration number: Not Applicable

P-153 Improving the performance of deep convolutional neural networks (CNN) in embryology using synthetic machine-generated images

M. Kanakasabapathy[1], C. Bormann[2], P. Thirumalaraju[1], R. Banerjee[1], H. Shafiee[3]

[1]Brigham and Women's Hospital, Division of Engineering in Medicine, Boston, U.S.A. ; [2]Massachusetts General Hospital, Obstetrics and Gynecology, Boston, U.S.A. ; [3]Brigham and Women's Hospital, Department of Medicine- Harvard Medical School, Boston, U.S.A.

Study question: Can we employ synthetic machine-generated images in empowering AI-based morphological assessment of cells with applications in embryology?
Summary answer: The addition of synthetic oocyte images significantly improved the performance of a CNN in oocyte assessment compared to a CNN trained on clinical oocyte images.
What is known already: CNNs have shown an enormous potential in embryology. These neural networks, in general, require large amounts of expertly annotated data to perform sufficiently well. However, the availability of datasets is limited to very few fertility centers worldwide. Generative adversarial networks (GANs), which excel in generating life-like images, may help in mitigating such data requirements. It has been shown previously that oocytes can be differentiated based on their potential for fertilization by CNNs through morphological analysis (Thirumalaraju et al., 2019). Here, we evaluate whether such a CNN when trained with additional data generated by a GAN can improve its performance.
Study design, size, duration: Using a retrospective dataset of clinical oocyte images with known fertilization outcomes (KFO) and synthetic oocyte images generated by a pretrained GAN, a CNN, henceforth called synthetic CNN (s-CNN), was trained to classify between oocytes that eventually fertilized normally, with 2 pronuclei (2PN), and abnormally (non-2PN). The network performance was compared to the performance of a CNN, henceforth called the original CNN (o-CNN), trained using clinical oocyte images only.
Participants/materials, setting, methods: A GAN was trained to generate life-like oocyte images from scratch. The s-CNN was trained using a dataset of 1411 clinical oocytes images with KFO and 1340 synthetic oocyte images generated by the GAN. The o-CNNs were trained as reported previously using only the 1411 clinical oocyte images with KFO. The trained networks were tested with a common set of 712 clinical oocyte images with KFO.
Main results and the role of chance: The o-CNN performed with an accuracy of 67.0% (95% CI: 63.4% to 70.4%) and an AUC of 0.6133 in classifying oocytes based on their eventual fertilization outcome, as reported previously (n=712). In contrast, the s-CNN performed with an improved accuracy of 82.58% (CI: 79.59% to 85.30%) and an AUC of 0.8123 (n=712) in differentiating the oocyte images based on their eventual fertilization outcomes.
Limitations, reasons for caution: Images were obtained using a single imaging platform (EmbryoScope) at a single timepoint. Fertilization assessments (2PN evaluations) we performed by individual embryologists from a single center.
Wider implications of the findings: The training with GAN-generated data helped s-CNN to outperform the conventionally trained o-CNN when evaluating real oocytes with KFO. Thus, GANs may hold the potential to improve the currently utilized CNNs in embryology.

P-154 Piezo-ICSI can produce significantly higher fertilization and blastocyst rates without increasing the risk of birth defects as compared to the IVF

K. Hiraoka[1], M. Ibayashi[1], A. Kuga[1], N. Uchida[1], T. Sujino[1], K. Kawai[1]

[1]Kameda IVF Clinic Makuhari, ART Laboratory, Chiba, Japan

Study question: Can Piezo-ICSI increase fertilization and blastocyst rates without increasing the risk of birth defects as compared to the IVF?
Summary answer: Piezo-ICSI can significantly increase fertilization and blastocyst rates without increasing the risk of birth defects as compared to the IVF
What is known already: Recently, the clinical usefulness of Piezo-ICSI has been reported by some investigators. All papers reported significantly higher survival or fertilization rates and embryo development in Piezo-ICSI as compared to conventional-ICSI. On the other hand, some papers reported that the comparison of conventional-ICSI and IVF children taking part in an identical follow-up study did not show any increased risk of birth defects and neonatal complications in the conventional-ICSI group. To the best of our knowledge, there is no paper comparing the ICSI results, embryo development and delivery outcome between Piezo-ICSI and IVF.
Study design, size, duration:

1. We retrospectively investigated 6,671 mature oocytes between May 2016 and December 2019. Of these, 3,156 mature oocytes were inseminated by IVF and 3,516 mature oocytes were inseminated by Piezo-ICSI and the ICSI results and embryo development were compared.
2. We retrospectively investigated 204 infants born after our IVF program since May 2016. Of these, 82 infants were derived from IVF and 122 infants were derived from Piezo-ICSI and the delivery outcomes were compared.

Participants/materials, setting, methods:

1. The fertilization, blastocyst and good quality blastocyst rates of IVF and Piezo-ICSI were compared.
2. The number of embryos transferred, monozygotic twin rates, dizygotic twin rates, gestational week, birth weight, the ratio of boy and girl and birth defects rates were compared.

The good quality blastocyst was defined as better than grade BB by Gardner's criteria. The data were analyzed by Unpaired T Student, chi-square test or Fisher's exact test.
Main results and the role of chance:

1. Among the IVF and Piezo-ICSI, there were no significant differences when comparing the average age of women at the insemination (34.3 ± 4.1 vs. 34.7 ± 4.1). The fertilization rates of IVF and Piezo-ICSI were 73.0% and 83.8%. A significantly higher fertilization rate was observed in Piezo-ICSI ($P < 0.01$). The blastocyst rates of IVF and Piezo-ICSI were 41.3% and 46.2%. A significantly higher blastocyst rate was observed in Piezo-ICSI ($P < 0.01$). The good quality blastocyst rates of IVF and Piezo-ICSI were 19.1% and 22.4%. A significantly higher blastocyst rate was observed in Piezo-ICSI ($P < 0.01$).
2. Among the IVF and Piezo-ICSI, there were no significant differences when comparing the average age of women at the embryo transfer (34.6 ± 4.0 vs. 35.1 ± 4.1), average number of embryos transferred (1.0 ± 0.3 vs. 1.1 ± 0.3), monozygotic twin rates (1.3% vs. 1.7%), dizygotic twin rates (1.3% vs. 0.8%), gestational week (38.8 ± 2.8 vs. 38.7 ± 2.7), birth weight (3036 ± 1751g vs. 3005 ± 1662g), the ratio of boy and girl (51:49 vs. 49:51) and birth defect rates (5.0% vs. 3.3%).

Data are expressed as mean ± SD.
Limitations, reasons for caution: The number of matured oocytes of IVF was calculated as the total number of 0PN (with no pronucleus and with1 or 2 polar bodies), 1PN (mono-nucleus), 2PN (two-pronucleus), ≥3PN (more than three-pronucleus) at the time of fertilization assessment. So, the 0PN oocytes might be immature at the time of insemination.

Wider implications of the findings: Piezo-ICSI can produce significantly higher fertilization and blastocyst rates without increasing the risk of birth defects as compared to the IVF. Therefore, Piezo-ICSI could be the main insemination method for human assisted reproductive technology to improve the effective utilization rate of precious oocytes.
Trial registration number: not applicable

P-155 Vitamin D (VitD) in follicular fluid (FF) correlates with the euploid status of the embryo in a VitD deficient Middle Eastern population.

A. Arnanz[1], N. De Munck[1], I. El Khatib[1], A. Bayram[1], A. El-Damen[1], A. Abdala[1], L. Melado[2], B. Lawrenz[2], A. Pacheco[3], H. Fatemi[2]

[1]IVIRMA Middle East Fertility Clinic LLC, IVF lab, abu dhabi, United Arab Emirates ; [2]IVIRMA Middle East Fertility Clinic LLC, Gynaecology, abu dhabi, United Arab Emirates ; [3]IVIRMA Madrid, Andrology, Madrid, Spain

Study question: Is there a correlation between VitD levels in individual FF and embryo ploidy status among Middle Eastern patients undergoing in vitro fertilization (IVF) treatments?
Summary answer: In a Vitamin D deficient population, euploid blastocysts showed significantly higher levels of 25-hydroxyvitamin D[25(OH)D] and bioavailable 25(OH)D in FF compared to the aneuploid ones.
What is known already: The widespread distribution of the VitD receptor in reproductive tissues suggests an important role for VitD in human reproduction. Despite the abundance of sunlight, due to socio cultural/religious habits, the prevalence of VitD deficiency/insufficiency in Middle Eastern women is known to be among the highest in the world.

The assessment of patient´s VitD is based on the 25(OH)D metabolite measurement. However, most of the circulating 25(OH)D is bound to either vitamin D-binding protein (VDBP) (88%) or albumin (12%) and less than 1% circulates free. The albumin-bound fraction of 25(OH)D plus free fraction equals the bioavailable fraction of 25(OH)D.
Study design, size, duration: A prospective observational study was performed between 2017 and 2019, including Middle Eastern couples planned for preimplantation genetic testing for aneuploidies (PGT-A). Trophectoderm biopsy was performed on 115 blastocysts from 37 couples and subjected to Next Generation Sequencing. Serum (S) samples were withdrawn on the day of the final oocyte maturation and 115 FF samples from follicles ≥14mm were individually collected during the oocyte retrieval for 25(OH)D, bioavailable 25(OH)D and free 25(OH)D measurement.
Participants/materials, setting, methods: Patients were classified into two groups according to the serum 25(OH)D levels; VitD deficient <20 ng/ml and insufficient/replete ≥20 ng/ml.

Quantitative measurement of total 25(OH)D was performed using the Roche total 25(OH)D assay with competition principle in an electrochemiluminescence (ECLIA) binding assay. VDBP was measured using an ELISA kit (R&D system). Free and bioavailable 25(OH)D were determined using the method reported by Bikle et al (1986) applying a modified Vermeulen formula.
Main results and the role of chance: The average maternal age in both groups was 31.1±6.0 vs 32.1±5.0; p=0.369, body mass index 26.1±2.9 vs 25.6±3.8; p=0.499, Antimullerian Hormone 3.8±2.2 vs 3.5±1.4; p=0.400, mature oocytes 14.2±6.9 vs 13.0±4.9; p=0.561, respectively in <20 ng/ml and ≥20 ng/ml group. Serum values were 13.2±4.0 vs 32.3±9.2; p<.0001, respectively. FF samples from a total of 40 and 75 blastocysts were analyzed of which 52.5% (21/40) and 61.3% (46/75) were euploid, respectively.

In <20 ng/ml group, the logistic regression showed that the average values of 25(OH)D and bioavailable 25(OH)D were significantly higher in follicles resulting in euploid vs aneuploid blastocysts (18.3 vs 13.9; p=0.029) vs (18.1 vs 13.7; p=0.029). However, in ≥20 ng/ml group, no significant differences were found (38.1 vs 40.6; p=0.417) and (37.7 vs 40.1; p=0.441), respectively.

A Pearson test (ρ) indicated a strong correlation between S and FF 25(OH)D, bioavailable 25(OH)D and free 25(OH)D values (r= 0.805 vs r= 0.805 vs r=0.834; p<.001 respectively).

In a multivariate model, confounding for age, BMI and AMH, sufficient/replete have a significantly higher probability to have a euploid embryo compared to deficient patients (Estimate:1.64, p=0.031). Moreover, in the deficient group, age was significantly higher for aneuploid blastocysts (33.3±5.5 vs 29.2±5.8; p=0.03).
Limitations, reasons for caution: This study is based on a good prognosis Middle Eastern population, who are mainly VitD deficient or insufficient (<30 ng/ml), therefore these results can not be extrapolated to other patient groups.
Wider implications of the findings: In a deficient VitD population, intrafollicular concentration of VitD is a marker of embryo competence. The mechanism of the impact of VitD on chromosomal status of the blastocysts needs to be further investigated. Preliminary data in the literature suggest that telomere length may be involved.
Trial registration number: NCT03073720

P-156 Piezo-ICSI can generate significantly higher survival, fertilization and blastocyst rates without increasing the risk of malformation as compared to the Conventional-ICSI

A. Kuga[1], K. Hiraoka[1], M. Ibayashi[1], N. Uchida[1], T. Suhara[2], T. Kaji[2], Y. Kamada[2], T. Sujino[1], K. Ohuchi[3], M. Hayashi[3], K. Kawai[4]

[1]Kameda IVF Clinic Makuhari, laboratory, Chiba, Japan ; [2]Kameda Medical Center, laboratory, Chiba, Japan ; [3]Kameda Medical Center, ART center, Chiba, Japan ; [4]Kameda IVF Clinic Makuhari, ART center, Chiba, Japan

Study question: Can Piezo-ICSI generate higher survival, fertilization and blastocyst rates without increasing the risk of malformation as compared with the Conventional-ICSI?
Summary answer: Piezo-ICSI can generate significantly higher survival, fertilization and blastocyst rates without increasing the risk of malformation as compared with the Conventional-ICSI.
What is known already: ICSI has been widely performed by using micropipette with spiking tip and usually, the cytoplasm is aspirated to break the membrane (Conventional-ICSI). Recently, the clinical usefulness of Piezo-ICSI has been reported by several investigators. In Piezo-ICSI, micropipette with flat tip is used and the membrane breakage is performed by applying piezo without aspirating the cytoplasm into the micropipette. When comparing the survival and fertilization rates between Conventional-ICSI and Piezo-ICSI, favorable results of Piezo-ICSI has been reported. However, little information is available comparing the ICSI results and delivery outcome between Conventional-ICSI and Piezo-ICSI.
Study design, size, duration:

1. We retrospectively investigated 5,748 mature oocytes between January 2012 and December 2019. Of these, 1,538 mature oocytes were inseminated by Conventional-ICSI and 4,210 mature oocytes were inseminated by Piezo-ICSI and the ICSI results and embryo development were compared.
2. We retrospectively investigated 178 infants born after our IVF program since January 2012. Of these, 89 infants were derived from Conventional-IVF and 89 infants were derived from Piezo-ICSI and the delivery outcomes were compared.

Participants/materials, setting, methods:

1. The survival, fertilization and blastocyst rates of Conventional-ICSI and Piezo-ICSI were compared.
2. The number of embryos transferred, monozygotic twin rates, dizygotic twin rates, gestational week, birth weight, the ratio of boy and girl and malformation rates were compared.

The data were analyzed by Unpaired T Student, chi-square test or Fisher's exact test.
Main results and the role of chance:

1. The survival rates of Conventional-ICSI and Piezo-ICSI were 92.9% and 95.2%. A significantly higher survival rate was observed in Piezo-ICSI ($P < 0.01$). The fertilization rates of Conventional-ICSI and Piezo-ICSI were 69.9% and 81.1%. A significantly higher fertilization rate was observed in Piezo-ICSI ($P < 0.01$). The blastocyst rates of Conventional-ICSI and Piezo-ICSI were 47.1% and 54.4%. A significantly higher blastocyst rate was observed in Piezo-ICSI ($P < 0.01$).

2. Among the Conventional-ICSI and Piezo-ICSI, there were no significant differences when comparing the average age of women at the embryo transfer (38.4 ± 4.3 vs. 38.7 ± 4.0), number of embryos transferred (1.2 ± 0.4 vs. 1.2 ± 0.4), monozygotic twin rates (4.7% vs. 0%), dizygotic twin rates (0% vs. 4.7%), gestational week (38.2 ± 1.7 vs. 38.3 ± 2.1), birth weight (2913 ± 462g vs. 2947 ± 489g), the ratio of boy and girl (38:62 vs. 53:47) and malformation rates (6.7% vs. 6.7%).

Data are expressed as mean ± SD.
Limitations, reasons for caution: In our IVF program, day 2 or 3 after oocyte retrieval, 1-3 good quality cleaved embryos were cryopreserved or transferred, so the blastocyst culture was performed excluding these embryos.
Wider implications of the findings: Piezo-ICSI can generate significantly higher survival, fertilization and blastocyst rates without increasing the risk of malformation as compared to the Conventional-ICSI. Therefore, Piezo-ICSI could be an alternative ICSI method to the Conventional-ICSI without losing valuable oocytes for human assisted reproductive technology.
Trial registration number: not applicable

P-157 Optimum timing of trophectoderm biopsy with cryopreservation for preimplantation genetic testing for aneuploidies (PGT-A) cycle

E.J. Yu[1], E.A. Park[1], S.A. Choe[1], M.J. Kim[1], Y.S. Kim[1], J.Y. Lee[1], E.B. Joe[1], H.S. Kim[1], J.H. Lee[1], H.O. Kim[1], Y.S. Kim[1], M.K. Koong[1], I.S. Kang[1], T.K. Yoon[1]

[1]CHA Fertility Center- Seoul Station, Department of Obstetrics and Gynecology, Seoul, Korea- South

Study question: Is the timing of trophectoderm(TE) biopsy before or after vitrification-warming associated with successful clinical outcomes after the embryo transfer(ET) of blastocyst subjected to preimplantation genetic testing for aneuploidies (PGT-A)?
Summary answer: TE biopsy(PGT-A) with cryopreservation may be the optimal timing for better clinical outcomes compared to the fresh TE biopsy without cryopreservation.
What is known already: Embryo biopsy and fresh embryo transfer are traditionally performed in the PGT-A cycle. However, before ET, the time allowed for genetic analysis of the specimens is restricted, particularly after blastocyst biopsy. Cryopreservation of blastocysts after biopsy instead of fresh transfer permits more sufficient time for performance of molecular diagnosis. The effect of cryopreservation and warming procedures on clinical outcomes in PGT-A cycle has not been effectively studied.
Study design, size, duration: Retrospective analysis of patients with PGT-A cycles was carried out from January 2016 to November 2019. 3684 blastocysts from cycles were subjected to TE biopsy for performing array comparative genomic hybridization test. Embryos were cultured to expanded blastocyst and performed TE biopsy on day 5 or day 6, depending on the timing of embryo expansion. Cycles with complete PGT-A diagnosis were 655, among them 349 of which had ET.
Participants/materials, setting, methods: The performance of different groups of PGT-A patients was evaluated. The groups were divided into three; first group (n=118 transfer/677 cases) contained fresh blastocysts that biopsied for PGT-A without cryopreservation followed by embryo transfer. In the second group (n=348 transfer/355 cases), the blastocysts that were biopsied prior to vitrification; and subsequently warmed euploid blastocysts for ET. The last group (n=189 transfer/248 cases), the vitrified blastocysts were warmed and then biopsied before proceeding with ET.
Main results and the role of chance: The total pregnancy and implantation rates of fresh blastocyst biopsied group was 42.4% (50/118), 35.7%(56/157); the cryopreserved-warmed-biopsied blastocyst group showed 56.6% (197/348), 51.2% (227/443); and finally biopsied and cryopreserved-warmed group showed 54.0% (102/189), 48.6% (123/253); respectively. Second group and third group are significant higher pregnancy rates than first group. Also, The second(biopsied and cryopreserved-warmed) group and third (cryopreserved-warmed–biopsied) group are significant higher implantation rates than first group. Also, The second group(36/197, 18.3%) showed higher numerical miscarriage rate than the first group(6/50, 12.0%) and third group(16/102, 15.7%).
Limitations, reasons for caution: In the case of biopsy after warming, it is difficult to determine the number of warming embryos and re-cryopreservation of surplus euploid embryo could increase embryo damage and miscarriage rate.
Wider implications of the findings: Using recently available data, when faced with the option of fresh embryos, before or after trophectoderm biopsy for PGT-A, our result supported performing TE biopsy of blastocyst for PGT-A before or after vitrification and warming may be the optimal timing for better clinical outcomes.
Trial registration number: Not applicable

P-158 A machine-learning (ml) based decision support framework with a case study in frozen-embryo-transfer (fet) in-vitro-fertilization (ivf) for patients with polycystic ovarian syndrome (pcos)

T.J Ramnath Babu[1], V.S. Roy[2], Y. Jambunath[1], D. Modi[3], S.B. Bhuvarahamurthi[1], N. T s[4]

[1]SpOvum Technologies Pvt. Ltd., Product Development, Bangalore, India ;
[2]Manipal Fertility - JP Nagar, Scientific Director & Chief Embryologist, Bangalore, India ;
[3]National Institute For Research In Reproductive Health ICMR-NIRRH, Molecular and Cellular Biology Lab, Bangalore, India ;
[4]Manipal Fertility - JP Nagar, Clinical Director, Bangalore, India

Study question: Can a data-driven framework not just predict, but also aid embryologists/ clinicians in decision-making during a FET-IVF treatment for patients with PCOS?
Summary answer: We show that one can augment the capability of prediction-tools and controllability of parameters using a ML-based framework towards improving 'clinical pregnancy rate' (CPR).
What is known already: Existing literature primarily focus on prediction, and seldom aid in the IVF treatment process. Recent decision-support systems in the IVF domain consider non-clinical parameters like demographic details. However, the efficacy of the decisions taken during the treatment are not considered. It is also noted that earlier case studies cover diverse population including several male and female causes of infertility, to predict IVF outcomes. One downside of including miscellaneous collection of infertility factors is that the model becomes highly uncertain. Specifically, no study has covered PCOS condition, the most common cause of infertility.
Study design, size, duration: We developed a supervised machine learning model covering only PCOS in FET-IVF cycle. The purpose of the study is to classify the CPR as either Yes/No. Anonymized clinical data along with CPR outcomes of 330 PCOS patients who underwent FET-IVF treatment at an IVF center between 2015 and 2019 were retrospectively analyzed. Patients with donor samples (donor oocyte/ sperm/ embryo), severe male infertility factors were excluded from this dataset, resulting in 187 (~56%) patient records
Participants/materials, setting, methods: We avoided sampling to reduce uncertainty. Feature engineering was performed to label the details including embryo details (quantity and grade of embryos before freezing, post thawing and before embryo transfer) as good or moderate or poor. Then we used naïve Bayes algorithm to classify CPR as Yes or No. Here, CPR as 'Yes' is defined as the ultrasound visualization of a pregnancy sac with fetal heart activity from six weeks after frozen embryo transfer.
Main results and the role of chance: The f-value statistical test results suggested that all the three parameters (good (~1) / moderate (~1.5)/ poor (~7)) related to the embryo grades are more correlated with CPR compared to other parameters. Our embryo-grades representation is intuitive and generic and can be performed across all clinics. For decision making, the embryologist's inputs are included as parameters (features) to the model.

A naïve Bayes classifier model was developed using 95% training dataset with seven features, and prediction performance were evaluated using macro f1-score and accuracy on the remaining 5%. Macro f1-score was calculated as the harmonic mean of precision and recall of each class label (Yes, No), hence reducing skewness in prediction.

Model predictions using test data resulted in 90% accuracy and 90% f1 score at best.

To demonstrate the role of the ML framework, we chose 'Day of freezing', 'Culture type' and 'Number of embryos transferred' as the controllable parameters for decision-making. The model calculates all scientifically possible

combinations of these parameters and ranks the suggestions with confidence scores. An embryologist can decide the pathway of the treatment using this rank list.
Limitations, reasons for caution: A limitation in this study was the small size of dataset collected from a clinic. This limitation could be overcome by using more data from multiple clinics, thus improving the model's performance.
Wider implications of the findings: The ML framework shall be able to support and guide embryologists on the different paths for them to plan and adhere-to in order to achieve better success rates. The framework also sensitizes the criticality of certain data-points which will further impact the perspective of an IVF treatment.
Trial registration number: Not applicable

P-159 Oocyte maturation changes mitochondrial gene expression patterns and the localization of polarized mitochondria but does not affect mitochondrial potential

F. Zambelli[1], M. Barragan[1], R. Vassena[1]

[1]Clinica Eugin, Research and Development, Barcelona, Spain

Study question: Are there changes in the oocyte mitochondrial transcriptome and membrane potential during meiotic maturation?
Summary answer: We identified a decreased mitochondrial gene expression and a more compact distribution of polarized mitochondria in MII compared to GV; mitochondrial membrane potential was unaffected
What is known already: Mitochondria localization and activity in oocytes from several species has been associated with the acquisition of developmental potential. Several studies have attempted to associate mitochondrial measurements such as DNA copy number and gene expression in human oocytes with reproductive outcomes after IVF. These tests rely on the assumption that a reduction in the abundance of certain transcripts directly translates to a modification in mitochondrial activity. However, this correspondence has not yet been proven. Moreover, a clear causation between an altered mitochondrial activity and the failure to reach MII in human oocytes hasn't been demonstrated yet.
Study design, size, duration: We analyzed the mitochondrial membrane potential and the localization of active mitochondria in human oocytes at GV, GV after 30 hours in culture (FTM-GV), and MII from GV after 30 hours in culture (IVM-MII). Further, we performed a transcriptomic-wide analysis via microarray of GV and in vivo matured MIIs (IVO-MII) to correlate functional and transcriptional measurements.
Participants/materials, setting, methods: 24 oocyte donors (ages 20 to 35) provided 63 oocytes (24 GV, 15 FTM-GV, 15 IVM-MII, 9 IVO-MII) for the study. Oocytes were stained with JC-1 to identify both polarized and non-polarized mitochondria and imaged by confocal microscopy. Intensities of the staining and spatial measurement of the polarized mitochondria layer were performed using ImageJ. Transcriptome-wide analysis via microarray (HTA 2.0 Affymetrix) was performed using 4 GVs and 9 in vivo matured MII
Main results and the role of chance: GV and IVO-MII oocytes presented 543 transcripts differentially expressed (516 more abundant in GV, 27 more abundant in MII). Oxidative phosphorylation and mitochondrial function were the most affected pathways by Gene Ontology analysis, with a significant decrease of mitochondrial transcripts like ATP5, PDHA, and POLG in MIIs. JC-1 staining indicated in all groups a rather thin layer of polarized mitochondria at the periphery of the oocyte (within 20 µm from the oolemma), while the inner part of the oocyte (>20 µm from the oolemma) only contained non-polarized mitochondria. We found no differences in the membrane potential of the peripheral mitochondria across groups, (39% increase in polarized mitochondria in FTM-GV, 15% increase in polarized mitochondria in IVM-MII compared to GV; $p>0.05$). We did observed differences in the distribution of mitochondria between GV, FTM-GV and IVM-MII. Both GV and FTM-GV had a wider distribution of the polarized mitochondria (9.7 ± 1.7 µm and 7.9 ± 1.5 µm, respectively), while in IVM-MII we observed a thinner layer (6.2 ± 1.7 µm), placed in the outermost part of the ooplasm ($p<0.001$).
Limitations, reasons for caution: The origin of MII (both in vitro and in vivo matured) may affect some of the comparative observations; GVs were collected after controlled ovarian stimulation and their transcriptome may be different from GVs from unstimulated ovaries.
Wider implications of the findings: Our results might inform the development of better culture media, where the presence of mitochondrial modulators might improve oocyte quality. Further, the differences between transcription and mitochondrial activity may be used to develop reliable predictive test for mitochondrial genetic screening
Trial registration number: not applicable

P-160 Remote embryo assessment: shifting the paradigm from traditional embryo grading

A. Picou[1], K.A. Wirka[2], A.B. Catherino[2], B. Hayward[2], M.D. VerMilyea[1,3,4]

[1]Ovation Fertility, Laboratory and Operations, Austin, U.S.A. ;
[2]EMD Serono, Fertility and Endocrinology, Rockland, U.S.A. ;
[3]Ovation Fertility, IVF Lab, Austin, U.S.A. ;
[4]Texas Fertility Center, IVF Laboratory, Austin, U.S.A.

Study question: How confident are embryologists with remote embryo assessment (REA) using time-lapse (TL) technology as an alternative to traditional embryo assessment (TEA) when performing morphology grading?
Summary answer: REA enables morphology grading with high confidence at fertilization assessment (Day 1) and Days 3, 5, 6 and 7 of embryo development.
What is known already: Despite other advances in assisted reproductive technology, morphology is the stalwart used by embryologists to grade embryos for transfer. To be able to assess and select embryos with minimal culture disturbance is highly desirable. The impact of REA enabled by TL technology in the *in vitro* fertilization (IVF) laboratory remains unknown, including its potential impact on embryo grading and selection compared with TEA (routinely performed with a light microscope). Most importantly, the level of confidence in embryo assessments performed remotely by embryologists using this novel technology has not been previously evaluated. Here we describe preliminary results of a feasibility study.
Study design, size, duration: Non-interventional, longitudinal study in a single IVF centre over 5 months. Seven embryologists performed Day 1–7 morphology gradings using TEA and REA (Geri Connect and Assess® [Genea BIOMEDX]). Embryologists rated their level of confidence (high/low) for each embryo grading and stated reasons for low confidence, when applicable. TEA was performed using standard procedures and REA performed after a ≥1 week washout period. This study was determined exempt from review by Sterling IRB, Atlanta, GA, USA.
Participants/materials, setting, methods: Data included 5458 morphology gradings from 72 embryo cohorts evaluated on Days 1,3,5,6 and 7. TL imaging was initiated on Day 0. TEA/REA were timed and performed by the same embryologist; elapsed recording time was used to match timing of TEA (performed in real time) to the retrospective REA (performed elsewhere at their convenience). REA Block I had no time restrictions; Block II simulated TEA's time sensitivity. Confidence in gradings and video usage were reported.
Main results and the role of chance: Mean durations (minutes ± standard deviation) of cohort assessments were TEA 2.14 (±1.30) and REA 2.02 (±1.18) with an average of 10.1 embryos per cohort. Embryologists reported high confidence in 94.4% (636/674) of Day 1 TEA-graded zygotes. REA matched high confidence in 88.1% (560/636). High confidence was reported for 98.5% (585/594) of Day 3 and 96.0% (1308/1363) of Day 5–7 TEA gradings; REA matched in 94.4% (552/585) and 95.0% (1242/1308), respectively. Among embryos graded with low confidence using TEA, 44.7% (17/38) of Day 1, 66.7% (6/9) of Day 3 and 72.7% (40/55) of Day 5–7 were graded with high confidence using REA. During REA Block I and II, video review was used for 5.1% (53/1033) and 0.5% (8/1666) of embryos, respectively, with 91.8% (56/61) of embryologists having improvement in confidence. The main low confidence reasons reported for TEA were "not able to roll embryo around" (56.0% [61/109]; mostly for Day 1, 59.0% [36/61]) and "need for a second opinion" (25.7% [28/109], all Day 5–7). Within the REA group, "poor focus or focal range" (55.9% [123/220], caused by device malfunction in 25.2% [31/123]) and "not able to roll embryo around" (23.2% [51/220]; mostly for Day 1, 54.9% [28/51]).
Limitations, reasons for caution: This study was conducted in a single clinic using a specific TL device and REA system; clinics using different devices and systems may not observe the same results.
Wider implications of the findings: This is the first study to evaluate embryologist confidence in embryo grading using a remote system. REA embryo gradings can be performed with high confidence compared with traditional assessment. Improved embryologist confidence for embryos previously graded

with low confidence may be associated with image replay and review enabled by REA.
Trial registration number: N/A

P-161 The effect of high humidity by using single step culture media on continuous embryo monitoring incubator.

C. Albert Rodriguez[1], M.A. Valera[1], S. Pérez-Albalá[1], L. Alegre Ferri[1], B. Aparicio-Ruiz[1], J. Remohí[2], M. Meseguer Escrivá[1]

[1]IVIRMA, Lab FIV, Valencia, Spain ;
[2]IVIRMA, Ob/Gym, Valencia, Spain

Study question: Is there any effect of high humidity culture conditions by using single step Media and Continiuous Embryo Monitoring (CEM) on reproductive outcome?
Summary answer: By using single step media and CEM incubator Geri, culturing embryos under high humidity does increase reproductive outcome
What is known already: The first goal of an IVF laboratory is to achieve stable conditions to allow the best embryo development. An incubator has control different variables, like temperature, gas. Usually we don´t need to use the humid conditions, as oil overlay has supported successful use of a dry incubator for culture human embryos, preventing changes in the pH, temperature. The evaporation of culture media may affect the osmolality. Therefore, the use of humid conditions avoid osmolality changes.
Study design, size, duration: A total of 5755 embryos from ovum donation programme and own oocytes and that were culture on a CEM system (Geri genea biomedix, Australia) were included in a retrospective and multicentric study from three consecutive years.
Participants/materials, setting, methods: This incubator has 6 separated incubators. Three of them works in a dry atmosphere (DC) and the other 3 in humid conditions (HC). In DC, 2630 embryos were cultured and a total of 3125 embryos were cultured under HC. Retrospectively, blastocyst, good morphology blastocyst rate, pregnancy, and euplody rate.
Main results and the role of chance: We found differences in embryo development. We had similar blastocyst rate when the embryos were culture under high humidity; 52.8% vs DC 53.1%. When we focused on those blastocyst with good morphology we had significantly high quality blastocyst in HC; 1.6% vs 9.9%. We also found differences in pregnancy rates between HC and DC, 62.4 vs 55.0% respectively. These differences disappeared in thawed procedures 46.7 % in HC and 50.0% in DC, but the embryos were cultured in normal dry incubator until transfer. In the group of PGT embryos, we had similar embryo ploidy proportional in both groups 39.6%vs 39.2 % in DC
Limitations, reasons for caution: The retrospective nature of this abstract maybe reduce the quality of the evidence presented although sample size is outstanding and embryos were cultured with the type of incubator that included a time-lapse system.
Wider implications of the findings: Culturing embryos with single step media may include high humidity as a preference to optimize pregnancy results.
Trial registration number: none

P-162 Effect of higher donor BMI on clinical pregnancy and live birth rates in IVF cycles.

E. Iovine[1], V. Casciani[1], A. Pristera[1], V. Zazzaro[1], F. Scarselli[1], G. Pirastu[1], D. Uva[1], K. Litwicka[1], A. Greco[1], P.F. Greco[1], M.C. Greco[1], M.T. Varricchio[1], A. Ruberti[1], M.G. Minasi[1], E. Greco[1]

[1]European Hospital, Reproductive medicine, Roma, Italy

Study question: Could higher donor BMI affect the IVF success rate in egg donation cycles?
Summary answer: Increasing donor BMI reduces fertilization rate and embryo development but not clinical outcomes.
What is known already: Excess weight could be deleterious for women causing cardiometabolic health risks and adverse reproductive outcomes. It was known that women with an overweight or obese BMI, experienced worse outcomes in terms of pregnancy and live birth rates that those with normal BMI. It remains unclear whether those effects are exerted at level of the oocyte quality or at the endometrial. The oocyte donor model is a good tool to separate the effect of obesity on oocyte/embryo quality from the effect of endometrial receptivity allowing to study if a higher donor BMI could affect oocytes quality and biological outcomes.
Study design, size, duration: We retrospectively analyzed 85 egg donation cycles (October 2014-January 2020) with ≥ 50% survival rate of vitrified/warmed oocyte. Only cycles with male age ≤ 45 years old were considered. Cycles were divided in two groups: grouP-1 included oocyte-donors with BMI≤23.9 whereas group 2 included donors with BMI≥24. All oocytes were injected with fresh ejaculated normozospermic semen (WHO, 2010). Data, shown as avarage±SD, were analyzed with Chi square or Student-t test.
Participants/materials, setting, methods: GrouP-1 included 57 cycles, donor BMI (21.28±2.76) and 437 oocytes; grouP-2 included 28 cycles, donor BMI (26.03±2.78) and 232 oocytes. Respectively, in grouP-1 and in grouP-2, donor age was 25.39±3.87 and 25.20±3.84, female recipient age was 42.3±3.69 and 41.9±4.18 (NS). The recipient BMI in grouP-1 and in grouP-2 was respectively (22.9±3.80) and (23.1±3.60) (NS), the male average BMI were respectively 25.6±3.43 and 25.8±3.46 (NS). Embryos were culture in a time-lapse incubator until day-3 or day-5.
Main results and the role of chance: Oocytes survival rate in grouP-1 and in grouP-2 was respectively 88.1% (385/437) and 84.9% (197/232)(NS). Fertilization rates in groups 1 and 2 were respectively 77.4% (297/385) and 67.5% (133/197) ($p<0.05$). In grouP-1, a total of 224 embryos (transferred and vitrified) were obtained whereas in grouP-2 total embryos were 91. When the efficiency of treatments was calculated as the ration between total embryos obtained per received oocytes, in grouP-1 a rate was obtained (51.1%, 224/437) higher than in grouP-2 (39.2%, 91/232, $p<0.05$). No statistical differences were found in beta-HCG positive (62.2%, 33/53, in grouP-1; 57.7%, 15/26, in grouP-2), clinical pregnancy rates (CPR) (52.8%, 28/53, in grouP-1; 53.8%, 14/26, in grouP-2) and implantation rate (IR) (40.9%, 35/86, in grouP-1; 45.4%, 20/44, in grouP-2).
Limitations, reasons for caution: In clinical outcomes, only fresh transfers were considered (cumulative data not fully available). Donors was stimulated with protocols according to their history and hormonal levels. The sample size of our population was reduced by selecting male partners <45 year old, a choice made to reduce the possible male-age-factor effect.
Wider implications of the findings: Increasing donor BMI could affect fertilization rate and the amount of embryos obtained suggesting that an ideal BMI value could be set as cut-off in donor screening. Since clinical outcomes were similar in the groups we can hypothesize that endometrial receptivity could adjust the donor BMI effects on oocytes quality.
Trial registration number: not available

P-163 Robust embryo scoring model based on artificial intelligence (AI) applied to a large time-lapse dataset

J. Rimestad[1], M.F. Kragh[2], J.T. Lassen[1], A. Tran[3], J. Berntsen[1]

[1]Vitrolife A/S, Product Development, Viby J, Denmark ;
[2]Vitrolife A/S & Aarhus University, Product Development, Aarhus, Denmark ;
[3]Harrison AI, Co-founder, Sydney, Australia

Study question: Does an AI-based automatic embryo scoring system perform consistently independent of patient age, fertilization method, year of treatment, incubation time, culture media and fertility clinic?
Summary answer: The trained AI model has shown to perform consistently regardless of patient age, fertilization method, year of treatment, incubation time, culture media and fertility clinic.
What is known already: Use of AI for robust selection of embryos requires models trained on large datasets that encompass a wide variation in patient cohorts and clinical practices. Training with a limited dataset would only be directly applicable to the clinical setting where it was developed and would require retraining should clinical practice change.

Previously, an AI model was reported to sort embryos with positive fetal heartbeat (FHB) from all remaining embryos with areas under the receiver operating curves (AUC) from 0.90 to 0.95 (IVY v1.0). However, training AI models can introduce unintentional biases that should be examined using an independent test set.
Study design, size, duration: An AI model was trained for binary classification of positive FHB from all remaining embryos, given time-lapse videos of 98583 embryos from 18 clinics across three continents. The following stratifications were analyzed on a test dataset with 17249 embryos not seen during

training: patient age (for the groups <30, 30-34, 35-39, >39), fertilization method (IVF, ICSI), year of treatment (2011-2019), incubation time (96-115, 115-117, 117-119, 119-130 hours post insemination), culture media and fertility clinic.

Participants/materials, setting, methods: A total of 115832 embryo videos generated by IVF or ICSI between 2011 and 2019 were included in the study. Patient age ranged from 18 to 52. Embryos were cultured using the EmbryoScope or EmbryoScope+ time-lapse system for at least 4 days. 101188 embryos were deemed non-usable due to PGT results or manual deselection by embryologists. 14644 embryos were transferred (fresh or frozen) resulting in 4337 positive FHB and 10307 negative FHB outcomes.

Main results and the role of chance: The AUC on all 17249 embryos in the test dataset was 0.95 [95% CI: 0.943-0.955], showing great overall performance.

For the four age groups, the n and AUC were <30: 2277, 0.97; 30-34: 4302, 0.95; 35-39: 4702, 0.95 and >39: 3857, 0.94. For fertilization methods, the AUC was 0.96 for IVF (n=4681) and 0.95 for ICSI (n=5073). For years of treatment with more than 250 embryos, the mean AUC across all years was 0.95 [0.91 to 0.98]. For the four incubation time groups, the n and AUC were 96-115: 1971, 0.92; 115-117: 3718, 0.94; 117-119: 2579, 0.94; 119-130: 1871, 0.92. For culture media, one clinic using two different brands (n=456 and n=536) was investigated and had AUCs of 0.92 and 0.91. All AUCs above showed only minor biases, indicating generalization across subsets.

Mean AUC across clinics was 0.94 [0.89 to 0.97] for the 12 clinics with more than 250 embryos in the test dataset. To evaluate model generalization to new clinics, leave-one-clinic-out cross validation was performed on these 12 clinics. Each clinic was evaluated on a model trained on the remaining 11 clinics, resulting in a mean AUC of 0.94 [0.91 to 0.97]. The similar AUCs indicate generalization across clinics.

Limitations, reasons for caution: The different clinics from which the data originated did not use a common strategy for embryo selection, which might have introduced biases in model performance. To further validate the AI for embryo selection power, a prospective study will be performed.

Wider implications of the findings: Automatic embryo scoring by AI shows convincing results for all provided subgroups of data and can therefore be expected to generalize well on new clinics, whose data have not been used for training the AI.

Trial registration number: not applicable

P-164 The effect of artificial oocyte activation (AOA) on morphokinetic pattern of human embryos in cases with severe male infertility

M. KARAGIANNI[1], M.I. Papadopoulou[1], C. Oraiopoulou[1], S. Sgoura[1], A. Chatzianastasiou[2], P. Moisidou Tsiorva[2], E. Taki[2], A. Vorniotaki[2], M. Moysidou[1], A. Papatheodorou[1], N. Christoforidis[3], A. Chatziparasidou[4]

[1]Embryolab, Embryology lab, Thessaloniki, Greece ;
[2]Embryolab, Andrology lab, Thessaloniki, Greece ;
[3]Embryolab academy - Embryolab, Clinical, Thessaloniki, Greece ;
[4]Embryolab academy - Embryolab, Embryology lab, Thessaloniki, Greece

Study question: Does artificial oocyte activation (AOA) in cases with severe male infertility alter the morphokinetic pattern of human embryos?

Summary answer: This study suggests that there is no significant difference in morhpokinetics using AOA in cases with 99% abnormal sperm morphology or testicular biopsy.

What is known already: Oocyte activation is the result of a cascade of events triggered by sperm. The moment sperm enters oocyte's cytoplasm it diffuses PLCz which in-turn triggers calcium oscillations followed by oocyte activation and fertilization. In cases were low fertilization rates is observed after ICSI for patients with low sperm count, motility and morphology or patients after testicular sperm extraction (TESE), sperm related activation deficiency may be suspected. To overcome low or no fertilization after ICSI, AOA has been used with varying success rate. At present the available published data is limited and the value of AOA has not been yet determined.

Study design, size, duration: This prospective cohort study included 44 ICSI treatments performed at Embryolab Fertility Clinic, in Thessaloniki, Greece between November 2018 and November 2019. The study population consisted of stimulated cycles with minimum 10 oocytes during oocyte pick up with own or donor oocytes which were fertilized with partner's sperm. The sperm was either from ejaculation with 99% abnormal morphology or from testicular biopsy.

Participants/materials, setting, methods: 44 cycles were analyzed in order to evaluate their morphokinetic pattern. Mature oocytes from each patient were divided in two groups: AOA group included oocytes that were incubated in Ca^{2+} ionophore (A23187, CultActive, Gynemed) after ICSI for 15 minutes and NO AOA group was the control. All oocytes were cultured in Embryoscope time-lapse incubator and the key time parameters and dynamic events were analyzed using t-test and Mann–Whitney U test.

Main results and the role of chance: There was no significant difference in fertilization rate between 2 groups (AOA-68.41% vs. NO AOA-65.88%, p>0.05). Furthermore, blastocyst rate was similar between the 2 groups (AOA-61.48% vs NO AOA-65.74%, p>0.05). The comparison for key time parameters and dynamic events (tPB2, tPNa, tPNf, t2, t3,t4, t5, t6, t7, t8, t9+, tSC, tM, tSB, tB, tEB, tHB, S2, S3, S5, CC2, CC3, Blastulation) showed no significant difference between the AOA group and NO AOA group in total (p>0.05). In addition, when AOA groups were divided into 2 subgroups a) ejaculated sperm with 99% abnormal morphology and b) testicular sperm, the morphokinetic comparison of these 2 separated groups to their control did not reach any significant differences (p>0.05).

Limitations, reasons for caution: Only a limited number of cases were included in this study. Apart from severe male infertility other maternal derived factors may also be involved. The results for pregnancy, clinical pregnancy and live birth were not available for all cases.

Wider implications of the findings: Artificial oocyte activation method does not seem to have an effect on the morphokinetic pattern and embryonic development. Additionally, a benefit on fertilization rate in cases of ejaculated sperm with 99% abnormal morphology or testicular sperm was not observed.

Trial registration number: N/A

P-165 KIDScore helps in selecting the best euploid embryo: a retrospective cohort study

L. Pellegrini[1], L. Parmegiani[1], A. Rastellini[1], A. Arnone[1], S. Bernardi[1], S. Lanzilotti[1], A.M. Maccarini[1], E. Troilo[1], G.E. Cognigni[1], M. Filicori[1]

[1]GynePro Medical Centers- NextClinics International, Reproductive Medicine Unit, Bologna, Italy

Study question: Does KIDScore D5v2 represent an additional tool for the selection of euploid blastocysts and for predicting their implantation?

Summary answer: KIDScore D5v2 appears to be predictive to discriminate between euploid and aneuploid embryos and euploid blastocysts with KIDScore 6.0-10.0 show a significantly higher implantation rate.

What is known already: Time-lapse microscopy (TLM) offers continuous monitoring of embryo development and KIDScore is the software used by the TLM incubator Embryoscope (Vitrolife, Sweden) to score embryo morphokinetics, but the prediction of chromosomal abnormalities using morphokinetics alone is still insufficient. Preimplantation Genetic Testing for Aneuploidy (PGT-A) discriminates between euploid and aneuploid blastocysts; KIDScore could be used to prioritize the transfer of euploid embryos identified by PGT-A diagnosis.

Study design, size, duration: Retrospective cohort study, from June 2016 to December 2019 on 508 embryos from 156 patients, cultured to blastocyst stage (DAY 5-7) and screened by PGT-A. Based on KIDScore, blastocysts were divided in two groups: Group 1 (KS 0 – 5.9; n=320), Group 2 (6.0 – 10; n=188) Main outcome measures: euploidy rate (number of euploid blastocysts/total blastocysts), implantation rate (number intrauterine gestational sacs observed by transvaginal ultrasonography/n° of transferred blastocysts).

Participants/materials, setting, methods: Mean female age ±SD was 36.0±4.4 (25-46). Blastocysts were cultured in Embryoscope, assessed by KIDScore model D5v2 and biopsied to perform PGT-A (Next Generation Sequencing Veriseq PGT protocol - Illumina, USA). Subsequently, blastocysts were vitrified and euploid blastocysts were warmed and transferred (100 blastocysts; mean 1.14± 0.35).

Main results and the role of chance: Female and male mean age was comparable between the groups. Euploidy rate was statistically different: 24.6% (79/320) in Group 1 (KS 0 – 5.9) versus 36.7% (69/188) in Group 2

(KS 6.0 – 10; P=0.0040 Chi-squared test), suggesting KIDScore seems to be predictive for selecting euploid blastocysts. Implantation rate was calculated over the 100 blastocysts transferred; the mean number of transferred embryos was comparable in each group (Group 1: 1.13±0.34; Group 2: 1.16±0.37). Implantation rate was significantly lower at 28.2% (13/46) in Group 1 compared to 51.8% (28/54) in Group 2 (P=0.0288 Yates's Chi-squared test). This result suggests a threshold value based on morphokinetic features that could help embryologists to prioritize euploid blastocysts prior to transfer. Selecting euploid blastocysts with KIDScore > 6 seems to promote increased chances of implantation.

Limitations, reasons for caution: This study is limited to patients from only one centre with a relatively low number of blastocysts. Further and larger studies are needed to validate these results and to permit efficient clinical implications.

Wider implications of the findings: Blastocyst selection through time-lapse technology alone should not be considered as a replacement for PGT. According to our findings, KIDScore seems to be a potentially valuable tool for identifying the euploid blastocysts having a higher probability of implantation.

Trial registration number: N/A

P-166 The impact of incubator humidity, protein supplementation and time-lapse dish design on media osmolality during culture.

M. Garcia-Jimenez[1], E. Mestres[1], A. Casals[1], I. Vanrell[1], A. Villamar[1], M. Acacio[1], Q. Matia[1], J. Cohen[2], N. Costa-Borges[1], G. Calderon[1]

[1]Embryotools S.L., Research & development, Barcelona, Spain ;
[2]ART Institute of Washington, IVF Laboratory, New York- NY, U.S.A.

Study question: How do incubator humidity, protein supplementation and time-lapse dish design affect the osmolality of culture media over time?

Summary answer: Incubator humidity and time-lapse dish design play an important role in the stability of osmolality during culture. Protein supplementation does not alter osmolality over time.

What is known already: Uninterrupted embryo culture is a widespread practice, but certain key conditions must be considered to avoid osmolality increasing above detrimental thresholds. Humidified incubation may protect against evaporation, but humidity is a non-binary condition and can vary between incubators.

Proteins (like albumin) can have emulsifying properties and may have a potential effect on osmolality during culture under oil. Time-lapse systems are usually dry incubators and embryos are cultured uninterruptedly. In addition, the preparation of time-lapse dishes is time-consuming and uses reduced volumes of media and oil, which may result in some evaporation.

Study design, size, duration: Medium osmolality was measured daily between 0-168h in Petri dishes with 20µl drops overlaid with oil, comparing incubation in a humid *vs.* dry atmosphere and media with 0 *vs.* 20mg/ml HSA. Osmolality was also measured in six different types of time-lapse dishes after 0h (set-up), 72h (Day 3), 120h (Day 5) and 168h of culture (Day 7). All readings were performed with a last-generation vapour pressure osmometer (VAPRO 5600, Wescor).

Participants/materials, setting, methods: For the humid *vs.* dry and protein *vs.* no-protein experiments, 35mm Petri dishes were prepared following an underlay method by placing the medium droplets below the oil to avoid any evaporation during setup. Each type of time-lapse dish was prepared according to its manufacturer's instructions. All six types of time-lapse dishes were cultured in a joint dry benchtop incubator. For two of those models, culture and measurements were replicated in their time-lapse incubator.

Main results and the role of chance: Results are shown as the difference between the initial osmolality (once the dish was set-up) and after 120/168h of culture. When assessing the effect of protein supplementation, osmolality increased by 28/41 and 30/45 mOsm/kg in the 0 and 20 mg/ml HSA groups, respectively. In a humid atmosphere, a rise of 15/19 mOsm/kg was observed, compared with 34/42 mOsm/kg in a dry incubator.

The set-up of all the studied time-lapse dishes lead to medium evaporation by 5 mOsm/kg in relation to the medium vial. An additional increase of osmolality was detected during culture, notably varying depending on the dish design. For the six studied dish models, the observed increases in a dry benchtop incubator were: 12/20, 16/20, 15/22, 22/30, 27/35 and 31/42 mOsm/kg. Two dish types could be cultured in their corresponding time-lapse dry incubators, as well. In these cases, the osmolality increase was comparable to that observed in the dry benchtop suggesting that a direct dish fit in the heated plate within time-lapse incubators does not significantly increase evaporation.

Limitations, reasons for caution: The humidity level in benchtop incubators may vary and is not usually monitored. In this study, time-lapse dishes were cultured in a dry benchtop incubator. However, some time-lapse incubators allow for a humidified atmosphere, and its effects on osmolality must be studied in each specific dish incubator.

Wider implications of the findings: The starting osmolality of culture media, incubator humidity and time-lapse dish design are important factors to consider during *in vitro* embryo culture. An excessive evaporation during uninterrupted culture will result in osmolality increase and may have a detrimental effect on embryo development.

Trial registration number: N/A

P-167 Antagomir-Mediated Silencing of let-7a-5p in Mouse Embryo can improve blastocyst Implantation Rate.

J. Shakerzadeh[1], M. Movahedin[2], A. Eidi[1], N. Hayati Roudbari[1], K. Parivar[1]

[1]Science and Research Branch- Islamic Azad University, Department of Biology, Tehran, Iran ;
[2]Faculty of Medical Sciences- Tarbiat Modares University- Tehran- Iran., Department of Anatomical Sciences, Tehran, Iran

Study question: To evaluate the role of murine let-7a-5p blastocysts in implantation failure and the possibility of let-7a-5p suppression in improvement of implantation *in vivo.*

Summary answer: Our results suggested that suppression of embryonic murine let-7a-5p could improve embryonic implantation through the upregulation of Igf1, Itgb3 and Tgfb1.

What is known already: Blastocyst implantation needs appropriate molecular and cellular communications between blastocyst. microRNAs-mediated gene expression of both endometrial tissues and/or blastocyst have impact in the process of implantation and fetal development.

Study design, size, duration: This is a case-control study and totally 100 adult female mice and 10 adult male mice during 2018-2019 were included (Strain NMRI). We analyzed the expression of murine let-7a-5p in the control, sham, and treatment embryos (8-cells stage) by quantitative reverse transcription PCR (qRT-PCR).

Participants/materials, setting, methods: In the treatment group, IVF drops were transfected with mmu-let-7a-5p antagomir (ABM, Inc., Richmond, BC, Canada) using ViaFect™ Transfection Reagent (Promega, Madison, WI, USA), while the sham group receive only transfection reagent, and control group receive no treatment. Expression levels of mRNA targets of let-7a-5p (Igf1, Il1, Itgb3 and Tgfb1) were analyzed by qRT-PCR. The blastocysts were transfer to the pseudopregnant mice to evaluate the effect of let-7a-5p supression on embryo implantation.

Main results and the role of chance: : Our results showed that there were not significant changes in the developed embryo to the blastocyst stage between the study groups (P> 0.05). Expressions level of let-7a-5p in the treatment group were significantly downregulated compared with the controls (FC=0.352, P=0.039). In contrast, no significant changes were observed between the sham and control groups (P> 0.05). Expression level of the four mRNA targets was not significantly different between the sham and control group (P> 0.05). Expression level of Igf1 (FC=1.8, 0.021), Itgb3 (FC=1.3. P=0.039) and Tgfb1 (FC=1.4, P=0.032) were significantly upregulated in the anatgomir treated group compared to the control group. The implantation rates were significantly higher in the treatment group compared to the control (P< 0.05).

Limitations, reasons for caution: Since each microRNA can target many of transcripts, we should explore the other potential mRNAs of let-7a-5p in the process of implantation.

Wider implications of the findings: A higher implantation rate following the suppression of murine let-7a-5p embryo suggested that microRNAs have important roles in the process of implantation.

Trial registration number: not applicable

P-168 A prospective study of the effect of laser-assisted hatching on the clinical outcome of single frozen/thawed embryos transfer cycles

V. Torres Monserrat[1], M.C. Delpiccolo[1], M.N. Lardizabal[1], N. Carizza[2], T. Leiva[2], E. Navall[2], S. Dominici[2], R. Sol Ariadna[2], C. Carizza[3]

[1]Fertya-Grupo Oroño, Embryology Laboratory, Rosario, Argentina ;
[2]Fertya-Grupo Oroño, Gynecology, Rosario, Argentina ;
[3]Fertya-Grupo Oroño, Medical Director, Rosario, Argentina

Study question: Does laser-assisted hatching (AH) improve clinical pregnancy outcome of frozen/thawed embryo transfer cycles taking into consideration the day of embryo development and patients´ prognosis?
Summary answer: Laser-assisted hatching does not improve clinical pregnancy rate in frozen/thawed embryo transfer. However, good prognosis patients that transfer single day-5 embryos are affected with AH.
What is known already: Although assisted hatching (AH) is routinely performed in frozen/thawed embryo transfer cycles, there is not enough data to conclude the benefit of this technique. Despite its widespread use, there is a limited number of prospective studies that have examined the effect of AH on clinical pregnancy and multiple pregnancy. Most of the investigations with good scientific evidence conclude that AH can benefit clinical pregnancy rate in patients with poor prognosis, but it could also increase multiple pregnancy. However, there are not studies that evaluate the effect of AH and the day of embryo development in frozen/thawed embryo transfer
Study design, size, duration: A prospective analysis of the effect of laser-assisted hatching on clinical and multiple pregnancy rates in 331 patients that underwent frozen/thawed single embryo transfer in our clinic from April to December 2019. Before treatment, patients were explained about actual evidence of the technique for them to decide to do it or not. We compare Control Group, 120 transfer without AH, and Treatment Group, 211 patients with AH. Embryo development day and patient's prognosis were analysed
Participants/materials, setting, methods: Embryos were incubated in K-System® G-185 incubator with Sage® Medium. Kitazato® Medium Kits were used to vitrify and thaw. Single embryo transfer was performed the same day embryo was thawed. AH was performed immediately after thawing with Lykos® laser set in the multipulse mode (pulse duration 200us). The chi square independence test and Fisher's exact test were used to compare groups about clinical pregnancy and multiple pregnancies rates, significance represented by a $p<0.05$
Main results and the role of chance: Laser-assisted hatching does not improve clinical pregnancy rate (Control Group: 31% vs Treatment Group: 27%, P-value=0.404) nor affect multiple pregnancy rate (Control Group: 5.4% vs Treatment Group: 1.8%, P-value=0.561) when considering all patients undergoing frozen/thawed single embryo transfer. When analysing only patients with bad prognosis, Control Group: 9% vs Treatment Group: 20%, P-value=0.083, this technique does not improve clinical results either. The same result was obtained when studying patients with good prognosis, Control Group: 45% vs Treatment Group: 33%, P-value=0.088. In addition, we analysed the same groups and divided them considering the day of embryo development when vitrified. When considering all patients undergoing frozen/thawed day-5 embryo transfer, clinical pregnancy was not benefited by AH (Control Group: 39% vs Treatment Group: 28%, P-value=0.125). However, when this sub-group was divided according to prognosis, good prognosis patients were affected by laser-assisted hatching (Control Group: 53% vs Treatment Group: 32%, P-value=0.021), whereas, bad prognosis patients were not affected (Control Group: 13% vs Treatment Group: 24%, P-value=0.257). Surprisingly, these results were not seen in the sub-group of day-6 embryo transfer where clinical pregnancy is not affected by performing AH in the general population (P-value=0.617), nor in good prognosis (P-value=0.759) or bad prognosis (P-value=0.255) patients
Limitations, reasons for caution: The main limitation of this study is the lack of randomness between control group and treatment group
Wider implications of the findings: This prospective study shows that assisted hatching does not benefit clinical pregnancy rates of frozen/thawed single embryo transfer cycles. This is the first prospective study that analyse the effect of AH on frozen/thawed single embryo transfer in relation to embryo development day and patients prognosis.
Trial registration number: -

P-169 Early recombinant-LH supplementation improves oocyte competence acting on oxidative stress in young poor responder IVF-patients.

M. Santonastaso[1], F. Caprio[2], A. Natella[2], F. Mottola[3], L. Rocco[3], R. Ianniello[2], D. Mele[2], N. Colacurci[1]

[1]Università degli Studi della Campania L. Vanvitelli, Dpt. of Woman-Child and General and Special Surgery, Naples, Italy ;
[2]Azienda Ospedaliera Universitaria L. Vanvitelli, Gynecological-obstetric clinic, Naples, Italy ;
[3]Università degli Studi della Campania L. Vanvitelli, Dpt. of Environmental-Biological and Pharmaceutical Sciences and Technologies, Caserta, Italy

Study question: Does early recombinant (rec)-LH supplementation in ovarian stimulation protocol affect oxidative stress in cumulus cells as well as IVF outcome in poor responder patients?
Summary answer: Early rec-LH supplementation enhances ovarian response to stimulation and embryological parameters reducing oxidative stress markers in young women with poor ovarian reserve in ICSI cycles.
What is known already: Management of women with poor ovarian response (POR) to stimulation is a major challenge in reproductive medicine. The POR primary causes remain unknown and oxidative stress was recommended as one of causes. Multiple interventions have been proposed to improve reproductive outcomes in POR but showed conflicting results. Ovarian stimulation may have a direct impact on oxidative stress markers with Reactive Oxygen Species (ROS) production and perturbation of oxidant-antioxidant balance. IVF outcome is adversely affected if imbalance exists between ROS and antioxidants in oocyte microenvironment. Early rec-LH supplementation impact in POR ovarian stimulation protocol to improve IVF outcome are still unclear.
Study design, size, duration: This prospective randomized controlled study included 132 POR patients stratified according to POSEIDON classification group 3(age < 35, poor ovarian reserve parameters)from March 2015 to April 2018. All patients enrolled underwent controlled ovarian stimulation according to GnRH antagonist protocol. Patients were randomized to rec-LH supplementation(A group) or no rec-LH supplementation(B group) from second day of the cycle. Oxidative stress markers in cumulus cells,oocyte number and quality,fertilization rate, embryo quality, pregnancy rates are the outcome measures.
Participants/materials, setting, methods: Exclusion criteria: PCOs, endometriosis,metabolic and endocrinology diseases, severe oligoasthenoteratozoospermia. On the day of oocyte retrieval, cumulus cell samples were mechanically removed from oocyte. The intracellular ROS were assessed by H2DCF-DA (2',7'-dichlorofluorescein diacetate) fluorescent probe. DNA fragmentation index (DFI) and apoptotic gene (BAX and BCL-2) expression was assessed by TUNEL Test and qPCR-Real Time respectively. The data were analyzed using the unpaired Student's t-test by IBM SPSS-STATISTICS versions 20.0 and considered significant if P-value ≤ 0.05.
Main results and the role of chance: There was no significant difference in the baseline clinical characteristics and the number of oocyte retrieval in both groups. The mature oocytes number and number of fertilized oocytes were higher in patients treated with rec-FSH + rec-LH (A group). The average number of high-quality embryos on day 3 in patients treated with rec-FSH + rec-LH and rec-FSH was 1.70±0.75 and 0.66±0.47 respectively ($p\leq 0.05$). After the two ovarian stimulation protocols the differences of number of transferred embryos was statistically significant. The pregnancy rate was statistically higher in patients treated with rec-FSH + rec-LHcompared to patients treated with rec-FSH (59.37% versus 34.30%, $p\leq 0.05$). Intracellular ROS percentage was significantly lower in POR patient treated with rec-FSH plus rec-LH compared POR patients no rec-LH supplementation (23±5.80 vs. 43±7.50, $p\leq 0.05$). Cumulus cell DNA fragmentation was significantly lower in in patients treated with rec-FSH + rec-LH. Cumulus cells surrounding oocytes retrieved from patient treated with rec-FSH + rec-LH expressed significantly higher BCL-2 mRNA levels than those from patient treated with rec-FSH ($p\leq 0.05$) whereas BAX mRNA levels resulted to decrease significantly ($p\leq 0.05$) in the patients treated with rec-FSH + rec-LH compared to patients treated with r-FSH.
Limitations, reasons for caution: Lifestyle factors (i.e. smoking, diet) are not considered. The cumulus cell samples are pooled.
Wider implications of the findings: This study showed that rec-LH supplementation reduces oxidative stress markers in term of intracellular ROS

production, DNA fragmentation and apoptosis as well as influences oocyte competence in POR patients. Early rec-LH supplementation in controlled ovarian stimulation protocol act for strategy to improve IVF reproductive outcomes in young POR patients.

Trial registration number: N° 48 (30/01/2015)

P-170 Non-invasive detection of metabolically impaired euploid blastocysts with low implantation potential

S. Cabello-Pinedo[1], H. Abdulla[2], M.L. Seth-Smith[1], M. Escriba[3], J. Crespo[3], J.A. Horcajadas[1], S. Munne[1]

[1]Overture Life SL, Scientific Department, Madrid, Spain ;
[2]Texas A&M University Corpus Christi, Chemistry, Corpus Christi, U.S.A. ;
[3]Juana Crespo Clinic, Embryology, Valencia, Spain

Study question: As not all euploid embryos implant, is it possible to identify non-implanting euploid blastocysts from their spent media metabolomics profile?

Summary answer: Analysis of the spent media metabolomics profile could predict about 30% implantation failure of euploid embryos, coinciding with the upper limit of PGT-A success.

What is known already: Embryo implantation potential and euploidy rates decrease with advancing maternal age. Preimplantation Genetic Testing (PGT) is been used in routine clinical practice to avoid the transfer of aneuploid embryos with minimal chance of resulting in a viable pregnancy. However, even the best PGT-A published results do not exceed 70% ongoing pregnancy rates. Little is understood of the causes of failure of euploid embryos to implant, and methods to discriminate between viable euploid embryos and non-viable euploid embryos, that will not result in a successful pregnancy, have not been developed yet.

Study design, size, duration: This study includes spent media samples collected before trophectoderm biopsy from embryos that were later analyzed by PGT and transferred. To develop the algorithm, this study used a dataset that included 37 samples collected using Vitrolife media that were classified as pregnancy (P) or non-pregnancy (NP) according to embryo implantation outcome after transfer. The algorithm was then tested on spent media of 42 euploid blastocysts.

Participants/materials, setting, methods: For the training subset (n=37), patients undergoing infertility treatments were included. For the validation stage (n=42), patients whose embryos were analyzed through PGT were recruited. In both cases, spent media samples (20-40ml) were collected after incubation between days 3 and 5 and just before biopsy. Before the analysis, samples were diluted with distilled water, ultrafiltered to remove molecules >3KDa and run through a UPLC-Fusion Orbitrap MS/MS system to determine metabolite concentration.

Main results and the role of chance: Samples from the training subset were processed, detecting more than 5,550 metabolites in spent media samples. Several statistical techniques were applied to reduce this large number of metabolites to the most informative ones for pregnancy outcome. This led to the definition of a Vitrolife specific MPI (Metabolite Pregnancy Index), which has proved to be highly predictive of both P and NP embryos. This technique was tested in a completely different data subset showing an ability to identify 78% of P samples and 61% of NP samples.

For the validation part of the study, metabolic profile of culture media coming from euploid embryos (n=42) was studied in order to assess whether the implantation failure of some euploid embryos may be due to metabolic impairment. A 30.95% of euploid embryos in the validation subset showed a metabolomic profile predicting poor implantation potential despite being euploid.

Although further research is necessary, these results open the possibility of applying metabolomics to differentiate, within euploid embryos, those that are viable from the ones that will not result in a successful pregnancy.

Limitations, reasons for caution: The study was retrospective but a prospective clinical trial is underway. In addition, all the samples were collected using the same culture media and the metabolomic algorithm is media specific. The study needs to be validated in multiple culture media and test its outcome comparing it with more clinical data.

Wider implications of the findings: This study represents an initial step in the development of non-invasive methods based on metabolomics approach, that allow identification of viable embryos, not only based on ploidy status. The optimization of embryo selection techniques, without altering embryology protocols, may result in an improvement in pregnancy outcomes in women undergoing ART.

Trial registration number: NA

P-171 Is the frequency of aneuploidy and mosaicism at blastocyst stage associated to the embryo sex?

P. Villanueva[1], J. Huayhua[2], L. Noriega-Hoces[3], F. Vizcarra[1], J. Noriega-Portella[3], L. Guzman Masias[1]

[1]Laboratorios PRANOR, Embriologia, Lima, Peru ;
[2]ADN Diagnostico, Genetics, Lima, Peru ;
[3]Clinica Concebir, Departamento Medico, Lima, Peru

Study question: Is the chromosome constitution associated to the embryo sex?

Summary answer: Male blastocysts are less likely to be euploid considering confounding variables. Additionally, they have a higher chromosomal unbalances (aneuploidy+mosaicism) in the same embryo.

What is known already: There is very limited information about embryo euploidy and mosaicism in relation to embryo sex. In our study, chromosome constitution at blastocyst stage was evaluated by next-generation sequencing (NGS) and confounding factors were controlled. Previous studies with lower data found that embryo sex was not significantly associated with ploidy status.

Study design, size, duration: Data was collected retrospectively from June 2016 to October 2019. In total, 1212 PGT-A cycles were included.

Participants/materials, setting, methods: In total, 4434 blastocysts analysed with PGT-A were generated from 1212 cycles. The chromosome constitution was classified: euploid, single-aneuploid, double-aneuploid, complex-aneuploid, single mosaic, double mosaic, complex mosaic, mix (aneuploid and mosaic) and complex mix.

A multilevel model was made and associations between variables by logistic regression adjusted according to maternal age, blastocyst grade, biopsy day, inner cell mass and trophectoderm grade, fertilization method, and embryologist.

Main results and the role of chance: The mean maternal age was 36.2 ± 4.2. The genetic results of 4434 blastocyst were as follow: euploid 46.4% (N= 2058); single aneuploid 14.4% (N=640); double aneuploid 4.7% (N= 208), complex aneuploid 2.1% (N=94); single mosaic 13.7% (N=607), double mosaic 4.7% (N=210); complex mosaic 6.6% (N=291); mix 2.8% (N=123) and complex mix 4.6%(N=203). When results were classified according to the embryo sex, 49.1% (N=1010) were euploid female blastocyst and 50.9% (N=1048) were male euploid blastocyst. For single aneuploidy was 47.7% (N=305) and 52.3% (N=335); double aneuploid was 46.2% (N=96) and 53.8% (N=112); complex aneuploidy was 46.8% (N=44) and 53.2% (N=50); single mosaic was 44.3% (N=269) and 55.7% (N=338); double mosaic was 52.9% (N=111) and 47.1% (N=99); complex mosaic was 46% (N=134) and 54% (N=157) and complex mix 47.8% (N=97) and 52.2% (N=106) in female and male blastocyst respectively (p≥0.05). Male embryos are more likely to have a mix chromosome constitution (aneuploid and mosaic) than female embryos (OR=1.63, 95% CI (1.12-2.36), p=0.010). Furthermore, they are less likely to be euploid (OR=0.88, 95% CI (0.78-0.99), p=0.037) adjusted for all variables.

Limitations, reasons for caution: The results observed in this study should be confirmed using a larger number of samples.

Wider implications of the findings: Our data suggest that male blastocyst are associated with a lower euploidy and a higher mixture of chromosomal unbalanced.

Trial registration number: none

P-172 The transcriptome of paired human oocytes related to progesterone primed ovarian stimulation

F. Martinez[1], S. Mateo[1], E. Clua[1], N. Coca[2], J. Rodriguez-Lumbiarres[2], L. Armengol[2], M. Roca[1], S. Garcia[1], N. Polyzos[1]

[1]Hospital Universitari Dexeus, Obstetrics- Gynecology and Reproduction, Barcelona, Spain ;
[2]qGenomics, qGenomics, Barcelona, Spain

Study question: Is there any difference in the human oocyte transcriptome under two specific Controlled Ovarian Stimulation (COS)/LH suppression protocols: progesterone-primed cycles (PP) and GnRH-antagonist cycles (ANT).
Summary answer: Different modes of controlling the endogenous LH secretion do not translate in a significantly different oocyte transcriptome.
What is known already: Although the use of and oral progesterone (PP) instead of (ANT) has been effective in controlling LH surge during ovarian stimulation, evidence from a randomized trial reported lower live birth rates from PP-derived oocytes, suggesting a detrimental effect on oocyte competence. A novel potential method to assess an effect of stimulation on the oocyte level is single-cell transcriptome, though powerful genomic techniques allow this even in a single-cell. In the current study we aimed to evaluate the effect of PP stimulation on oocyte developmental competence, through transcriptome analysis of In-vivo-matured oocytes (transcriptome remarkably stable across ages and ovarian reserve).
Study design, size, duration: Retrospective study comparing single-cell transcriptome of 24 mature paired oocytes from four oocyte donors (OD) who underwent two consecutive COS/IVF cycles at private, university-based IVF center between January 2017 and March 2018 were included.

OD underwent two COS/IVF cycles, under two LH suppression protocols (PP-Group: 75mg daily oral Desogestrel; ANT-Group: 0.25mg daily s.c. Ganirelix) until GnRH agonist trigger.
Participants/materials, setting, methods: Four healthy oocyte donors underwent two consecutive COS/IVF cycles, under two LH suppression protocols (PP-Group: 75mg/day Desogestrel; ANT-Group: 0.25mg/day Ganirelix) until trigger. Mature MII oocytes were vitrified according to standard procedure. Three oocytes from each cycle (PP/antagonist) from the same donor were thawed, total-RNA was extracted, cDNA was prepared and labeled prior to hybridization on PrimeView Human Gene Expression arrays(Affymetrix). Gene expression levels were normalized (RMA) and compared between treatments after data normalization (LIMMA).
Main results and the role of chance: Overall, we analyzed the transcriptome from 24 oocytes derived from 4 oocytes donors who underwent 2 consecutive ovarian stimulation cycles, 1 with GnRH antagonist and 1 with PP (12 oocytes from ANT and 12 oocytes from PP).

Comparisons in the gene expression profile from total single-cell RNA extracted from oocytes derived from ANT or PP ovarian stimulation did not demonstrate any significant difference. Following, adjusting P-values for multiple testing, no statistically significant differences in gene expression levels were observed between oocytes obtained from the two evaluated Controlled Ovarian Stimulation (COS)/LH suppression protocols. Despite that single-cell transcriptome profile did not differ when comparing different LH suppression protocols (ANT vs. PP), of interest, other experimental conditions have been have significantly influenced oocyte transcriptome (P<0.05).
Limitations, reasons for caution: The study was restricted to healthy OD and thereby other conditions related to infertility or older age were not considered. This is a descriptive study with a limited number of samples reflecting the difficulty to recruit human oocytes, especially from women with infertility.
Wider implications of the findings: To our knowledge this is the first study utilizing singe-cell transcriptome analysis in order to evaluate the effect PP suppression of LH on oocyte developmental competence. Our results add reassuring information to the clinical available data regarding the safety of the PP ovarian stimulation protocols
Trial registration number: Not Applicable

P-173 Interest of laser assisted hatching prior to good-quality blastocyst transfer: intermediate results of a prospective randomized study

C. Herbemont[1], Y. Boumerdassi[1], B. Bennani Smires[1], S. Sarandi[1], O. Selmi[1], C. Vinolas[2], C. Lethielleux[2], F. Krief[2], I. Cedrin-Durnerin[2], M. Peigné[2], M. Grynberg[2], C. Sifer[1]

[1]Hôpital Jean Verdier, Histologie-Embryologie-Cytogénétique-Biologie de la Reproduction-CECOS, Bondy, France ;
[2]Hôpital Jean Verdier, Médecine de la Reproduction, Bondy, France

Study question: The aim was to assess the impact of laser assisted hatching (AH) on the implantation potential of good-quality blastocysts (GQB) transferred in a selected population.
Summary answer: In good-prognosis patients and those with recurrent implantation failure, implantation rates (IR) of GQB were similar whether laser-AH was performed or not before transfer.
What is known already: In assisted reproductive techniques, embryo development conditions are deeply modified. Indeed, the increasing use of extended culture and vitrification may induce a zona hardening, possibly resulting in a defective hatching process and implantation failure. Assisted Hatching, defined as the artificial breakage of the zona pellucida (ZP), appears to be a tool to overcome this issue and improve IVF/ICSI outcomes. To date, several studies have focused on the outcomes of AH performed at the cleavage-stage, concluding to an increase in clinical pregnancy rates, especially in poor-prognosis patients. However, investigations on the interest of AH at the blastocyst stage are still controversial.
Study design, size, duration: This prospective randomized study has been in progress since September 2017. Inclusion criteria were: female age ≤37 years, fresh/vitrified day-5 GQB (defined as: blastocoel expansion B3/B4, inner cell mass and/or trophectoderm graded A/B, according to the grading system described by Gardner and Schoolcraft), absence of risk factors for implantation failure. So far, 260 fresh/vitrified GQB transfers have been randomly allocated to AH group (n=122): laser-AH performed prior to transfer; or no-AH group (n=138): no hatching.
Participants/materials, setting, methods: In AH group, a single hole completely through the ZP was performed using a 200-µsecond laser pulse (Lykos, Hamilton Thorne).

In the preliminary analysis, the included population was stratified by number of good-quality (GQ) embryos previously transferred, leading to "good prognosis" (GP) and "recurrent implantation failure" (RIF) subgroups (respectively defined as ≤4 and >4 GQ cleavage-stage embryos, or ≤2 and >2 GQB transferred without proven implantation). Clinical outcomes were compared between AH and no-AH groups.
Main results and the role of chance: In the "GP" analysis, AH (n=108) and no-AH (n=117) groups were comparable considering female age, body mass index, type and cause of infertility, and attempt rank. On average, 1,13±0,34 and 1,08±0,28 GQB were transferred in AH and no-AH groups, respectively (p=0,29). Quality of the transferred blastocysts was similar as well: 57,4% of toP-blastocysts [B4AA/AB/BA] in AH group vs. 59,1% in no-AH group, respectively (p=0,60). IR and clinical pregnancy rates (CPR) were not significantly different whether laser-AH was performed or not prior to transfer (IR: 39,4% in AH group vs. 43,6% in no-AH group; p=0,51, and CPR: 40,7% vs. 45,3%, respectively; p=0,17).

Considering the "RIF" subgroups, patients' characteristics and the mean number of GQB transferred (1,57±0,51 vs. 1,46±0,51, respectively; p=0,51) were similar between AH (n=13) and no-AH (n=23) groups. There was no difference in the proportion of toP-blastocysts transferred (66,7% vs. 69,7%, p=0,82). Interestingly, GQB transferred after laser-AH yielded similar IR and CPR compared to GQB transferred without laser-AH (IR: 42,9% in the two groups; CPR: 50,0% vs. 54,5%, p=0,79).
Limitations, reasons for caution: These preliminary results need to be confirmed on a larger series, especially in the "RIF" subgroup. Moreover, a potential impact of AH on twin pregnancy rates should be examined.
Wider implications of the findings: If confirmed, these findings would suggest that assisted hatching might not be beneficial to young patients, with or without history of implantation failure, as long as good-quality blastocysts are transferred. Finally, the hypothesis of zona hardening due to exposure to culture and/or vitrification media might be questioned.
Trial registration number: 2018-A02395-50

P-174 The effect of ovine whole ovary cryopreservation on the antral follicle oocyte and its developmental potential

A. Dadson[1], D. Wang[1], J. Hernandez-Medrano[1], W. Maalouf[1]

[1]University of Nottingham, Department of Obstetrics and Gynaecology, Nottingham, United Kingdom

Study question: Are oocytes obtained from antral follicles of sheep viable with the capacity to mature following whole ovarian cryopreservation (WOCP) using the slow freezing method?
Summary answer: Oocytes isolated from whole ovary cryopreserved and thawed antral follicles fail to mature *in vitro* and record high level of induced apoptosis.

What is known already: Whole ovary cryopreservation using slow freezing and transplantation restores ovarian function and natural fertility resulting in multiple live births in sheep. This is as a result of the preservation and survival of primordial and preantral follicles.
Study design, size, duration: A total of 540 antral follicle oocytes (control, CT, n=304 and WOCP, n=236) were aspirated from abattoir-sourced sheep ovaries. After collection, oocytes were classified according to cumulus oocyte complex (COC) morphology into normal (A&B) or abnormal (C&D). Oocytes were matured *in vitro* and nuclear maturation assessed after 24 hours. The viability and apoptosis of antral follicle oocytes was also assessed immediately following cryopreservation and subsequent thawing.
Participants/materials, setting, methods: Ovaries were randomly allocated into fresh (control, CT) and WOCP. WOCP and thawing was as described by Onions et al 2008. COCs were then retrieved and grouped into the various grades based on the cytoplasm and presence or absence of cumulus cells. The oocytes were then assessed for viability and apoptosis using propodium iodide (PI) and terminal deoxynucleotidyl fluorescein-dUTP nick end labelling (TUNEL) respectively. Nuclear maturation was assessed by DAPI following *in vitro* maturation (IVM).
Main results and the role of chance: Percentage of COCs classified as normal was similar (P>0.05) between WOCP (54.5±12.7%) and CT (54.3±8.0%). Moreover, PI positive oocyte percentages were comparable (P>0.05) between WOCP and CT: 32.6% (n=23/70) and 19.8% (n=15/76), respectively. However, nuclear maturation was lower (p<0.05) in WOCP (8%, n=1/64) compared to CT oocytes (67%, n=53/65), whereas TUNEL apoptotic index was higher in WOCP oocytes than controls (75.4%, n=52/69 vs. 26.6%, n=17/76).
Limitations, reasons for caution: Whole ovary cryopreservation caused a significant loss of cumulus cells in the oocytes obtained from antral follicles. These results depict clearly shows the inability of the oocytes to develop further, however does not conclude on the quality of the oocyte.
Wider implications of the findings: Isolating oocytes from antral follicles of freeze-thawed sheep ovary for *in vitro* maturation and fertilisation may not be a feasible path for clinical application.
Trial registration number: not applicable

P-175 The impact of anti-centromere antibodies (ACAs) on embryonic and pregnancy outcomes following IVF and single vitrified-warmed blastocyst transfer

T. Okubo[1], K. Omi[1], T. Hayashi[1], N. Onda[1], T. Segawa[1]

[1]Shimbashi Yume Clinic, Advanced medical research institute of fertility, Tokyo, Japan

Study question: Do anti-centromere antibodies (ACAs) negatively influence embryonic and pregnancy outcomes following IVF and single embryo transfer?
Summary answer: ACA negatively influences embryonic outcomes following IVF, while pregnancy is not affected once expanded blastocysts are produced and transferred.
What is known already: ACA is a member of the anti-nuclear antibody (ANA) family. It has been considered that ACA may be the major antibody of ANA group, which has adverse effects on clinical outcomes following IVF-ET. Since the population of ANA positive (+) and ACA positive (+) infertile patients is low, studies regarding the significance of ACA, among the types of ANA, in the possible interference with embryonic and pregnancy outcomes are limited.
Study design, size, duration: A retrospective cohort study of 601 cycles (223 patients, mean age: 39.9±4.1 years), including 560 cycles (213 patients, mean age: 40.0±4.0 years) involving ANA (+)/ACA (-) and 41 cycles (10 patients, mean age: 39.0±4.3 years) involving ANA (+)/ACA (+), was conducted between May 2017 and March 2019 in a single centre. Embryonic and pregnancy outcomes following single ET were compared among the groups.
Participants/materials, setting, methods: A total of 1,419 oocytes (ANA (+)/ACA (-): 1,224 and ANA (+)/ACA (+): 195) were retrieved. Oocyte maturation status was defined by first polar body visualization or meiotic spindle confirmation. Oocytes were inseminated using IVF or ICSI. The primary outcomes were normal fertilization, multiple nucleation (3PN<), cleavage, and good-quality blastocyst formation rates (Gardner criteria: grade >3). Secondary outcomes were clinical pregnancy (gestational sac observation) and ongoing pregnancy rates (foetal heartbeat observation).
Main results and the role of chance: The ANA (+)/ACA (-) group had normal fertilization and multiple nucleation rates of 80.0% (1389/1737) and 6.8% (118/1737), respectively, while the ANA (+)/ACA (+) group had rates of 60.2% (80/133) and 26.3% (35/133), respectively. The ANA (+)/ACA (+) group showed a significantly higher multiple nucleation rate (p<0.05). Although there were no significant differences in cleavage rates among the groups (ANA (+)/ACA (-): 75.4%, 1310/1737 and ANA (+)/ACA (+): 58.6%, 78/133), the occurrence of fragmentation in cleaved embryos was significantly higher in the ANA (+)/ACA (+) group (ANA (+)/ACA (-):42.2%, 553/1310, and ANA (+)/ACA (+):57.7%, 45/78, p<0.05). The good-quality blastocyst formation rates were significantly lower in the ANA (+)/ACA (+) group than in the ANA (+)/ACA (-) group (ANA (+)/ACA (−): 32.7%, 429/1310); ANA (+)/ACA (+): 14.1%, 11/78), p<0.05). A total of 268 and 11 cycles of single vitrified-warmed blastocyst transfer were performed in the ANA (+)/ACA (-) and ANA (+)/ACA (+) groups, respectively. No significant differences were observed between the groups in clinical pregnancy and ongoing pregnancy (ANA (+)/ACA (−):53.4%, 143/268 and 44.0%, 118/268; ANA (+)/ACA (+):72.7%, 8/11 and 54.5%, 6/11).
Limitations, reasons for caution: The main limitation of the present study was its retrospective design and small sample size. The rate of ANA (+)/ACA (+)was small (0.8%, 10/1,227) in all IVF patients during the study period. Therefore, these were the only cases of ANA (+)/ACA (+) available.
Wider implications of the findings: Oocytes in ANA (+)/ACA (+) patients showed a significantly higher incidence of multiple nucleation, which was associated with a significantly lower good-quality blastocyst formation rate. However, acceptable pregnancy outcomes in those patients would be achievable if good-quality blastocysts are obtained and transferred.
Trial registration number: None.

P-176 Effects of maternal ageing on trophectoderm transcriptome dynamics and the potential impact on embryo-endometrial interactions.

P. Ntostis[1], G. Kokkali[2], D. Iles[1], J. Huntriss[1], A. Pantou[2], K. Pantos[2], H. Picton[1], D. Miller[1]

[1]LICAMM Institute, Discovery and Translational Science, Leeds, United Kingdom ; [2]Genesis Athens Clinic, Reproductive Medicine Unit, Athens, Greece

Study question: What differences are there in the human trophectoderm transcriptome among young, intermediately aged and older women with respect to the receptive endometrium?
Summary answer: The most significant gene ontologies from young/intermediate to advanced maternal age trophectoderm involved extracellular exosomes and, when receptive endometria were considered, the regulation of apoptosis.
What is known already: Chromosomal nondisjunction is the most frequent cause of recurrent miscarriages, with women over 35 years of age also experiencing lower pregnancy rates. Euploid embryo transfer reported decreased live birth rates in women over 35 years, with women over the age of 40 experiencing significantly lower implantation and pregnancy rates. Several factors involved in embryo-endometrial communication may contribute to lower success rates, with blastocyst-secreted exosomes potentially affecting endometrial receptivity and gene expression, regulating embryo implantation. To date, no study has specifically explored the trophectoderm transcriptome with respect to the maternal age and endometrial receptivity.
Study design, size, duration: Fifteen women treated for infertility in a single IVF unit agreed to participate in this study. Trophectoderm biopsies (Day 5 blastocysts) were obtained from 4 women below 30 years (young cohort), 8 women aged 30-39 years (intermediate cohort) and 3 women over 40 years old (AMA cohort). Samples were collected over a 6-month period and RNA was isolated. Our study design also included the analysis of transcriptome data from receptive endometria.
Participants/materials, setting, methods: Library construction and deep RNA sequencing included 10 trophectoderm biopsies derived from young women (24.4±2.0 years), 16 from intermediate aged women (34.3±2.6 years) and 6 from women of advanced maternal age (AMA) (42.0±1.1 year) (mean±SD). RNA expression profiles were obtained from all 32 trophectoderm biopsies (Day 5 blastocysts). Trophectoderm characterisation and ontological analysis were followed by the investigation of the complementarity between young/AMA trophectoderm and receptive/non-receptive endometrial transcriptomes. Chromosome aneuploidy analysis was also performed.

Main results and the role of chance: RNA sequencing revealed 233 significantly differentially expressed genes (DGE) (580 transcripts), between young and AMA trophectoderm transcriptomes, with FDR ranging between 5.59 x E-08 and 0.049 in the young and 7.29 x E-06 to 0.049 in the AMA cohorts. These results correspond to log fold changes of between 0.66 and 9.97 in the young and between -0.98 and 9.24 in the AMA cohort, respectively. No significantly differentially expressed genes were revealed between young and intermediate cohorts.

Cellular component analysis of the differentially expressed genes between young and AMA trophectoderm, revealed factors potentially participating in molecular trophectoderm-endometrial communication, including 42 genes strongly associated with extracellular exosomes (FDR 8.2E-06). Considered alone, the AMA cohort did not reveal any significant ontologies, however a trend for higher representation of mitotic spindle and cytosol ontologies was noted. These results may suggest the role of extracellular exosomes in the communication between trophectoderm and endometrium in human. When additional endometrial gene expression data were included in our analysis, the regulation of apoptosis was strongly represented in both embryonic and endometrial transcripts, suggesting that this could be an important process linked to successful implantation.

Limitations, reasons for caution: The relatively high variation in trophectoderm RNA expression presents a reason for caution. However, the relatively low variation within the young and AMA cohorts and the fact that a minimum of 6 samples were analysed (from at least 3 different women per cohort), minimized the potential impact on our analysis.

Wider implications of the findings: Understanding the effects of maternal ageing on the trophectoderm RNA, could identify processes that delineate normal embryo development. Considering also the receptive endometrial transcriptome, further insights into the mechanisms involved in successful implantation may be revealed. These findings have the potential to increase the low implantation rates of AMA women.

Trial registration number: N/A

P-177 Clinical application, safety and efficacy of Day 4 biopsy for preimplantation genetic testing. A retrospective cohort analysis.

G. Liperis[1], H. Swearman[1], J. Crittenden[1], C. Sjoblom[1]

[1]Institute of Reproductive Medicine- University of Sydney, Westmead Fertility Centre, Sydney, Australia

Study question: To evaluate the safety and efficacy of Day 4 embryo biopsy

Summary answer: The developmental potential of embryos and cycle outcomes suggest that day 4 biopsy is a safe and effective stage at which to perform embryo biopsy.

What is known already: Embryo biopsy routinely takes place on day 3 (cleavage stage) or day 5-6 (blastocyst stage) of embryonic development; with the latter preferred due to the ability to biopsy more cells, providing increased genetic material for analysis. A limitation of blastocyst biopsy is that several embryos capable of generating a pregnancy may not be biopsied if they fail to reach the blastocyst stage. In a recent study, transfer of euploid embryos following morula biopsy on day 6 has shown significantly lower implantation rate and birth rate compared to transfer of euploid blastocysts.

Study design, size, duration: A retrospective analysis was undertaken of patients having day 4 embryo biopsy at a single Centre between 2014 and 2017. The reasons for PGT-A included implantation failure, history of recurrent miscarriages and advanced maternal age, whilst PGT-M was employed for specific gene defects and PGT-SR for structural rearrangements. Average patient age was 36.4 ± 4.8 years. A total of 152 cycles of PGT from 148 couples were biopsied on day 4 (1890 embryos).

Participants/materials, setting, methods: Participants were consented patients undergoing IVF/ICSI cycles combined with PGT. Following fertilisation, fresh or frozen-thawed embryos, cryo-preserved at the 2PN stage for banking purposes, were cultured to day 4. On day 4, all embryos suitable for biopsy were decompacted in Ca^{2+}/Mg^{2+} free medium and 2-6 cells were removed for analysis. The genetic analysis was performed on the same day and euploid/non affected embryo(s) were either transferred on day 5 or vitrified.

Main results and the role of chance: Couples had an average of 12.4 ± 4.1 embryos biopsied with an average of 2.7 ± 1.3 cells per embryo aspirated. Following genetic analysis, 2.5 ± 1.9 euploid/normal embryos available per couple (22.6% per couple, 451/1890 total embryos). Clinical pregnancy following the day 4 biopsy was 44.5% (53/119, 1.1 embryos per ET) for con-current transfers and 36.2% (17/44, 1.1 embryos per ET) for follow-up FET cycles resulting in overall clinical pregnancy of 42.9% (70/163) and 66 live births. Neonatal outcomes included five preterm deliveries (5/63, 7.9%) with zero babies born with small for gestational age weight and zero days in NICU for deliveries ≥37 weeks of gestation (0.03 ± 0.2 days). A high proportion of biopsied embryos per patient with no genetic abnormalities reached the blastocyst stage (79.2%) when assessed on day 5. However, a large proportion of utilised embryos per patient did not reach the expanded blastocyst stage on day 5 (45.4%). A total of 11 live births resulted from day 4 biopsy method from embryos that would otherwise not have met the requirements for undergoing a day 5 blastocyst biopsy.

Limitations, reasons for caution: The results represent the experience gained from current practice and not of a prospective controlled study. No embryos were cultured to day 6, therefore the developmental potential of certain embryos classified as not expanded blastocysts at day 5 of embryo development is unknown.

Wider implications of the findings: Day 4 embryo biopsy can be a safe and effective stage for obtaining genetic material for PGT. Therefore this method can be used as an alternative approach to current embryo biopsy practices or used in combination with blastocyst biopsy when there is a small cohort of available embryos for biopsy

Trial registration number: Not applicable

P-178 Does assisted hatching of vitrified blastocysts increase clinical pregnancy rates? A randomised controlled trial

C. Cordero Rosales[1], S. Cortés[1], C. Andrés[1], R. Pandolfi[1], C. Rodriguez[1], M. Saladino[1], J. Harper[2]

[1]Clínica Tambre, FIV Labotary, Madrid, Spain ;
[2]Institute for womwn`s health, Universyty College, London, United Kingdom

Study question: Does assisted hatching (AH) of vitrified blastocysts increase clinical pregnancy rates?

Summary answer: Our study found that AH of warmed vitrified blastocysts had no effect on clinical pregnancy rates.

What is known already: The use of AH has been controversial. Some studies have shown a benefit of AH on clinical pregnancy rates for various groups of patients, including those with cryopreserved embryos, but these effects are not seen on live birth rates. Other studies have shown no difference at all. Few studies have looked at the effects of AH on vitrified blastocysts.

Study design, size, duration: This randomised controlled trial was performed between September 2018 and December 2019. 210 patients undergoing blastocyst warming were randomly allocated into a control or AH group. All patients had a single blastocyst transfer (sET). Patients undergoing PGT-A, day 3 frozen embryo transfers and double embryo transfers (dET) were excluded. T-test was performed as statistical analysis, and $p<0.05$ were considered statistically significant.

Participants/materials, setting, methods: The embryos were frozen at the blastocyst stage using the open system, Kitazato vitrification and thawing protocol. Only blastocysts of good quality were frozen (AA,AB,BA,BB) using the Gardner scoring system. Blastocysts were frozen for between 4 days and 4 years. After warming, the AH was performed immediately with the Octax-Laser at 2.6ms performing in between 2-3 pulses. Blastocysts were cultured for a minimum of 2 hours before transfer. A routine embryo transfer was performed.

Main results and the role of chance: 132 patients were allocated into the AH group and 126 to the control group. The age of the woman's egg whose blastocyst was frozen ranged from 18-45 and there was no difference between the AH and control group.

For the AH group, 70 patients had a positive hCG (53.03%), and 55 had a confirmation of clinical pregnancy by ultrasound scan by a positive heart beat (41,67%). 9 of the clinical pregnancies had a miscarriage (13%). To date, from the ongoing pregnancies there are 16 live births. For the control group, 60 patients had a positive hCG (47,61%), and 57 had a confirmation of clinical pregnancy by ultrasound scan by a positive heart beat (45,23%). 15 of the clinical pregnancies had a miscarriage (25%). To date, from the ongoing pregnancies there are 10 live births.

There were no statistical differences after comparing positive B-HCG from patients undergoing AH and those that were not (p:0.45; 95% CI). There were no significant differences in the outcomes between groups (p:0.16 95% CI).

Limitations, reasons for caution: Currently we do not have all the live birth rate for this study.
Wider implications of the findings: There has been much ongoing debate about the use of AH in clinical embryology. In our clinic, we no longer perform AH routinely after blastocyst warming. Clinics need to carefully consider if they are charging for this procedure.
Trial registration number: Not applicable

P-179 Cell-free mitochondrial DNA facilitates granulosa cells apoptosis and reduces developmental competence of oocytes from aged mice

Y. Liu[1], Q. Shen[1], W. Xiang[1], L. Zhang[1]

[1]Tongji Medical College- Huazhong University of Science and Technology, Institute of Reproductive Health and Center for Reproductive Medicine, Wuhan, China

Study question: Is the addition of cell-free mitochondrial DNA(cf-mtDNA) to the culture medium affects mouse granulosa cells function and developmental competence of oocytes matured *in vitro*?
Summary answer: Cf-mtDNA may bind to TLR9 and activate NF-κB /MAPK signal pathways, subsequently induces granulosa apoptosis and reduces developmental competence of oocytes from aged mice.
What is known already: Quantitative analysis of cf-mtDNA in human follicular fluid showed that the relative content of cf-mtDNA was positively correlated with patient age, and the relative content of cf-mtDNA may be closely related to oocyte developmental competence. MtDNA, like bacterial DNA containing a large number of unmethylated CpG sequences, can causes inflammation as a damage-associated molecular pattern molecule when it is released out of the cells.
Study design, size, duration: C57BL/6J mouse ovarian granulosa cells and cumulus-oocytes complex were cultured accompanied with cf-mtDNA *in vitro*. Mitochondrial function, expression levels of genes and proteins related apoptosis and signal transduction pathway in granulosa cells, estrogen and progesterone levels in the media were tested. 2-cell embryos and blastocysts were also counted after maturation and fertilization *in vitro* of oocytes from young and aged mice.
Participants/materials, setting, methods: Mitochondrial function was assessed by measuring mitochondrial membrane potential, ATP levels, mtDNA copy numbers, and the apoptosis genes and apoptosis pathway proteins expression were evaluated by Western-blot assay, the mRNA expression of the apoptosis genes were also tested. Chemiluminescence immunoassay (CLIA) was used to detect the levels of estrogen and progesterone.
Main results and the role of chance: Granulosa cells in the cf-mtDNA treatment group had lower ATP content ($P<0.05$),higher apoptotic cells percentage ($P<0.01$), and higher mRNA and protein levels of apoptosis-related factors than the control. Also, the expression levels of TLR9, NF-κB and MAPK proteins in granulosa cells were significantly increased in the cf-mtDNA treatment group ($P<0.05$), suggesting that cf-mtDNA induced apoptosis of granulosa cells was associated with the binding of cf-mtDNA to TLR9 receptors and then activation of NF-κB and MAPK pathway. Blastocyst formation rate of oocytes matured *in vitro* from aged mice decreased significantly ($P<0.05$), however, developmental competence of oocytes from young mice had not been affected when cf-mtDNA was supplemented into *in vitro* maturation medium, suggesting that increase of cf-mtDNA in media for aged mouse oocytes could be a factor to affect oocyte quality.
Limitations, reasons for caution: Findings *in vitro* might not be suitable for *in vivo*.
Wider implications of the findings: This study suggests that extracellular mtDNA could cause to damage to granulosa cell function and subsequently decrease of oocyte developmental competence.
Trial registration number: no

P-180 An unbiased classification system including both fresh and first freeze-all cycles for reporting and comparing IVF results

P. Saldeen[1], K. Källén[2]

[1]Institution of Clinical Sciences Malmö- Lund University, Nordic IVF Malmö, Malmö, Sweden ;
[2]Institution of Clinical Sciences Lund- Lund University, Center of Reproductive Epidemiology- Lund University, Lund, Sweden

Study question: Is it more justified to include not only fresh, but also first freeze-all cycles in a classification system for reporting IVF result
Summary answer: In a series of 31017 oocyte retrievals, the 22.7% delivery rate after fresh embryo transfers (ET) increased to 25.7% when including also first frozen ETs
What is known already: Based on 12732 fresh IVF cycles, we presented in 2010 a "totally inclusive and mutually exclusive" clinically relevant classification system for reporting IVF results, imitating Robson's 10-group model for classifying cesarean sections. The most important factors for predicting delivery after IVF were female age, number of aspirated oocytes, cumulative gonadotropin dose, number of previously failed IVF cycles, and previous IVF delivery. The system has since then been used in Sweden for open and fair comparisons of delivery rates between IVF clinics, and for revealing temporal changes. However, after introduction of the freeze-all strategy the system is no longer "totally inclusive
Study design, size, duration: The material was obtained from the Swedish national quality register for assisted reproduction (Q-IVF) during 30 months 2015-2017. The register includes six public and 12 private clinics. The delivery rate per oocyte retrieval and ET, respectively,was calculated separately for fresh ETs and when including first frozen ETs (FFET) within 6 months when freeze-all was done.
Participants/materials, setting, methods: 31017 oocyte retrievals resulted in 25987 ETs and 7967 deliveries. The revised model included 10 groups: Female age (1) >42 years; (2) 40-41; (3) 36-39, previously ≥3 failed fresh IVF cycles; (4) <36, ≥3 failed fresh IVF cycles; (5) 36-39, previous IVF child; (6) < 36, previous IVF child; (7) 38-39, no previous IVF child; (8) 36-37, no previous IVF child; (9) 31-35, no previous IVF child; (10) ≤30, no previous IVF child.
Main results and the role of chance: By adding FFETs performed within 6 months after oocyte retrieval to fresh ETs, i.e. including FFETs when cycle cancellation was done due to freeze-all, the rate of delivery per oocyte retrieval increased from in mean 22.7% (95% CI 22.3-23.2; range 7.5-35.8%) to 25.7% (95% CI 25.2-26.2; range 8.4-39.1%). The mean increase was 2.4% with the lowest increase in group 2 (0.6%) and the largest in group10 (5.0%). The corresponding figures for delivery per ET were 27.1% (95% CI 26.6-27.7; range 9.6-39.4%) and 30.7% (95% CI 30.1-31.2; range 10.8-43.1%). For both delivery per oocyte retrieval and delivery per ET, the lowest success rates were found in group 1 (Fresh ET 7.5%, FFET after cancelled cycle 8.4% per oocyte retrieval; 9.6% respectively 10.8% per ET) and the highest in group 6 (Fresh ET 35.8%, FFET 39.1% per oocyte retrieval; fresh ET 39.4%, FFET 43.1% per ET).
Limitations, reasons for caution: The classification system should include deliveries after freh ETs and FFETs, but not both in an individual, and exclude multiple ETs of frozen/thawed embryos. A Swedish consensus decided the 6 month limit, since later FFETs may happen very occasionally.
Wider implications of the findings: Our 10-group classification system will reflect variations in IVF results over time in a clinic, and between clinics on national and international levels. The system can reveal inferior results in specific groups, to be scrutinized and improved. Further sub-classifications relative to ovarian sensitivity indices are optional.
Trial registration number: Not applicable

P-181 Embryo Biopsy on Morphologically Poor Quality Blastocyst – will it help improve the Reproductive Outcomes?

S.T. Mathew[1], K. Mantravadi[2], D.G. Rao[3]

[1]Oasis Fertility, Embryology, Vishakapatanam, India ;
[2]Oasis Fertility, Embryology, Hyderabad, India ;
[3]Oasis Fertility, Medical, Hyderabad, India

Study question: Embryo biopsy on morphologically poor quality blastocyst – will it help improve the reproductive outcomes?
Summary answer: Transfer of PGT-A screened euploid, morphologically poor quality blastocyst (MPB) can improve the overall pregnancy outcome compared to non-screened MPBs.
What is known already: Traditionally embryo quality based on morphological parameters is considered as a major predictive factor for the pregnancy outcome in ART. Particularly, a strong association has been reported between the blastocyst morphology and pregnancy outcomes. However, morphological assessment is still not an ideal way to select and de-select embryos to optimize reproductive outcomes. Currently, the focus is to find a method, which enables us to pick the best embryo for optimal results.
Study design, size, duration: All autologous frozen blastocyst embryo transfers (FET) with known pregnancy outcomes from January 2016 to March 2019 were analyzed. Patients who had a day 5/6 transfer with one or two MPBs were

considered in this study. A total of 86 patients underwent FET with non PGT-A MPB and 18 patients with PGT-A MPB. Statistical analysis of the obtained data was performed to find an association between the PGT-A of MPB and reproductive outcomes.

Participants/materials, setting, methods: A total of 104 patients were recruited for the retrospective study. Group I had 86 patients who underwent FET with non PGT-A MPB and group II had 18 patients with PGT-A MPB.

Among the clinical outcomes clinical pregnancy rate (CPR), miscarriage rate (MR), implantation rate (IR) and live birth rate (LBR) were included and perinatal outcomes includes average birth weight (BW), preterm delivery and delivery complications.

Main results and the role of chance: The CPR, MR, IR and LBR between group I and group II were found to be 43.02% vs. 66.67%, 15.12% vs. 16.67%, 26.53% vs. 66.67% and 16.46% vs. 50% respectively. Among the perinatal outcomes there was no incidence of low birth weight (LBW) or any congenital anomalies. Average birth weights and preterm delivery rates were 2.8 vs. 2.5kgs and 1.27% vs. 0% respectively. Clinical outcomes seem to be better with PGT-A group. Perinatal outcomes were comparable between both the groups. Results obtained in this study re-assure that embryo biopsy technique on poor morphology embryos doesn't seem to affect the perinatal and neo-natal outcomes. PGT-A on MPB can be used as an additional tool to pick the best embryo.

Limitations, reasons for caution: Retrospective study, Small sample size, Relative subjectivity of embryo scoring.

Wider implications of the findings: Our findings may help to reassure women that morphologically poor quality embryos can be screened for PGT-A and if euploid, can offer the best reproductive outcomes. Apart from morphology, PGT-A can be an additional tool for selecting and de-selecting the embryos for optimizing pregnancy outcomes.

Trial registration number: not applicable

P-182 Acute exposure to Etoposide does not activate DNA damage checkpoints in Meiosis I of human oocytes.

M. Botzaki[1], K. Agapitou[1], E. Nikitos[1], S. Kallergi[1], K. Niaka[2], P. Marangos[2]

[1]INSTITUTE OF LIFE-IASO Maternity hospital, IVFunit, Athens, Greece ; [2]University of Ioannina, Department of Applications and Technology-, Ioannina, Greece

Study question: Can spindle disruptions induced by Etoposide, a topoisomerase II inhibitor, activate DNA damage checkpoints in Meiosis I of human oocytes?

Summary answer: DNA damage accumulated in meiosis-I, does not prevent polar body extrusion and therefore could persist in morphologically normal metaphase-II oocytes.

What is known already: Severe spindle disruption activated the checkpoint to prevent polar body extrusion, moderate spindle insults fail to prevent polar body extrusion, causing defective chromosome segregation that likely leads to uneuploidy. Studies showed that mouse oocytes with damaged DNA can resume meiosis and undergo Germinal Vesicle Breakdown (GVBD), but then arrest in metaphase of meiosis-I in a process involving Spindle Assembly Checkpoint (SAC) signalling.Such a mechanism could help prevent the generation of metaphase-II (Met-II) eggs with damaged DNA.Little has been known about the spindle checkpoint in human oocytes.

Study design, size, duration: Donor immature oocytes aged <35years in a time frame of two years.

Experiments performed: 8 experiments involving 4 control and 8 oocytes treated with 100μg/ml Etoposide for 1h, from 8 individual donors.

26 experiments involving 54 control and 57 oocytes treated with 20μg/ml Etoposide for 1h, from 16 individual donors.

Histone H2AX and is used as an immunofluorescence marker for the detection of double-strand breaks. Draq7 is used for DNA staining. GV-stage oocytes are fixed immediately after treatment.

Participants/materials, setting, methods: Human oocytes were recovered from donor ovaries. Germinal Vesicle (GV)-stage oocytes were treated with high (100μg/ml) and lower (20μg/ml) concentrations of Etoposide for 1h. Following Etoposide treatment, treated and control oocytes were placed in the incubator at 37.5oC under 7.1% CO2.

Live imaging by time-lapse monitoring began immediately after oocyte transfer to the incubator, by the use of the Primo Vision. All data analysis was performed using ImageJ/Fiji.

Main results and the role of chance:

- Lower concentrations of Etoposide cause DNA damage but most oocytes progress through meiosis-I and subsequently extrude the first polar body (PB1) to form a metaphase-II egg, revealing the absence of a DNA-damage-induced SAC response.
- DNA damage accumulated in meiosis-I, such as could occur during in vitro maturation procedures, does not prevent polar body extrusion and therefore could persist in morphologically normal metaphase-II oocytes.

Limitations, reasons for caution: no limitations or reasons for caution

Wider implications of the findings: Multiple aspects of the clinical IVF environment could potentially damage the DNA of cultured oocytes.

This may explain poor embryo quality and repetitive implantation failures in many of the cases.

Trial registration number: not applicable

P-183 Oxygen concentration in culture media equilibration: does it have an impact on pregnancy rate?

E. De Martino[1], P. Filardi[1], G. Terrado[2], N. Passi[2], M. Gomez Peña[1], M. Papayannis[1], J. Maidana[1], I. De Zúñiga[2], L. Kopcow[2], M. Horton[2], A. Oubiña[2], F. Sobral[2], C. Bisioli[1]

[1]Pregna Reproductive Medicine, Embryology Laboratory, Buenos Aires, Argentina ; [2]Pregna Reproductive Medicine, Reproductive Medicine, Buenos Aires, Argentina

Study question: Can we culture human embryos at low oxygen in media that has been equilibrated overnight at atmospheric oxygen without affecting pregnancy rates?

Summary answer: Pregnancy rates are not affected when embryos are cultured at low oxygen in media that has been equilibrated at atmospheric oxygen concentration.

What is known already: Low oxygen has been shown to be crucial to culture embryos up to the blastocyst stage. Despite this, many laboratories still culture embryos in atmospheric conditions. Others use the old incubators for media equilibration overnight in order to save space in the low oxygen ones. When oocytes or embryos are placed into these high oxygen dishes they will be exposed to a temporary atmospheric state while low concentration is finally reached. Although it is generally pointed out that embryo culture must be entirely done at low oxygen, there are few studies proving that this is true.

Study design, size, duration: This prospective cohort study included 146 women performing fresh ART treatment between May 2018 and July 2019. Exclusion criteria included couples with severe male factor and donor cycles.

Participants/materials, setting, methods: According to the culture media equilibration methods used in our laboratory (overnight dishes at atmospheric or low oxygen) and the incubators space availability, patients were randomly divided into two groups:

- Group 1: Atmospheric oxygen (n=94)
- Group 2: Low oxygen (n=52)

Primary outcome was clinical pregnancy rate. Secondary outcome was implantation rate. No differences in patient age, insemination method and infertility diagnosis were observed. Chi-square and Student's t test were used as appropriate.

Main results and the role of chance: No significant differences were found in clinical pregnancy rate (23.4% vs. 21.1%) and implantation rate (15.4% vs 14.5%) between groups. Treatment outcome seems not to be affected by an exposition of around 4 hours to an atmospheric oxygen concentration in the beginning of the culture. Although several studies suggest a negative impact of oxidative stress in embryo development, there are still few regarding the effect of a brief exposition to atmospheric oxygen. Nevertheless it is generally recommended by personal communications that embryo culture must be done at low oxygen since the very beginning.

Limitations, reasons for caution: Our study is limited by its sample size and the need to go beyond pregnancy and implantation rates. In this sense it would be important to also study the possible effect that these two different

oxygen concentrations may have on the embryo physiology or on the newborn health.
Wider implications of the findings: To the best of our knowledge, this is the first analysis comparing two media equilibration conditions using atmospheric oxygen incubators as a possible viable option in cases of new technologies access limitations. More studies are necessary to elucidate the possible effects of transient oxygen concentration variation on human embryo development.
Trial registration number: Not applicable

P-184 The usefulness of metaphase I oocytes for intracytoplasmic sperm injection

J.P. Bilibio[1], A.J.C. Meireles[2], Y. Maciel[3], P. Sales[2], F. Nascimento[2], P.L. Lorenzzoni-[4]

[1]Universidade Federal do Pará, Ginecologia e obstetrícia, Belém ;
[2]Clínica de Reprodução Assistida Pronatus-, Reprodução Assistida, Belém, Brazil ;
[3]Universidade Federal do Pará, Ginecologia e obstetrícia, Belém, Brazil ;
[4]Grupo de Pesquisa Bilibio, Reprodução Assistida, Belém, Brazil

Study question: The aim was to evaluate the fertilization rate and blastocyst formation rate of oocytes in metaphase I (MI) in women who underwent controlled ovarian hyperstimulation for intracytoplasmic injection.
Summary answer: MI oocytes collected at stage MI after controlled ovarian hyperstimulation that did not mature in vitro to MII have a blastocyst formation rate of 0.6%.
What is known already: It is known that an increased pregnancy rate is directly related to the number of embryos in the blastocyst stage obtained by the in vitro fertilization (IVF) cycle, and this number depends on the quantity and quality of MII oocytes collected. As the number of these oocytes is inversely proportional to the age of the patient, the use of MI oocytes for IVF, especially in couples with advanced age, has been discussed as an alternative.
Study design, size, duration: A prospective cohort study was performed among women from whom at least 1 MI and 1 MII oocyte was obtained after controlled ovarian hyperstimulation for intracytoplasmic sperm injection during the study period,June 2018 to June 2019.

We collected 1907 oocytes from 164 women (1291 MII, 352 MI and 258 prophase I or atresic)
Participants/materials, setting, methods: After oocyte classification, the MII and MI oocytes were incubated for 4 hours.

After 4 hours in the single step balanced embryonic culture medium (Global Total), 1649 oocytes were fertilized by intracytoplasmic injection (ICSI), of which 1291 were in the MII stage (Group MII); of the 358 oocytes in the MI stage, 205 matured to MII oocytes (Group MI-MII), and 153 remained in stage MI (Group MI).
Main results and the role of chance: After 4 hours, the maturation rate was 57.2%; 205 matured in vitro to MII (Group MI-MII) and 153 remained in stage MI (Group MI).

The normal fertilization rate was directly associated with oocyte maturation, with rates of 79.1%, 60.2%, and 31.9% in MII, MI-MII and MI oocytes, respectively (P <0.001).

The MI group had an odds ratio (OR) of 7.6 (IC 5.2 - 11.2, P <0.001) for abnormal fertilization compared with the MII group.

The risk of embryo polyploidy was higher in the MI group, with an OR of 2.6 (1.28-5.41,P = 0.008), than in the MII group.

The blastocyst formation rate was directly associated with oocyte maturation: 36.4% for MII, 11.4% for MI-MII and 0.6% for MI.

MI oocytes had an OR of 86.9 (CI 12.1 - 623.4, P <0.001) for not forming a blastocyst compared with MII oocytes.
Limitations, reasons for caution: We found a decrease in the blastocyst formation rate from MII oocytes but no difference in MI-MII oocyte in patients over 40 years of age. Maternal age does not seem to influence the rate of blastocyst formation from MI-MII oocytes, but these results need to be confirmed in other studies.
Wider implications of the findings: Oocytes collected at stage MI after controlled ovarian hyperstimulatio that do not mature to MII in vitro have a blastocyst formation rate of only 0.6%, so their use should be discouraged. On the other hand, the use of MI-MII oocytes may increase the amount of blastocysts available for embryo transfer.
Trial registration number: 55625115.0.0000.0018

P-185 The non invasive embryoscope morphokinetic kidscore grading system and PGT-A ploidy status

P. Sopaboon[1], M. Tuntipoj[1], P. Suanbooncharoen[1], S. Chanchamroen[1], W. Quangkananurug[2], S. Seweewanlop[1], P. Assawakittananon[1], T. Thongsook[1]

[1]Safe fertility Center, Laboratory, Bangkok, Thailand ;
[2]Safe fertility Center, Medical Director, Bangkok, Thailand

Study question: Could the KIDscore number indicate the risk of aneuploid? Does the euploid and aneuploid embryos differ in KIDscore number?
Summary answer: There is no particular KIDscore number in indicating euploid embryo. The euploid and complex aneuploid embryos were statistical significant difference in KIDscore number.
What is known already: It has been shown that euploid embryo tend to implant. The invasive biopsy followed by PGT-A is widely use to identify the ploidy status of embryo. The non-invasive embryo selection is expected to predict ploidy status to enhance the possibility of implantation. The time-lapse incubator recently play a role in culturing and selecting the best embryo to transfer. EmbryoScope(Vitrolife) has launched the KIDscore system to be the evaluation tool for scoring the embryos according to their statistical viability. The time-lapse incubator combined with the software is costly and not much data have been published about the use of this algorithm.
Study design, size, duration: Randomized prospective study. 205 blastocysts in IVF/PGT-A cycle from couples attending an independent IVF clinic (Safe Fertility Center, Bangkok, Thailand) between April to May 2019 were enrolled in this study.
Participants/materials, setting, methods: All embryos were cultured in time-lapse incubators (EmbryoScope, Vitrolife). Embryo grading was done by both morphology grading (ACE/NEQAS system) and morphokinetic grading (KIDscore, Vitrolife). The KIDscore morphokinetic parameters observed were PN assessment, PN fading, time (t) to 2, 3, 4, 5 and 8 cells, tSB and tB followed by morphology grading of ICM and TE. The blastocysts were biopsied on Day 5/6 and analysed by PGT-A(NGS, Illumina).
Main results and the role of chance: The blastocyst formation rate, blastocyst analyzed for PGT-A rate were 64.50% and 86.13% respectively. Of the 205 blastocysts, 134 were euploid, 14 were mosaic, 33 were single chromosome aneuploid, 19 were complex chromosome aneuploid and 5 were DNA degradation. The overall KIDscore average range was 6.0±2.25. The euploid embryos had 6.27±2.24 on average in KIDscore number with 95% Confident Interval (CI):5.89-6.66. While the mosaic, single chromosome aneuploid, complex chromosome aneuploid and DNA degradation were 6.04±2.29 (95% CI:4.72-7.37), 5.75±2.17 (95% CI:4.98-6.52), 4.99±2.34 (95% CI:3.86-6.12) and 5.42±2.01 (95% CI:2.92-7.92).There are statistically significant difference in euploid and complex chromosome aneuploid group (P=0.021)in KIDscore number. The KIDscore number 8.0-9.9 bound to be euploid, mosaic, single chromosome aneuploid and complex chromosome aneuploid as 76.74%, 9.30%,13.95% and 9.30% respectively. Whereas the mid-grade KIDscore number 4.0-6.0 had 64.58%,10.41%, 27.08% and 14.58% in euploid, mosaic, single chromosome aneuploid and complex chromosome aneuploid respectively. The data could imply that the high grade KIDscore number has more chance to be euploid than the mid-grade and low-grade score.
Limitations, reasons for caution: The current sample size is small and data were collected from a single clinic which has a limited generalizability and potential bias. As routinely use is running, we will report on a larger sample size to provide more reliable effectiveness.
Wider implications of the findings: When selecting the embryo to transfer, considering not only the morphology scoring, the other scoring may benefit to help select the best embryo to get the best chance to implant. The non invasive evaluation tools could be consider to use as it less harming to the embryo.
Trial registration number: not applicable

P-186 Effect of different equilibration times on clinical and neonatal outcomes in human blastocyst vitrification

S. Mitsuhata[1], Y. Fujii[1], Y. Endou[1], M. Hayashi[1], H. Motoyama[1]

[1]Kurashiki Medical Clinic, IVF center, Kurashiki, Japan

Study question: What are the effects of shortened or prolonged equilibration time during human blastocyst vitrification?

Summary answer: A shorter (5–11 min) equilibrium time is sufficient for vitrifying smaller, non-expanded blastocysts.
What is known already: In human embryo vitrification, the duration of embryo's suspension in the vitrification solution is a critical consideration. This process should be strictly controlled within 1 min. However, exposure to the equilibration solution is flexible. A prolonged exposure to the equilibration solution may be harmful and may influence the embryonic developmental potential, whereas a shortened exposure may impair the penetration of cryoprotectants into the blastomeres. With regard to human blastocysts, few studies examine the effects of different equilibration times on clinical and neonatal outcomes.
Study design, size, duration: This was a retrospective study based on data collected between November 2008 and November 2015. A total of 225 blastocysts, 105 non-expanded blastocysts and 120 expanded blastocysts, obtained from 173 patients were analyzed. Non-expanded and expanded blastocysts were divided into 2 groups according to the equilibration time: 5–11 min and 12–15 min. Clinical and neonatal outcomes of warmed blastocysts were compared in each group.
Participants/materials, setting, methods: The blastocysts were vitrified and warmed following the Cryotop method. Blastocysts with blastocoels occupying less than half of the embryo volume and showing no signs of zonae thinning or expansion were categorized as non-expanded blastocysts. Blastocysts with thinning zonae and blastocoels that occupied greater than half of the embryo volume were identified as expanded blastocysts. Hatching blastocysts were classified as expanded blastocysts.
Main results and the role of chance: Both equilibration times (5–11 min and 12–15 min) in the non-expanded blastocyst group resulted in effective vitrification. There were no differences in the survival (96.9% vs. 92.5%, 95% CI: 0.48–13.4), implantation (20.0% vs. 20.0%, 95% CI: 0.38–2.62) and live birth rates (12.3% vs. 17.5%, 95% CI: 0.23–1.92) between the groups. While the results for the expanded blastocysts, the survival (86.7% vs. 96.7%, 95% CI: 0.05–0.99, P<0.05), implantation (23.3% vs. 45.0%, 95% CI: 0.17–0.81, P<0.05) and live birth rates (16.7% vs. 38.3%, 95% CI: 0.14–0.75, P<0.01) were significantly decreased in the 5-11 min group compared with 12-15 min group. There were no differences in gestational age, birthweight, proportion of male babies, rates of cesarean section, and congenital abnormalities.
Limitations, reasons for caution: This study is limited by sample size. There is possible dispersion of the embryo quality and cause of infertility. Further prospective randomized studies will be needed to confirm the findings of this study.
Wider implications of the findings: Prolonged exposure to cryoprotectants may incur harmful effects on embryonic development; thus, shortening exposures to equilibration solution are desirable. This study shows that outcomes are satisfactory if unexpanded blastocysts are vitrified with shorter exposure times. Therefore, reducing the cytotoxicity of cryoprotectants and vitrification process is completed faster.
Trial registration number: not applicable

P-187 Cleavage stage versus blastocyst stage embryo transfer in Bologna poor responders: a retrospective analysis.

J. Errazuriz[1,2], F. Pais[1], A. Racca[2], G. Verheyen[2], I. Filselcker[1], P. Gonzalez[1], H. Tournaye[2], C. Blockeel[2]

[1]Centre for Reproductive Medicine, Departamento de Ginecología y Obstetricia- Clínica Alemana- Facultad de Medicina- Universidad del Desarrollo., Santiago, Chile ;
[2]Centre for Reproductive Medicine, Universitair Ziekenhuis Brussel- Vrije Universiteit Brussel., Brussels, Belgium

Study question: Do poor ovarian responders (POR) with only one available embryo on day 3, achieve higher pregnancy rates by transferring cleavage or blastocyst stage embryos?
Summary answer: In POR with only one embryo available, transferring the embryo on day 5 was found to achieve higher live birth rates compared with day 3.
What is known already: IVF/ICSI cycles in POR remain challenging regarding ovarian stimulation, and are characterized by low live birth rates (LBR) and high cancellation rates. Traditionally, embryo transfer was carried out on day 3; however, in recent years there has been a shift in practice towards embryo transfer at the blastocyst stage. Nevertheless, these studies have not addressed the dilemma of how to proceed when only one embryo is available, as frequently observed in POR. Therefore, the implantation rate and pregnancy outcomes in relation to an individual embryo remain unclear.
Study design, size, duration: This is a retrospective cohort study including 622 patients with POR who underwent IVF/ICSI cycles in two reproductive centers (from Belgium and Chile) between January 1st 2011 and December 1st 2018.
Participants/materials, setting, methods: All women who fulfilled the Bologna criteria POR and underwent IVF/ICSI cycles with only one available embryo on day 3, were included. The decision to transfer one embryo on day 3 or day 5 was made by the treating clinician and only Grade I-III were transferred. Embryo quality was similar in both groups. We excluded patients who did not have an available embryo on day 5.
Main results and the role of chance: 622 Bologna criteria POR patients with only one available embryo on day 3 were included in the analysis: 498 were categorized to the "day 3 group" and 124 to the "day 5 group". There were no baseline differences between the groups. In the day 5 group, higher clinical pregnancy rates per started cycle (28% versus 19%, P <0.001) and higher live birth rates (18% versus 11%, P = 0.043) were obtained compared to the day 3 group. Multivariate logistic regression analysis for relevant confounders, showed that the only independent variable that significantly associated to higher LBR was the day of the transfer (OR 1.97, 95% CI 1.12-3.44, P = 0.02).
Limitations, reasons for caution: The main limitation in our study is the retrospective design. In addition, the decision to transfer the embryo on day 3 or day 5 was made by the treating clinician during their IVF cycle and according to the progress in embryo development, which may be a potential source of bias.
Wider implications of the findings: In POR with only one viable embryo on day 3 of embryonic development, performing the transfer on day 5 was found to achieve higher pregnancy and LBR compared with day 3 transfer. This challenges current practices to be modified to improve fertility outcomes in this specific group of patients.
Trial registration number: not applicable

P-188 Sorbitol accumulation decreases oocyte quality of aging mice through increasing oxidative stress

Y. Zhang[1], H. Liu[1], L. Li[1], Z. Yan[1], Y. Mao[1], L. Gao[1], J. Liu[1], Y. Cui[1]

[1]State Key Laboratory of Reproductive Medicine- Clinical Center of Reproductive Medicine, First Affiliated Hospital- Nanjing Medical University, Nanjing, China

Study question: Whether could the sorbitol accumulation in oocytes decrease the quality of aging oocytes ?
Summary answer: The excessive sorbitol decreases the oocyte quality of aging mice, and the sorbinil supplementation, inhibiting theproduction of sorbitol, can improve the quality of aging oocytes.
What is known already: Sorbitol is a by-product of glucose metabolism through the polyol pathway. Many studies have demonstrated that the excessive sorbitol can decrease the cellular activation due to the increased ROS.
Study design, size, duration: This is an in vitro study with COCs obtained from 9 month-old female mice, to explore the sorbitol accumulation related with oocyte quality.
Participants/materials, setting, methods: The COCs obtained from 9 month-old female mice were *in vitro* cultured with or without sorbinil, a kind of aldose reductase inhibitor as the control and the inhibitor group. In the young group, the COCs obtained from 6-8 week-old female mice were cultured the same as the control. MII oocytes were collected. The ROS and GSH were tested. The level of Aldose reductase, SOD_1 were measured. The contents of sorbitol were measured by HPLC/MS.
Main results and the role of chance: The maturity rate of oocytes in the inhibitor group was significantly higher than that in the control group (increased 16%, P<0.05). The ROS florescence intensity in the inhibitor group was decreased by 42% comparing with the control group (p<0.0001). The GSH florescence intensity in the inhibitor group was increased by 17% comparing with the control group (P<0.05). Interestingly, SOD_1 was upregulated in the inhibitor group (P<0.05). The content of sorbitol in the control group was drastically increased comparing with the other groups (P<0.001). The level of Aldose reductase was increased in the *in vitro* aging oocytes of 9 month-old female mice and the in vitro maturation oocytes of 6-8 week-old female mice (both P<0.05).

The sorbitol was accumulated in the *in vitro* aging oocytes comparing with the MII oocytes matured *in vivo* of 9 month-old female mice (P<0.05).
Limitations, reasons for caution: Sorbitol accumulation decreases the oocyte quality of aging mice, while whether the content of sorbitol in human oocytes increases during in vitro maturation is sparsely understood.
Wider implications of the findings: The excessive sorbitol may decreases the oocyte quality of aging mice, and the inhibition of sorbitol production during IVM may improve the oocyte quality by decreasing the oxidative stress.
Trial registration number: not applicable

P-189 Slowly developing blastocysts: fresh embryo transfer on day 5, on day 6 or frozen embryo transfer?

A. Reignier[1], A. Inquel[1], S. Loubersac[1], J. Lammers[1], P. Barriere[1], T. Lefebvre[1], T. Freour[1]

[1]*CHU Nantes, Biologie et médecine de la reproduction, Nantes, France*

Study question: Should slowly developing blastocysts be transferred on day 5, when expanded on day 6, or be frozen in order to optimize live birth rate (LBR)?
Summary answer: Fresh day 5 early cavitating blastocyst transfer resulted in higher LBR than fresh expanded day 6 blastocyst transfer or frozen-thawed day 6 embryo transfer.
What is known already: LBR are higher after fully expanded blastocyst fresh transfer on day 5 than after slow-growing expanded blastocysts fresh transfer on day 6. Embryo-endometrial asynchrony could explain this decrease. In this respect, some studies suggested day 6 blastocysts should systematically be frozen, but this still remains unclear. Moreover, there is no consensus about the best strategy to adopt with slowly developing blastocysts which are stil at the early cavitating stage (B1 or B2 according to Gardner & Schoolcraft criteria) on day 5, as to whether they should be transferred on day 5, 6 or vitrified on day 6.
Study design, size, duration: This was a retrospective monocentric cohort follow-up study including 306 cycles performed between 2016 and 2017 with at least 1 early cavitating blastocyst available on day 5 which was either transferred fresh on day 5 or cultured up to day 6 and transferred fresh or vitrified.
Participants/materials, setting, methods: All patients with early cavitating blastocyst on day 5 (Gardner stage B1 or B2) were included and allocated to 3 groups. Group 1 had fresh unexpanded blastocyst transfer on day 5 (n=68), group 2 had fresh full expanded blastocyst transfer on day 6 (n=57) and group 3 had frozen embryo transfer after vitrification on day 6 (n=181). LBR was the main outcome and was compared between the 3 groups.
Main results and the role of chance: Female age (33.8, 32.9, 34.1 years old) and smoking status (19.1, 14.0, 13.3%) were comparable between the groups 1, 2 and 3 respectively. Female BMI was significantly higher in group 1 than in groups 2 and 3 (26.1 versus 24.7 and 23.7 kg/m² respectively). Serum AMH level was significantly higher in group 3 than in groups 1 and 2 (3.1 versus 2.3 and 2.4 ng/mL respectively). LBR was significantly higher in group 1 (fresh transfer on day 5) than in group 3 (frozen day 6 transfer): (26.4%) versus (13.8%); p < 0.05. LBR was 14.0% for group 2 (fresh transfer on day 6) without significant difference with groups 1 and 3.
Limitations, reasons for caution: The relatively limited numbers of cycles included as well as the retrospective design of the study are significant limitations. Vitrification of early blastocysts on day 5 has not been evaluated in this study.
Wider implications of the findings: Fresh day 5 transfer should be promoted for early cavitating blastocyst rather than fresh day 6 transfer or vitrification. These preliminary results should be integrated when the embryo culture and transfer strategy is considered by the clinicobiological IVF staff, and should be used to improve patients' counselling.
Trial registration number: none

P-190 Should we transfer poor quality embryos?

A. Kirillova[1]

[1]*Federal State Budget Institution "National Medical Research Center for Obstetrics-Gynecology and Perinatology named after Academician V.I. Kulakov of the Ministry of Healthcare of Russian Federation", Department of preservation and restoration of the,*

Study question: Should poor quality embryos be transferred?
Summary answer: It is safe to transfer poor quality embryos when they are the only option for fresh ET.
What is known already: Implantation potential of poor morphology embryos is much lower than of those of good and fair quality. At the same time, there are indications that it might be safe to transfer embryos of poor quality as such transfers do not increase the rate of chromosomal abnormalities, congenital malformations of children born, or perinatal complications and mortality. However, the data available on the outcomes of IVF cycles in which poor quality embryos are transferred is limited. It is also uncertain which developmental stage: cleavage or blastocyst is more favorable for poor quality embryos to transfer.
Study design, size, duration: A retrospective analysis using individual patient data with positive controls. All patients undergoing fresh embryo transfers of poor quality embryos between 2012 and 2016. 738 poor quality embryos from 488 patients were assessed. The control group consisted of 9893 fair and good quality embryos from 5994 patients.
Participants/materials, setting, methods: IVF cycles with or without ICSI involving fresh embryo transfers of poor quality embryos on day 3 or on day 5. The main outcomes of day3 and day 5 poor quality embryo transfers were compared. We also compared the main outcomes of cycles with poor quality embryo transfers with good and fair quality embryo transfers.
Main results and the role of chance: No significant differences in the biochemical pregnancy rate, implantation rate, clinical pregnancy rate, miscarriage rate and live birth rate were found between the groups of poor quality embryos transferred on day 3 or on day 5. Although the biochemical pregnancy rate and implantation rate were lower for the group of poor quality embryos than for the control (13.9% vs 37.2%, p<0.001 and 6.9% vs 29.4%, p<0.001 respectively), statistically significant differences between the portion of the biochemical pregnancies which resulted in clinical pregnancies and the portion of clinical pregnancies which resulted in live births in both groups were not observed (72% vs 78.3%, p=0.2313 and 79.6% vs 79.3%, p= 0.9636 respectively).
Limitations, reasons for caution: This was a single-center retrospective study. Embryo morphology grading was assessed by 5 experienced embryologists, but it still remains a subjective type of evaluation.
Wider implications of the findings: Unlike the common belief, our data suggest that transfers of poor quality embryos do not increase the rate of miscarriages or stillbirths and should be considered safe. Transfer of embryos of poor morphology results in lower but still acceptable live birth rates.
Trial registration number: not applicable

P-191 Pre-maturation culture with CNP before IVM does not improve oocyte competence and embryo development in women with PCOS

Y. Lin[1], X. Zheng[1], J. Yan[1], X. Song[1], R. Li[1], J. Qiao[1], C. Ma[1]

[1]*Peking University Third Hospital, Center for Reproductive Medicine, Beijing, China*

Study question: Whether a pre-culture with C-type natriuretic peptide (CNP) before in vitro maturation (IVM) improves oocyte competence and embryo developmental potential or not?
Summary answer: Pre-maturation culture (PMC) with CNP before IVM does not improve oocyte competence and embryo development in women with polycystic ovarian syndrome (PCOS).
What is known already: Numerous studies in animal models have indicated the benefit of a pre-culture with CNP on IVM of immature oocytes. In 2017, Sánchez et al reported that a new IVM culture system enhances human oocyte competence and embryo yield and thought that the improvements were mainly attributed to the PMC step in presence of CNP. However the positive effects of CNP on IVM has not yet been repeated by other research teams.
Study design, size, duration: A prospective self-control study involved 192 cumulus–oocyte complexes (COCs) from 15 women with PCOS to evaluate effects of PMC with CNP on oocyte competence and subsequent embryo developmental potential. This study was conducted from March 2019 to November 2019.
Participants/materials, setting, methods: PCOS women undergoing laparoscopic salpingectomy for hydrosalpinx in a university-affiliated reproductive center were recruited and COCs were retrieved while surgery. COCs obtained were randomly allocated to control group (conventional IVM for 30h) or PMC group (PMC with CNP for 24h + conventional IVM for 30h). Oocyte maturation

and embryo development after ICSI were compared between groups. Cumulus cells (CCs) were collected for assessments of the expressions of *NPR2* and *GJA1* mRNA and cGMP level.
Main results and the role of chance: Fifteen patients were included in the study. Total 192 COCs were divided randomly into PMC group (n=93) and control group (n=99). Oocyte maturation rates were similar between PMC group (53.8%) and control group (47.5%, p=0.384). Subsequent fertilization rate (54.0% vs 63.8%) and available embryo rate (40.0% vs 53.2%) per mature oocyte also showed no significant difference (p=0.326 and 0.193, respectively) between groups. Six blastocysts were acquired in control group (12.8%) while no blastocyst formation in PMC group (0%, p=0.029). Expressions of *NPR2* and *GJA1* mRNA of CCs denuded from COCs were similar between two groups. No significant difference was found in cGMP level of CCs between groups too.
Limitations, reasons for caution: The sample size was not large as previous studies. As no blastocyst was acquired in PMC group, the planned analyses of morphology, cell number, aneuploidy rate, DNA methylation and imprinted genes of blastocyst were not undergone. Because of the discouraging results, imaging of cumulus-oocyte transzonal connection was not taken.
Wider implications of the findings: The results of this study found that pre-cultured with CNP before IVM did not improve oocyte competence and embryo developmental potential. Further studies exploring a better IVM culture system are still needed.
Trial registration number: 2018SZ-032

P-192 What are the best decision criteria for rescue intracytoplasmic sperm injection (ICSI), reducing the risk of artificial polyspermy?

T. Kishida[1], H. Kikuchi[1], K. Yamada[1], H. Kanno[1], R. Kishida[1], T. Sato[1], M. Yuki[1], A. Kitsu[1], S. Fumiya[1], M. Katagiri[1], M. Shinagawa[1], Y. Hiroaki[1]

[1]Sendai ART Clinic, ART Lab., miyagi, Japan

Study question: To establish the decision criteria (DC) for rescue ICSI, reducing the risk of artificial polyspermy using time-lapse imaging systems.
Summary answer: Postponing the observation time of the second polar body (PB) extrusion is most effective for reducing the risk of artificial polyspermy after rescue ICSI.
What is known already: The decision to perform rescue ICSI is determined by combining the observation time of the second PB extrusion following the conventional IVF and the second PB extrusion rate at that time. Artificial polyspermy, created by performing rescue ICSI to normally fertilized oocytes after conventional IVF, must be avoided. However, the optimal DC for rescue ICSI for reducing the risk of artificial polyspermy has not been established.
Study design, size, duration: This was a retrospective study conducted at Sendai ART clinic in Japan from 2017 to 2019. A total of 1480 mature oocytes, taken from 437 cycles, were cultured using a time-lapse incubator after short insemination (4 hours). These oocytes were checked from the time of insemination to the second PB extrusion and we determined the number of pronuclei.
Participants/materials, setting, methods: The target oocytes for rescue ICSI were extracted on the basis of various DC, using time-lapse images. DC were set by combining the extrusion time of second PB (<4, 4, 5, 6, or 7 hours after IVF) and the ratio of the oocytes extruding the second PB per mature oocytes (0%, 0-30%, or 0-99%). The normally fertilized oocytes rate following IVF among the extracted target oocytes were examined as the risk rate of artificial polyspermy.
Main results and the role of chance: The risk rates of artificial polyspermy, when setting the extrusion time of the second PB at <4 hours, were significantly higher than those at 4, 5, 6, and 7 hours (<4 hours: 37.0-40.8%, 4 hours: 15.0-25.8%, 5 hours: 6.3-9.0%, 6 hours: 2.0-4.3%, and 7 hours: 0-1.0%, P<0.05). The risk rates tended to decrease gradually as the extrusion time was delayed. Conversely, there was no significant difference in risk rates between the ratios of the oocytes extruding the second PB. The risk rates decreased to 0% when the extrusion time was set at 7 hours, and the ratios of the oocytes that extruded second PB were 0% or 0-30%.
Limitations, reasons for caution: This study is a single-center retrospective study. We expect the extrusion time of the second PB to change depending on the ART protocol (e.g., controlled ovarian stimulation protocol and start time of insemination).
Wider implications of the findings: This study found that rescue ICSI must be performed after 8 hours to eliminate the risk of artificial polyspermy. However, delaying fertilization may reduce the quality of the oocytes. Therefore, further studies are needed to determine new criteria for performing rescue ICSI as soon as possible.
Trial registration number: not applicable

P-193 Effect of Time Elapsed Between Thaw and Embryo Transfer on pregnancies rates in Patients with Cryopreserved-thawed embryo transfer: A Systematic Review and Meta-Analysis

L.H. Sordia-Hernandez[1], F.A. Morales Martinez[2], E. Gutierrez Orozco[1], O.H. Valdes Martínez[1], A. Flores Rodriguez[3], P. Leyva Camacho[4], N. Alvarez Villalobos[3], J.A. Zuñiga Hernandez[1]

[1]Universidad Autonoma de Nuevo Leon, Centro Universitario de Medicina Reproductiva, Monterrey, Mexico ;
[2]Universidad Autonoma de Nuevo León, Centro Universitario de Medicina Reproductiva, Monterrey, Mexico ;
[3]Universidad Autonoma de Nuevo Leon, Plataforma INVEST Medicina UANL – KER Unit Mayo Clinic KER Unit México-, Monterrey, Mexico ;
[4]Universidad Autonoma de Nuevo Leon, Plataforma INVEST Medicina UANL – KER Unit Mayo Clinic KER Unit México, Monterrey, Mexico

Study question: Does short or long culture time between thawing and transfer of cryopreserved embryos have an impact on reproductive outcomes after in vitro fertilization (IVF)?
Summary answer: There are no differences in reproductive outcomes if cryopreserved embryos are transferred after overnight culture or after two hours of culture after thawing
What is known already: There is currently no clear consensus on the optimal time for the thawing of embryos in freezing protocols, despite the fact that the identification of an adequate culture time would improve embryo culture environments allowing for better reproductive results
Study design, size, duration: A systematic review of studies evaluating the association of two different culture times after thawing, and before transfer, of cryopreserved embryos with the incidence of pregnancy, implantation, abortion, live birth or ongoing pregnancy, and ectopic pregnancy in individuals after IVF fertilization
Participants/materials, setting, methods: A literature search was performed in PubMed, EmBase, and the Cochrane library (from January 2000 to august 2019). A cumulative meta-analysis and evaluation of heterogeneity was performed for the clinical pregnancy rate. The quality of the included studies was assessed using Cochrane's Risk of Bias tool and ROBINS I for observational studies
Main results and the role of chance: Five studies were included, two were randomized controlled trials and three were retrospective published between 2010 and 2019. One study included exclusive transfers of day 5 embryos; four studies included only transfers of day 3 embryos. The clinical pregnancy rate had a high degree of heterogeneity and no difference was found between short and long embryo culture
Limitations, reasons for caution: One limitation was the quality of studies reported and included. Most were retrospective in design and only two were RCTs. The risk of bias was deficient, with moderate being the best quality. The small number of studies reported on this subject was a very important limitation
Wider implications of the findings: No differences were found if cryopreserved embryos were transferred after overnight culture or after two hours of culture after thawing. Large-scale randomized clinical trials should be conducted to definitively clarify if there is a difference in clinical outcomes after different culture time between thawing and transfer of cryopreserved embryos
Trial registration number: CRD42019137136

P-194 Feasibility of distance-based scoring in the Well-of-the-Well (WOW) culture system to improve blastocyst development

R. Minekawa[1], T. Yoshida[1], H. Ogata[1], S. Ogata[1]

[1]Ogata Family Clinic, Obstetrics and Gynecology, Hyogo, Japan

Study question: To provide quantitative assessment of optimal arrangement of embryos in the Well-of-the-Well (WOW) culture system to improve blastocyst development and quality.

Summary answer: Scorings that were based on numbers of surrounding embryos and distance between adjacent embryos were associated with blastocyst formation.

What is known already: It is known in bovine and mouse embryos that culturing embryos in groups is superior to single culture for blastocyst development due to secretion of autocrine and paracrine factors to neighboring embryos. The WOW system provides group culture environment in single drop of medium that could stimulate diffusion of autocrine and paracrine factors while observing individual embryo development simultaneously. It has been reported in human embryos that density may affect embryo quality in microwell group culture dish.

Study design, size, duration: This retrospective analysis of 476 embryos was conducted over a 24-month period between 2017 and 2019. Embryos originated from women <40 years old were enrolled in the study when nine and more embryos were obtained in each treatment cycle. The WOW system named LinKID®micro25 (DNP, Japan), which is consist of 5x5 microwells, were used. Embryos were cultured in single-step medium in LinKID®micro25 up to blastocyst stage without refreshment.

Participants/materials, setting, methods: Embryos were firstly compared between two groups according to number of adjacent embryos; Group A (1-4) and B (5-8) respectively. Secondly, considering different intra-microwell distance, cumulative scoring was set up as follows; 2 points were given when embryos were allocated side-to-side or up and down, and 1 point was given when embryos were situated diagonally. Then embryos were grouped based on total scores; Low (2-6), Intermediate (7-9), and High (10-12) points (P) groups.

Main results and the role of chance: Blastocyst formation rate and percentage of good quality blastocysts (≥3BB by Gardner grading scheme) were main outcome measures. In the first analysis the blastocyst formation rate was significantly higher in Group B (A: 50.3% vs B: 59.7%, P=0.048) but no differences were found in average age (A: 34.0 vs B: 34.2 years) and the percentage of good quality blastocyst (A: 67.0% vs B: 69.8%). In the second part of study, there was no difference among three groups in terms of average age; Low P (N=167) 34.1, Intermediate P (N=217) 34.0, High P (N=92) 34.6 years. Blastocyst formation rates were 50.3%, 56.7%, and 64.1% in Low P, Intermediate P and High P group respectively, and it was significantly higher in High P group compared to Low P group (P=0.037). The more points it gained, the higher percentage of good quality blastocyst (65.5% vs 69.9% vs 71.2%) was observed although there was no statistical significance.

Limitations, reasons for caution: This is a retrospective analysis of database, and sample size is limited as cases were restricted to patients obtained more than nine embryos for equalizing background conditions. Our study focused on blastocyst formation and quality, hence there is no enough data to evaluate pregnancy rate and birth outcomes.

Wider implications of the findings: This distance-based scoring approved possible autocrine/paracrine effect for human embryo development. It is the first quantitative method to propose optimal arrangement of embryos in the WOW culture, which could lead to better chance for clinical pregnancy. Cases with fewer embryos could also have benefit if included in the future study.

Trial registration number: Not applicable

P-195 Pulling vs Flicking. Does biopsy technique affect clinical outcomes on euploid embryos?

V. Montalvo[1], S. Novo[1], A. Garcia-Faura[1], B. Marques[1], F. Garcia[1], C. Castelló[1], M. López-Teijón[1]

[1]Institut Marques, Reproductive Medicine Service, Barcelona, Spain

Study question: Has the technique used during trophectoderm biopsy any effect on euploid embryos?

Summary answer: Pulling and Flicking techniques provide, when applied properly, optimal and similar results. Therefore, both techniques can be used indistinctly to perform trophectoderm biopsy.

What is known already: Embryo biopsy for Preimplantational Genetic Testing (PGT) has to accomplish two main goals: the biopsied material has to mirror the genetic constitution of the embryo, and embryo viability cannot be impacted. The strategy that comes closer to guarantee these two aspects is trophectoderm (TE) biopsy. Since there is no standardized TE biopsy procedure, two techniques are coexisting (Pulling and Flicking). The main difference between both techniques is how cells are detached from the embryo. Considering that TE biopsy could affect TE quality/integrity, hence implantation, studies are needed in order to evaluate the effect of different biopsy techniques

Study design, size, duration: This was a prospective observational study performed between 2018 and 2019. 286 PGT-A treatments with 990 TE biopsies were included. Of these, 145 euploid embryos were individually transferred, 84 biopsied using Pulling and 61 via Flicking. When using Pulling, laser pulses debilitate cell junctions and applying moderate tension the TE sample is detached. However, when using Flicking this tension is replaced by a cutting motion generated between the holding and biopsy pipettes.

Participants/materials, setting, methods: In every single embryo biopsy, the number (1-10) and intensity (ms) of laser pulses was registered, as well as the operator and the method used for the biopsy (Pulling or Flicking). Blastocyst area (μm^2) before and after TE biopsy as well as just before embryo vitrification was measured for each transferred embryo.

The main outcomes were implantation rates and embryo collapse-expansion dynamics.

Main results and the role of chance: No differences were found between groups regarding egg age (Pulling: 33.9 vs Flicking: 32.97; p=0.885), maternal age (Pulling: 39.69 vs Flicking: 39.68; p=0.94), PGT indication (p=0.422), embryo expansion (p=0.205) and quality (p=0.63), and laser intensity (Pulling: 416.4ms vs Flicking: 438.3ms; p=0.184). Otherwise, the number of laser pulses was higher when using pulling (Pulling: 5.4 pulses vs Flicking: 3.49 pulses; p<0.05). This difference was expected and intrinsically attributed to the technique. To ensure that this was not a confounding factor we analysed implantation rate based on the number of pulses and no significant differences were detected (1-3 pulses: 63.6%; 3-6 pulses: 58.1%; >6 pulses: 76.5%).

Clinical outcomes, such as implantation rate (Pulling: 65.0% vs Flicking: 58.2%), miscarriage rate (Pulling: 10.0% vs Flicking: 9.1%), and ongoing pregnancy rate (Pulling: 55.0% vs Flicking: 49.1%), were equivalent between groups (p>0.05). Regarding collapse-expansion dynamic, we found that embryos from Flicking group showed the highest collapse percentage ((μm^2 Pre-μm^2 Post)/μm^2 Pre) after biopsy (Pulling: 47.4% vs Flicking: 56.1%; p<0.05). Nevertheless, we did not found any difference in the speed of expansion (%expansion/hour) after biopsy (Pulling: 11.3%/h vs Flicking: 11.0%/h; p>0.05). Neither the percentage of collapse nor the speed of expansion seem to affect implantation rates (p=0.325).

Limitations, reasons for caution: These results are preliminary. In order to ensure the safety of both techniques more data should be analysed. If possible, the impact on live birth rates would be the ideal outcome to assess if any of these two techniques proves to be superior.

Wider implications of the findings: Our results show that the type of technique used to perform TE biopsy does not affect clinical outcomes on euploid embryos. Although Flicking proved to elicit a stronger contraction post biopsy, probably by generating more mechanical stress to the trophectoderm, this did not seem to impair reproductive potential.

Trial registration number: Not applicable

P-196 Impact of cell exclusion and extrusion during the peri-compaction period on blastocyst formation and subsequent live birth

K. Shimazaki[1], G. Coticchio[2], K. Ezoe[3], K. Ohata[3], M. Ninomiya[1], N. Wakabayashi[1], T. Okimura[1], K. Uchiyama[1], T. Kobayashi[4], C. Lagalla[2], A. Borini[5], K. Kato[4]

[1]Kato Ladies Clinic, IVF Laboratory, Tokyo, Japan ;
[2]9.Baby- Family and Fertility Center, IVF laboratory Unit, Bologna, Italy ;
[3]Kato Ladies Clinic, R&D Division, Tokyo, Japan ;
[4]Kato Ladies Clinic, Gynecology, Tokyo, Japan ;
[5]9.Baby- Family and Fertility Center, Reproductive Medicine IVF, Bologna, Italy

Study question: Are cell exclusion and extrusion during the embryo peri-compaction period associated with embryo development, pregnancy outcomes and patient characteristics after blastocyst transfer?

Summary answer: Cell exclusion and extrusion during peri-compaction are associated with impaired blastocyst expansion, reduced live birth rates, male age and low sperm-motility.

What is known already: The biological and clinical significance of morphological alterations in human morula stage embryos is poorly understood, in part because most assessments of morula morphology have been performed

statically. With the flexibility offered by time-lapse technology, different patterns have recently been identified in compacted embryos: fully-compacted morula (FCM), partially-compacted morula with cells excluded before compaction (Excluded-PCM), and partially-compacted morula with cells extruded after compaction (Extruded-PCM). Excluded-PCM and extruded PCM have been associated with decreased blastocyst formation, and increased degeneration rates, respectively. At present, our overall knowledge of possible associations between compaction patterns and pregnancy outcomes, and patient/embryonic characteristics is rather limited.

Study design, size, duration: Time-lapse videos from 384 morula stage embryos in 291 patients who underwent ICSI with minimal stimulation and single vitrified-warmed blastocyst transfer (SVBT) from April 2017 to March 2018 were retrospectively analysed. Compaction patterns were assessed and compared with embryonic and pregnancy outcomes after SVBT. Other factors possibly associated with compaction patterns, such as patient- and cycle-characteristics and early cleavage-stage development, were investigated.

Participants/materials, setting, methods: Following ICSI, time-lapse videos spanning fertilization to blastocyst stage were analysed. The number of cells excluded before compaction, and cells extruded after compaction (if any) were annotated. Possible correlations of compaction patterns with blastocyst expansion rates, blastocyst morphological grade, clinical and ongoing pregnancy rate, and live birth rate were evaluated. Other possible relationships between compaction patterns and patient characteristics, including serum hormone levels, semen parameters, and incidence of abnormal cleavage patterns were also assessed.

Main results and the role of chance: The incidences of FCM, Excluded-PCM, and Extruded-PCM were 51.8%, 29.7%, and 18.5%, respectively. Blastocyst formation and cryopreservation rates in Excluded-PCM and Extruded-PCM groups were significantly lower than that in the FCM group, particularly when the numbers of cells excluded and extruded were more than 3 and 2, respectively. Lower morphological grades of inner cell mass and trophectoderm were observed in both Excluded-PCM and Extruded-PCM groups compared with the FCM group. Cochran-Armitage trend testing demonstrated that the ongoing pregnancy and live birth rates were significantly lower in Excluded-PCM and Extruded-PCM groups than in the FCM group ($P = 0.0147$, $P = 0.0348$, respectively). Increases in incidence of cell exclusion and extrusion were significantly associated with increases in male age and decreases in sperm-motility ($P = 0.0108$, $P = 0.0019$, respectively). Furthermore, the embryos in the Excluded-PCM group exhibited significant correlations with higher incidence of direct cleavage, rapid cleavage, and asymmetrical division ($P = 0.0145$, $P < 0.0001$, $P = 0.0232$, respectively). Embryos in the Extruded-PCM group did not correlate with irregular division in early stage cleavage.

Limitations, reasons for caution: The number of analysed embryos is relatively limited; therefore, further studies are required to more reliably assess the clinical significance of these alternative patterns of compaction.

Wider implications of the findings: These results support the possibility that compaction patterns can serve as a predictive parameter for pregnancy outcomes. In addition, they shed new light on the phenomenology and importance of a poorly investigated stage of human preimplantation development.

Trial registration number: not applicable

P-197 The timing of the first cleavage of direct cleavage embryos was delayed compared to normal cleavage embryos.

H. Takahashi[1], R. Hirata[1], T. Habara[1], N. Hayashi[1]

[1]Okayama couple's clinic, laboratory, Okayama, Japan

Study question: Are the early dynamics of direct cleavage (DC) embryos different from normal cleavage embryos?

Summary answer: In DC embryos, blastocyst transfer led to live birth, but the timing of the first cleavage was delayed compared to normal cleavage embryos.

What is known already: DC embryos exhibit lower blastocyst formation rates. However, we previously reported that DC embryos exhibit a similar implantation potential to that of normal cleavage embryos if the blastocyst stage is reached, in which embryo selection for transfer is based on blastocyst grade and diameter. Prior reports suggest that the timing of the first cleavage is associated with embryo development and higher incidence of chromosomal abnormalities, but there are few reports regarding the timing of the first cleavage in DC embryos.

Study design, size, duration: This was a retrospective study of data acquired by time-lapse imaging. The study included 679 embryos from 353 IVF cycles in 286 patients that underwent intracytoplasmic sperm injection (ICSI) treatment for blastocyst cryopreservation between May 2018 and August 2019. A total of 373 blastocysts were cryopreserved, and of these, 190 were used for a single vitrified-thawed blastocyst transfer by December 2019. Embryo selection for transfer was based on blastocyst grade and diameter.

Participants/materials, setting, methods: Embryos with DC at the first cleavage were recorded as DC(+), and embryos with normal cleavage were recorded as DC(-). We compared the time from ICSI to the beginning of the first cleavage (t2), and the time from the beginning to the end of the first cleavage (d2) between groups. In addition, we compared implantation rates, miscarriage rates and live birth rates in single vitrified-thawed blastocyst transfer cycles between groups.

Main results and the role of chance: T2 and d2 of DC(+) embryos (27.9 hours and 5.5 hours, respectively) were significantly longer than those of DC(-) embryos (25.6 hours and 3.3 hours, respectively, p<.0001), even when the embryos developed into blastocysts on Day 5 (t2: 27.0 hours in DC(+) and 25.2 hours in DC(-), p<.0001, d2: 5.9 hours in DC(+) and 3.2 hours in DC(-), p<.0001). T2 of embryos that reached high-quality blastocysts or that were used in single vitrified-thawed blastocyst transfer were similar in DC(+) (25.7 hours and 26.1 hours, respectively) and DC(-) embryos (24.8 hours and 25.2 hours, respectively). However, d2 was significantly longer in DC(+) embryos (5.8 hours and 5.7 hours, respectively) compared to DC(-) embryos (3.0 hours and 3.1 hours, respectively, p<.0001). In addition, in DC(+) embryos, the rate of blastocyst formation on Day 5 was higher when t2 was <26 hours than when t2 was >=26 hours (80.3% vs. 22.9%, p<.0001). No significant differences were detected in implantation rates, pregnancy loss rates and live birth rates between DC(+) and DC(-) embryos (29.2% vs. 40.1%, p=0.303, 28.6% vs. 29.7%, p=0.390, 20.8% vs. 27.4%, p=0.494, respectively). Congenital abnormalities were not detected in either group.

Limitations, reasons for caution: Small sample size is the primary limitation. In this study, we focused only on the first cleavage, and therefore events after the second cleavage were not evaluated. Because chromosomal analysis is strictly prohibited in Japan, this study had no available data regarding the chromosomal ploidy of the blastocysts.

Wider implications of the findings: The time of the first cleavage was prolonged in DC embryos, which should be investigated in future studies. However, our results suggest that the timing of the beginning of the first cleavage could be a useful indicator for embryo selection when the only transferrable embryos are DC embryos.

Trial registration number: not applicable

P-198 Detailed quality assessment of direct cleavage embryos during the first division using a combined early cleavage with an embryo morphological grading method

H. Tomari[1], K. Honjo[1], Y. Nagata[1]

[1]IVF NAGATA Clinic, ART Lab, Fukuoka, Japan

Study question: Is it possible to perform a detailed quality assessment of direct cleavage (DC) embryos at the early embryonic stage (day2)?

Summary answer: The quality of DC embryos can be assessed in detail by combining the timing of the first cleavage and the morphological evaluation on day2.

What is known already: Several studies have reported a clear correlation between the occurrence of DC (divided into three or more cells) during the first division of an embryo and impaired embryo development potential in humans. In addition, it has also been reported that the pregnancy rate due to transfer of DC embryos that developed to blastocysts is similar to that of normal cleavage embryo transfer. However, only few studies have reported on methods for assessing DC embryo quality.

Study design, size, duration: This retrospective observational study was performed in a single *in vitro* fertilization (IVF) center. This study included patients undergoing IVF or intracytoplasmic sperm injection. We analyzed 1,242 DC embryos with normal fertilization using a time-lapse incubator. All study participants provided informed consent and the study design was approved by the

ethics committee of the IVF Nagata Clinic, Fukuoka, Japan. DC embryos were classified into 3- and ≥4-cell (4 cells or more) groups.
Participants/materials, setting, methods: Ex.1: We compared blastocyst formation rates between the two groups. Ex.2: The two groups were further classified into six grades by the following method. Embryos were evaluated for early cleavage (EC) or late cleavage (LC) at 27 hours after insemination and morphology was scored on day2 (poor, ≥4-cells with ≥50% frag.; fair, ≥4-cells with <50% and ≥20% frag.; good, ≥4-cells with <20% frag. and equal blastomere). The blastocyst formation rates of each group were compared.
Main results and the role of chance: Ex. 1: Among the 1,242 DC embryos, 669 were in the 3-cell group and 573 were in the ≥4-cell group. The blastocyst and high-quality blastocyst formation rates were significantly higher (p<0.01) in the 3-cell group than in the ≥4-cell group (53.5% vs. 32.7%, 28.0% vs. 14.1%, respectively). Ex. 2: Among the 669 embryos in the 3-cell group, 211 were in the EC-fair embryos, 141 were in the EC-poor embryos, 75 were in the LC-fair embryos, and 242 were in the LC-poor embryos. Among the 573 ≥4-cell group, 102 were in the EC-fair embryos, 127 were in the EC-poor embryos, 90 were in the LC-fair embryos, and 254 were in the LC-poor embryos. The blastomeres of DC embryos were unequal and no embryo was evaluated as good. The blastocyst and high-quality blastocyst formation rates were significantly higher (p<0.05) in the EC-fair embryos of the 3-cell group than in the other groups (71.6% vs. 18.5%–57.8%, 44.1% vs. 5.1%–33.3%, respectively).
Limitations, reasons for caution: This study lacked data about implantation rates after embryo transfer. To investigate the implantation ability of DC embryos, it is necessary to increase the number of cases where data were analyzed after embryo transfer.
Wider implications of the findings: The EC-fair embryos of the 3-cell group had high blastocyst development ability for DC embryos. The results suggest that the detailed evaluation of DC embryos at the early embryonic stage is not only predictive of embryogenic potential, but also useful for the selection of embryos for early embryo transfer.
Trial registration number: Not applicable

P-199 The impact of the oocyte donor's age on the recipient's outcomes: Should we exclude very young women from oocyte donation?

M. Roca Feliu[1], E. Clua[1], M. Tresánchez[1], S. García[1], N.P. Polyzos[1], F. Martínez[1]

[1]Hospital Universitari Quirón Dexeus, Obstetricia- Ginecología y Reproducción, Barcelona, Spain

Study question: Does the oocyte donor's age have an impact on the live birth rate (LBR) in the recipients?
Summary answer: The LBR is significantly lower when donors are younger than 25 years and, especially, when they are younger than 20 years.
What is known already: Donor's age becomes one determining factor for successful in oocyte donation programs (OD). It has been demonstrated that success is determined by embryo quality which depends on the oocyte quality which in turn depends on the donor's age. In most countries where OD is anonymous, law or guidelines establish that age must be between 18 and 35. Previous studies have shown that donor age < 25 was not associated with better outcomes. However, no studies have separately analysed LBR in very young donors (<20 years) despite previous reports suggesting a higher aneuploidy rate in women between 18 and 25 years.
Study design, size, duration: A retrospective study of 3766 oocyte reception cycles performed between January 2009 and December 2018 was carried out. Cycles using vitrified oocytes, PGD or TESE were excluded.
Participants/materials, setting, methods: The cycles were categorized considering the donors' age groups: < 20, 20-25 and ≥26 years. The statistical tests used were Chi-square test for evaluating the differences in LBR and ANOVA to test differences in fertilisation and embryo development rates as well as for testing embryo quality. A generalized linear mixed model was applied to estimate the odds for every endpoint. Patient was treated as random factor to avoid repeated observations effect.
Main results and the role of chance: A total of 3766 oocyte reception cycles were analysed. The pregnancy rate was 51.4% and the LBR was 40.7%. In 4.7% of the cycles the age of the donor was <20 years, in 41.1% was between 20-25 years and in 54.2% was ≥26 years. When we analysed LBR according the donors' age we found significant differences: 33.9% for the youngest group, 39.1% for the group of 20-25 years and 42.5% for donors over 25 years (p=0.022). When adjusting by confounding factors (recipient age, number of transferred embryos, and day of embryo transfer), LBR was lower to the <20 years' group (OR: 0.70; CI 95%: 0.50-0.99) and to the 20-25 years' group (OR: 0.85; CI 95%: 0.74-0.98) compared to the ≥26 years' group. No significant differences were observed neither in fertilisation rates (74.2%, 76.1% and 77.5%) nor in embryo development rates (57%, 61.4% and 62%). The number of good-quality embryos transferred was significantly lower in the <20 years' group (1.03±0.71; 1.18±0.69; 1.19±0.67; p=0.015).
Limitations, reasons for caution: The group of donors <20 years included in our study was relatively small and smaller as compared with the groups of 20-25 years and ≥26 years. Nonetheless, the sample size had adequate statistical power in order to identify significant differences in live birth rate.
Wider implications of the findings: Oocyte donor age <20 years as compared with older oocyte donors is associated with significantly lower live birth rates among oocyte recipients. Further studies are needed to confirm our findings, in order to determine whether in the future oocyte donation programs should also have a lower age limit.
Trial registration number: -

P-200 Blastocyst utilization rate – is it a matter of culture media?

M. Schenk[1], N. Reinschissler[2], C. Fritz[3], M. Hörmann-Kröpfl[3], G. Weiss[4]

[1]Das Kinderwunsch Institut Schenk GmbH, Research & Development, Dobl, Austria ;
[2]Das Kinderwunsch Institut Schenk GmbH, Research and Development, Dobl, Austria ;
[3]Das Kinderwunsch Institut Schenk GmbH, Embryology, Dobl, Austria ;
[4]Das Kinderwunsch Institut Schenk GmbH, Research and Development, Dobl bei Graz, Austria

Study question: Is there a difference in blastocyst formation rates in embryos cultured with G-TL™ (*Vitrolife*) versus GM501 (*Gynemed*)?
Summary answer: G-TL™ reveals a higher blastocyst formation rate compared to GM501.
What is known already: A variety of studies have been carried out to compare the effects of different culture media types on embryo development, showing controversial results. A recent Cochrane review suggested that available data are insufficient to conclude the best culture medium for embryo quality, pregnancy and implantation. Besides the use of the medium, the day of embryo transfer is also under debate. A current meta-analysis showed no differences in reproductive outcomes comparing blastocyst (d5) and cleavage-stage (d3) embryo transfer in clinical practice, however, the trend for a blastocyst transfer is increasing since it resembles the natural process of implantation.
Study design, size, duration: The prospective study included 641 embryos from patients undergoing IVF (in vitro fertilization) and ICSI (intracytoplasmic sperm injection) treatment. Patients with ≥ 6 MII oocytes were included in the study. Oocytes were splitted equally into the two media types GM501 and G-TL™, both overlaid with mineral-oil (Gynemed).
Participants/materials, setting, methods: The study was designed and conducted at the Kinderwunsch Institut Schenk GmbH (Dobl, Austria) in 2019. Fertilized occytes from women aged 18 - 41, cultured in Embryoscope time-lapse system (Vitrolife) were included while oocytes/embryos with polar body biopsy/trophectoderm biopsy were excluded. The utilization rates of day 3 and day 5 embryos were analyzed.
Main results and the role of chance: The number of achieved fertilized oocytes was 308 in GM501 media and 333 with G-TL™, respectively. Overall the utilization rate was 45.7% using G-TL™ media compared to 36% in the GM501 group. A subgroup analysis of day 3 revealed a utilization rate of 13.6% with GM501, compared to 10.5% in the G-TL™ group. Additionally, the utilization rate of day 5 embryos was 22.4% using GM501 versus 35.1% with G-TL™.
Limitations, reasons for caution: The sample size may be seen as study limitation. However, statistically significant results were obtained. Nonetheless, results should be confirmed with a higher sample size.
Wider implications of the findings: The data show a significant better rate of blastocyst utilization with G-TL™ media. Since around 5 days after fertilization

the uterus is particularly receptive, it is tempting to speculate that transferring blastocysts in general is more favorable for a successful treatment outcome.
Trial registration number: Not Applicable

P-201 supplementation of culture medium with melatonin improves blastocyst development and reverses glucose intolerance in IVF mice

Y. Jia[1], W. Liu[1], D. Bai[1], K. Li[1], M. Chen[1]

[1]Center for Reproductive Medicine- Shanghai First Maternity and Infant Hospital, Tongji University, Shanghai, China

Study question: Whether the adverse effects of in vitro fertilization (IVF) on glucose metabolism could be reversed by supplementation of culture medium with melatonin in mice?
Summary answer: Supplementation of culture medium with melatonin improved IVF blastocyst differentiation, reduced excessive weight gain after birth and normalized glucose intolerance in IVF male mice.
What is known already: Approximately more than 8 million children have been conceived by assisted reproductive technologies worldwide. Increasing evidence suggests that IVF treatment may be associated with an increased risk of developing obesity and metabolic diseases in adulthood. IVF mouse models confirmed adult IVF offspring showed excessive weight gain on a high fat diet, impaired glucose metabolism and cardiovascular dysfunction compared with naturally conceived mice. Notably, in vitro culture impaired blastocyst developmental kinetics and differentiation, independently of ovarian stimulation. Moreover, it has been shown that addition of melatonin to culture medium may improve embryo development and prevent cardiovascular alterations in IVF mice.
Study design, size, duration: A cross-sectional mouse model was utilized, wherein blastocysts were generated by natural mating (control group) or IVF with or without melatonin (10^{-6}M) (mIVF and IVF group respectively) in clinical grade fertilization and culture media. Blastocysts were transferred to pseudo-pregnant ICR females. Cell lineage allocation was assessed for 30-40 blastocysts from each group. Body weight, glucose tolerance, energy expenditure, hepatic gene expression was measured in 6-10 mice from each group.
Participants/materials, setting, methods: C57BL/6 females and DBA2 males were used to generate blastocysts. Cell numbers of inner cell mass (SOX2) or trophectoderm (Cdx2+) were determined by immunohistochemistry. Males were weaned at 3 weeks of age onto a chow diet or a high-fat diet (60% fat) for 8 weeks. Glucose tolerance was assessed by an intraperitoneal glucose tolerance test (2g/Kg). Energy metabolism was examined in metabolic cages. Hepatic gene expression was measured by RNA-Seq and validated by qPCR.
Main results and the role of chance: Blastocyst rates were similar in the two IVF groups. Reduced inner cell mass, trophectoderm and total cell number were observed in IVF blastocysts, compared with the control group ($P<0.05$). IVF pups had significantly lower birth weight and body weight before weaning, but exhibited increased body weight and liver weight at 11 weeks of age compared with controls ($P<0.05$), independently of diet. IVF mice were glucose intolerant shown as an increased glucose area under the curve, and had decreased energy expenditure as well as a large number of differentially expressed genes related to metabolic pathways in the liver tissue compared with the control group ($P<0.05$), independently of diet. The mIVF group showed intermediate cell numbers in blastocysts, body weight, liver weight and differentially expressed hepatic genes compared with the IVF group and control group, and normalized glucose tolerance and energy expenditure compared with the IVF group ($P<0.05$), independently of diet. Importantly, there was no significant difference in glucose tolerance and energy expenditure between the mIVF group and the control group.
Limitations, reasons for caution: The findings in C57BL/6J x DBA2 F1 mice may not represent human infertility which is complex and often multi-factorial. Further studies are needed to confirm these findings in human settings and investigate the underlying mechanisms by which melatonin improves embryonic development and adult metabolic phenotypes.
Wider implications of the findings: The data shows that melatonin mitigated the detrimental effects of in vitro fertilization and culture on mouse embryo development and catch-up growth after birth, and reversed glucose intolerant in adult male offspring. Therefore supplementation of culture medium with melatonin may be beneficial for human IVF.
Trial registration number: not applicable

P-202 Synchronizing blastocyst at hatching status in frozen embryo transfer cycles: A randomized controlled trial

Y. Magdi Abd-Elkreem[1], M.H. Zidan[2], M.A. Ibrahim[3], Y. Edris[3], A. El-Gohary[3], A. Elattar[4]

[1]Al-Yasmeen Fertility and Gynecology Centerv, IVF Laboratory, Banha, Egypt ; [2]Gannah IVF Hospital, IVF Lab. director, Cairo, Egypt ; [3]Faculty of Medicine- Benha University, Department of Obstetrics and Gynecology, Benha, Egypt ; [4]Al-Yasmeen Fertility and Gynecology center, . Department of Obstetrics and Gynecology, Benha, Egypt

Study question: Is culture of vitrified-warmed blastocysts for another day after warming and selection of only blastocysts that could reach hatching status associated with improved outcomes?
Summary answer: Culture blastocyst with ≤ 3grade of expansion for another day after warming may be associated with improved implantation and ongoing implantation rates.
What is known already: Failure of blastocyst hatching has been identified as a potential obstacle limiting human implantation efficiency. On the other hand, discordance between the stage of transferred blastocyst and the receptive endometrium. We aimed in the present study to identify whether transferring frozen/thawed blastocysts at hatching status could improve the ongoing implantation rate in case of adjusting the thawing time to achieve this stage at the transfer day.
Study design, size, duration: This randomized controlled trial was conducted at two private ART centers in Egypt, and involved cycles of vitrified-warmed blastocyst transfer after ICSI. Recruitment of first participant was on April 25, 2017, and the last participant was on May 10, 2018. A total of 469 women undergoing frozen embryo transfer (FET) were randomized into two groups.
Participants/materials, setting, methods: Randomization was performed 2 days prior to a scheduled FET. Participants received FET either with hatching or hatched blastocysts achieved by incubation of ≤ 3 grade of expansion blastocysts after thawing 18-24 hours (study group, n=232) or with ≤ 3 grade of expansion blastocysts incubated only 2-4 hours (control group, n=237).
Main results and the role of chance: Baseline and treatment characteristics of the study population were balanced for the two study groups**.**
The implantation rate (45.6% vs. 38.2%; OR 1.35, 95% CI 1.03 to 1.78) and ongoing implantation rate (38.2% vs. 30.5%; OR 1.4; 95% CI, 1.06 to 1.87) were statistically significantly improved in the study group compared with the control group. There was no significant difference in the rates of livebirth (47.4% vs. 38.8%; OR 1.42, 95% CI, 0.98 to 2.05), clinical pregnancy (56% vs. 50.2%; OR1.26, 95% CI, 0.88 to 1.82), ongoing pregnancy (50% vs. 42.6%; OR 1.35, CI, 0.94 to 1.94), and miscarriage (5.6% vs. 5.9%; OR 0.95, 95% CI, 0.44 to 2.06) in the study group compared with the control group. The multiple pregnancy rate was similar in the study group (62/232; 26.7%) compared with the control group (48/237; 20.3%; OR 1.44; 95% CI, 0.93 to 2.21; P=0.1).
Limitations, reasons for caution: The age of the study population was relatively young, thus we should also be cautious to extend the results to older patients. Further large scale multicenter randomized controlled studies are required to confirm our findings.
Wider implications of the findings: Prolonged culture of blastocysts with ≤3grade of expansion may not only provide better embryo–endometrium synchrony, but also induces self-selection of the most viable blastocysts which have the capacity to resume its development.

P-203 Successful pregnancies following transfer of blastocysts derived from delayed-intracytoplasmic sperm injection (delayed-ICSI)

J.P. Sam[1], A.Y.X. Lim[1], Z.Q. Tee[1], C.S.S. Lee[2]

[1]Alpha IVF & Women's Specialists, IVF laboratory, Petaling Jaya, Malaysia ; [2]Alpha IVF & Women's Specialists, Medical Director, Petaling Jaya, Malaysia

Study question: To evaluate the clinical outcome of delayed-ICSI on day1-matured oocytes.
Summary answer: Blastocysts derived from day1-matured oocytes can result in successful pregnancies and thus can be considered for transfer when there is no blastocyst available from day0-ICSI.

What is known already: Delayed-ICSI is defined as the ICSI procedure performed on oocytes matured via extended culture (day1-matured oocytes). It is a routine procedure in Alpha IVF & Women's Specialists in order to improve cycle outcomes of selected patients, especially poor responders.
Despite the lower fertilisation, blastulation and blastocyst utilization rates of delayed-ICSI compared to day0-ICSI, the pre-implantation genetic testing for aneuploidies (PGT-A) revealed that delayed-ICSI blastocysts can be chromosomally normal (euploid) and can therefore be considered for embryo transfer (Lee, C.S.S., 2018).

This abstract reports the successful pregnancies following the transfer of delayed-ICSI blastocysts.

Study design, size, duration: A total of 370 IVF treatments at Alpha IVF & Women's Specialists between January 2018 and December 2019 had delayed-ICSI done on their day1-matured oocytes (mean maternal age: 37.6; range 23.0-47.0). Indications for a delayed-ICSI includes immature oocytes retrieved on day-0 (*n*=50); fail or abnormal fertilization on day0-ICSI (*n*=36); poor fertilization on day0-ICSI (<50%) (*n*=11); low oocyte maturation rates (<50%) (*n*=8); and poor responders (≤6 oocytes injected for day0-ICSI) (*n*=265).

Participants/materials, setting, methods: The immature oocytes were cultured in incubators for 18-24 hours and delayed-ICSI (PIEZO, Japan) was performed on oocytes that were mature on day-1. Injected oocytes were cultured up to 7 days and utilisable blastocysts were vitrified (Cryotec, Japan) on Day5, Day6 and/or Day7 with/without trophectoderm biopsy. Cells biopsied were amplified and screened using Next Generation Sequencing (NGS) (IonTorrent, USA). Selected blastocysts were thawed for frozen single blastocyst transfer (SBT) and the clinical outcome was analysed.

Main results and the role of chance: Delayed-ICSI was done on 980 day1-matured oocytes, of which 644 were 2PN (65.7%), 122 were >2PN (12.5%), 136 were <2PN (13.9%) and 78 were degenerated (8.0%). The blastulation and utilisation rates (per 2PN) were 36.5% (235/644) and 19.9% (128/644) respectively. Of the 128 utilisable blastocysts, 108 blastocysts had PGT-A screening and 26.9% (29/108) were chromosomally normal (euploid). At the time of writing, a total of 12 delayed-ICSI blastocysts (10 euploid, 1 mosaic and 1 untested) were thawed (post-thaw survival rate=100%) for frozen SBTs as no suitable day0-derived blastocysts were available for transfer (mean age: 36.0; range:31.0-42.0). Nine (9) had positive β-HCG reading and gestational sacs were seen in all nine patients (clinical pregnancy rate = 75.0%; implantation rate = 75.0%). Seven (7) patients have ongoing pregnancies ranging from 11-36 weeks whereas 2 patients were known to have miscarried at the 8th and 11th week of pregnancy.

Limitations, reasons for caution: The immature oocytes were further cultured up to 18-24hours *in-vitro*. The long incubation duration may result in post-mature oocytes that could affect blastocyst development. Further studies could employ other maturity assessment tools such as spindle visualization prior to delayed-ICSI, rather than having a fixed incubation duration to optimise delayed-ICSI outcomes.

Wider implications of the findings: Good pregnancy and implantation rates can be obtained with blastocysts derived from delayed-ICSI. Therefore, patients who are unlikely to have a good number of normally fertilized oocytes on day-0 should have their immature oocytes cultured to day-1 for delayed-ICSI to generate more utilisable blastocysts.

P-204 Impact of maternal age and in vitro maturation on the transcriptome of denuded human oocytes.

S. Llonch[1], M. Barragán[2], P. Nieto[3], A. Mallol[1], M. Elosua[3], S. Ruiz[3], F. Zambelli[2], H. Heyn[3], B. Payer[1], R. Vassena[2]

Study question: Does maternal age affect the transcriptome of human oocytes at the germinal vesicle (GV) stage or at metaphase II (IVM-MII) after maturation *in vitro*?

Summary answer: Oocytes' gene expression is predominantly affected by maturation stage and less by maternal age.

What is known already: Female fertility is inversely correlated to maternal age due to a depletion of the oocyte pool and a reduction in oocyte developmental competence. Few studies have addressed the effect of maternal age on the mature oocyte (MII) transcriptome, which is established during oocyte maturation. However, reduced sample numbers have been analysed, and the bias represented by distinct genetic backgrounds was difficult to control for. Here, we characterise and compare the transcriptional patterns of a large cohort of fully grown GV and IVM-MII oocytes from women of varying reproductive age, age can be considered as a continuous variable.

Study design, size, duration: In this basic research study 38 women were recruited from May 2018 to June 2019. The mean woman age was 28.8 years (SD=7.6, range 18-43). A total of 82 immature GV oocytes were included in the study as: GV (n=40), IVM-MII (n=32) or GV unable to mature after *in vitro* maturation (n=10). Their transcriptome was compared by single-oocyte RNA-seq analysis.

Participants/materials, setting, methods: Oocytes were collected either as GV or after *in vitro* maturation for 30 hours in G2^{TM} medium, and individually frozen in lysis buffer until processed according to Smart-Seq2 single-cell RNA-seq protocol. The RNA-seq data obtained was analysed using the Seurat R package, which has been recently developed for the quality control, analysis and exploration of single-cell RNA-seq data.

Main results and the role of chance: Data quality control was applied and samples containing >30% of mitochondrial DNA and less than 1,000 genes were filtered out, leaving 75 oocytes for further analysis. Preliminary exploration of the RNA-seq data using an algorithm for dimensionality reduction identified two clusters of oocytes according to their maturation stage (GV and IVM-MII) with 10430 and 8744 detected genes, respectively; and independently of maternal age. To identify differentially expressed genes according to maternal age, we set a cut-off at 35 years old, which is the accepted clinical definition of advanced maternal age. Gene expression was analysed in GV and IVM-MII comparing both age's groups (<35 vs. ≥35 years old); however, in our preliminary analysis, no candidate gene has been identified. Taking advantage of our dataset, which contains oocytes representing a continuous age range, we looked for genes that would show gradual change with age. Here, we considered the set of genes that do not change their expression due to maturation stage (i.e. those which would be necessary to provide developmental competence to the oocyte) and we independently analysed both, GV and IVM-MII. Although we found some transcripts with a tendency to increase or decrease according to age, a deeper analysis is required.

Limitations, reasons for caution: GVs were collected after ovarian stimulation and MII were *in vitro* matured. Therefore, their transcriptome might not represent the *in vivo* GVs or MIIs.
Non-polyadenylated transcripts, which regulate gene expression and could be responsible for impaired oocyte developmental potential with age, are not detected with our sequencing method.

Wider implications of the findings: Our analysis suggests that advanced maternal age does not strikingly affect oocyte gene expression at GV or IVM-MII stages. Nonetheless, some genes showed a tendency to change their expression with age. A deeper analysis is required to discriminate whether those changes have clinically relevant effects on reproductive outcomes.

[3]Juana Crespo Clinic, Embryology, Valencia, Spain

Study question: Are there metabolites in the spent media that can act as biomarkers to predict embryo implantation?

Summary answer: A set of culture-media specific biomarkers were identified that highly predicted implantation potential in several fertility centers.

What is known already: A critical step in IVF cycles is the selection of the best embryo to be transferred, since treatment success strongly depends on this choice. The standard of care tool for embryo selection has been morphokinetics criteria, which has low predictability to ascertain implantation potential. The effectiveness of ART remains limited and only 10%-30% of embryos

replaced in the uterus implant. During the last 20 years, the alternative has been PGT (Preimplantation Genetic Testing), an invasive method that requires embryo biopsy. For this reason, novel non-invasive embryo screening methods are required to optimize embryo selection using AI-morphokinetics, metabolomics and non-invasive PGT.

Study design, size, duration: This retrospective study was done on 197 samples collected in three different clinics, using two different culture media (Sage n=129, and Vitrolife n=68), over a period of two years. Sixty-nine of the spent media samples came from embryos that implanted (P) and 128 from non-implanted embryos (NP). Embryos were obtained and cultured using routine IVF practices. 20 - 40 µL of spent media were collected after incubation between days 3 and 5.
